## 1. Definition of the theory and its canonical formulation

With the aim of obtaining simultaneously perturbative renormalizability and unitarity, Hořava[1] has introduced a gravitational theory with higher orders only in spatial derivatives, breaking the symmetry of general diffeomorphisms over the spacetime. Indeed, the very concept of spacetime is substituted by the one of foliation of spacelike hypersurfaces along an absolute line of time. The theory is defined in terms of the ADM (Arnowitt-Deser-Misner) variables $N$, $N_i$ and $g_{ij}$. They are understood as tensors over the spacelike hypersurfaces that evolve in time. The gauge symmetry is given by the FDiff (diffeomorphisms that preserve the foliation), defined on the ADM varaibles. The Lagrangian has a kinetic terms that is of second order in time derivatives,

$$\mathcal{L}_K = \sqrt{g} N G^{ijkl} K_{ij} K_{kl}\,, \quad G^{ijkl} \equiv \frac{1}{2}(g^{ik}g^{jl} + g^{il}g^{jk}) - \lambda g^{ij}g^{kl}\,, \tag{1}$$

and $K_{ij}$ is the extrinsic curvature of the hypersurfaces. This kinetic term is FDiff covariant for any value of the dimensionless coupling constant $\lambda$. Our concern in this paper is a particular formulation of the Hořava theory, which we call the kinetic-conformal theory, given by a critical value of $\lambda$. For spatial hypersurfaces of dimension 3, the critical value for $\lambda$ we refer to is $\lambda = 1/3$. This value defines a dynamically different formulation of the Horava theory, in the sense that the structure of constraints is discontinuous to the generic formulation with $\lambda \neq 1/3$. That is, the constraints of the kinetic-conformal theory cannot be obtained by continuously varying $\lambda$. At $\lambda = 1/3$ the hypermatrix $G^{ijkl}$ becomes degenerated and this leads to the raising of the primary constraint $\pi \equiv g_{ij}\pi^{ij} = 0$, where $\pi^{ij}$ is the canonically conjugate of $g_{ij}$. There is an additional secondary constraint that emerges when the time preservation of $\pi$ is imposed. As a consequence, the kinetic-conformal theory propagates less physical degrees of freedom than the generic formulation of the nonprojectable Hořava theory with $\lambda \neq 1/3$. It propagates two physical modes, the same number of General Relativity. The so-called extra mode of the generic formulation theory is absent in the kinetic-conformal formulation. We consider this an interesting feature that deserves to be explored. Furthermore, at $\lambda = 1/3$ the

kinetic term (1) gets an *anisotropic* conformal symmetry defined by the anisotropic Weyl transformations [1]

$$\tilde{g}_{ij} = \Omega^2 g_{ij}\,, \qquad \tilde{N} = \Omega^3 N\,, \qquad \tilde{N}_i = \Omega^2 N_i\,, \tag{2}$$

where $\Omega = \Omega(t, \vec{x})$. This motivates the name kinetic-conformal. The full theory is not conformally invariant since the potential is not, unles it is defined with specific conformal terms.

In Ref. 2 several versions of the Hořava theory were associated to the algebra of the Newton-Cartan geometry. In summary, depending of the connection used in the gauging and the central extension on the side of the Newton-Cartan algebra, the correspondence is

- Torsionless connection: projectable Hořava theory.
- Twistless-torsional connection: nonprojectable Hořava theory.
- Central Bargmann extension: $U(1)$ extension of the Hořava theory.

Thus, the kinetic-conformal formulation can be found in the twistless-torsional-gauging case, by fixing the values of some coupling constants on the side of the Newton-Cartan dynamics. The extrinsic curvature arises via the covariant derivatives of the inverse vielbein denoted by $v^\mu$ in Ref. 2. Then the kinetic term (1) emerges from the terms that are quadratic in derivatives of $v^\mu$,

$$c_3 \nabla_\mu v^\mu \nabla_\nu v^\nu + c_4 \nabla_\nu v^\mu \nabla_\mu v^\nu = c_4 \left( K_{ij} K^{ij} - \frac{c_3}{c_4} K^2 \right) . \tag{3}$$

Thus, the kinetic-conformal theory is achieved by adjusting $c_3$ and $c_4$ according to

$$\frac{c_3}{c_4} = \frac{1}{3}\,. \tag{4}$$

The action of the nonprojectable Hořava theory is [1,3]

$$S = \int dt d^3x \sqrt{g} N \left( G^{ijkl} K_{ij} K_{kl} - \mathcal{V} \right), \tag{5}$$

where to define the kinetic-conformal theory we consider that the value $\lambda = 1/3$ has been fixed. The potential $\mathcal{V}$ should include all the inequivalent terms that are FDiff covariant and up to sixth order in spatial derivatives ($z = 3$ terms), as required for the power-counting renormalizability [1]. Among them, the terms that contribute to the action of second order in perturbations, hence contributing to the propagator, are [4]

$$-\mathcal{V}^{(z=1)} = \beta R + \alpha a_i a^i\,, \tag{6}$$

$$-\mathcal{V}^{(z=2)} = \alpha_1 R \nabla_i a^i + \alpha_2 \nabla_i a_j \nabla^i a^j + \beta_1 R_{ij} R^{ij} + \beta_2 R^2\,, \tag{7}$$

$$-\mathcal{V}^{(z=3)} = \alpha_3 \nabla^2 R \nabla_i a^i + \alpha_4 \nabla^2 a_i \nabla^2 a^i + \beta_3 \nabla_i R_{jk} \nabla^i R^{jk} + \beta_4 \nabla_i R \nabla^i R\,, \tag{8}$$

where $a_i = \partial_i \ln N$.

In order to determine the dynamical consistency of the theory we have performed its Hamiltonian formulation [5]. The phase space is spanned by the conjugate pairs

$(g_{ij}, \pi^{ij})$ and $(N, P_N)$. The Hamiltonian, with the primary constraints added, is given by

$$H = \int d^3x \left( \frac{N}{\sqrt{g}} \pi^{ij} \pi_{ij} + \sqrt{g} N \mathcal{V} + N_i \mathcal{H}^i + \mu \pi + \sigma P_N \right) , \tag{9}$$

and the full set of constraints is

$$\mathcal{H}^j \equiv -2 \nabla_i \pi^{ij} + P_N \partial^j N = 0 \, . \tag{10}$$

$$P_N = 0 \, , \quad \pi = 0 \, , \tag{11}$$

$$\frac{1}{\sqrt{g}} \mathcal{H} \equiv \frac{1}{g} \pi^{ij} \pi_{ij} - \beta R + 2\alpha \frac{\nabla^2 N}{N} - \alpha a_i a^i = 0 \, , \tag{12}$$

$$\frac{1}{\sqrt{g}} \mathcal{C} \equiv \frac{3}{2g} \pi^{ij} \pi_{ij} + \frac{\beta}{2} R - 2\beta \frac{\nabla^2 N}{N} + \frac{\alpha}{2} a_i a^i = 0 \, . \tag{13}$$

$\mathcal{H}^i$ is a first-class constraint whereas the four constraints $P_N$, $\pi$, $\mathcal{H}$ and $\mathcal{C}$ are of second class. In the Hamiltonian formulation the shift vector $N_i$ plays the role of Lagrange multiplier (as in GR), as well as $\mu$ and $\sigma$. When applying Dirac's programme for extracting the constraints, the time preservation of the second-class constraints leads to equations for $\mu$ and $\sigma$. Considering the complete potential $\mathcal{V}$, it can be shown[5] that these are elliptic (sixth-order) equations, hence they can be consistently solved with appropiated boundary conditions. This ends Dirac's programme, the set of constraints is closed. The constraints $\mathcal{H}$ and $\mathcal{C}$ can also be casted as elliptic equations if the appropiated field variables are chosen to solve them, see[6]. This analysis shows that the Hamiltonian formulation of the theory is consistent. Considering the second-class nature of $P_N$, $\pi$, $\mathcal{H}$ and $\mathcal{C}$, it results that the theory propagates two physical modes, coinciding with the number of modes of GR.

The presence of the $\pi = 0$ constraint is intriguing, since it generates the Weyl scalings on $g_{ij}$ and $\pi^{ij}$, but this theory is not conformally invariant. This is in agreement with the fact that $\pi$ is of second-class, hence it is not the generator of gauge symmetries. Contrasting with an exactly anisotropic conformal Horava theory, which is given by a conformal potential, we have that $\pi = 0$ can be combined with the $P_N = 0$ constraint to form the full generator of the anisotropic conformal transformations (2), which is

$$\varpi = \pi + \frac{3}{2} N P_N \, . \tag{14}$$

In the anisotropic conformal theory this is a first-class constraint. It is preserved without further conditions, hence no furhter constraints are generated. Therefore, in the exact anisotropic conformal case there is a symmetry more than in the kinetic-conformal formulation, the anisotropic Weyl scalings, but a second-class constraint less (the $\mathcal{C}$ constraint). Hence the number of physical degrees of freedom is the same in both cases (at least in the sense of classical field theories, since there is evidence[7] for a conformal anomaly in the anistropic conformal theory), and it is the same of

GR. Further developments in the relationship bewteen the kinetic-conformal theory and the exact anisotropic conformal formulation can be found in[8].

## 2. Quantization: propagators and the superficial degree of divergence

A perturbative analysis considering all the terms (6) - (8) allows to check explicitly the consistency of the Hamiltonian formulation of the theory and to obtain the propagators of the physical modes. We work on the transverse gauge $\partial_i h_{ij} = 0$, where $h_{ij}$ represents the perturbative metric around the flat background. The momentum constraint eliminates the longitudinal sector of the canonical momentum at first order in perturbations. Constraints $\mathcal{H}$ and $\mathcal{C}$ are consistently solved for $h_{kk}$ and the pertubative version of the lapse function, $n$, fixing these variables to zero at first order in perturbations (with asymptotically flat conditions). Constraint $\pi = 0$ elminates the trace of the canonical momentum. There remains the transverse-traceless sector $(h_{ij}^{TT}, p_{ij}^{TT})$ as the independent propagating physical modes. The corresponding propagators are[6]

$$\left\langle h_{ij}^{TT} h_{kl}^{TT} \right\rangle = \frac{P_{ijkl}^{TT}}{\omega^2 - \beta \vec{k}^{\,2} + \beta_1 \vec{k}^{\,4} + \beta_3 \vec{k}^{\,6}}\,, \tag{15}$$

where $P_{ijkl}^{TT}$ is the transverse-traceless projector.

Another important issue of the perturbative quantization is the distribution of Fourier momentum in Feynmann diagrams. We recall that this is a theory with second-class constraints, hence standard techniques of gauge field theories which only have first-class constraints do not apply. One plausible scheme of quantizaton is to solve the second-class constraints perturbatively. It can be shown that the perturbative field variables used to solve the constraints end with a balance of zero Fourier momentum[6]. Therefore when the solutions are substituted in the Lagrangian they do not alter the order in momentum of the interacting terms, the weight in Fourier momentum of the vertices is the same of the off-shell theory. These results allow to evaluate the superficial degree of divergence of Feynman diagrams, since the badly divergent diagrams are those with vertices corresponding to the terms of the Lagrangian of highest order, which is the sixth order. The internal lines scale also with sixth order according to the propagator (15). With these considerations we may show[6] that the superficial degree of divergence of the badly divergent diagrams is given by the order 6. This implies that counter-terms of 6th order in spatial derivatives must be added to the bare Lagrangian, but this is precisely the order of the bare Lagrangian designed for power-counting renormalizability. Thus, the theory passes the criterium given by the superficial degree of divergence needed for the renormalization of the theory.

## 3. Gravitational waves and observational bounds

The coincidence in the number physical degrees of freedom between the kinetic-conformal Hořava theory and GR raises interest on the behavior of the gravitational waves in this theory. This was analyzed in[9] using the equivalence of the large-distance effective action with the Einstein-aether theory[10]. The Einstein-aether theory implements the breaking of the Lorentz invariance keeping the gauge symmetry of general diffeomorphisms over spacetime by using a dynamic unit time-like vector (the aether). The analysis of gravitational waves in the kinetic-conformal Hořava theory done in[9] was achieved in a gauge-invariant way, involving the aether field in the construction of the gauge invariants. The first main result is that the transverse-traceless sector is propagated with a wave equation, $\sqrt{\beta}$ being the speed of the gravitational waves.

For the case of an isolated source, the dominant mode of its gravitational radiation in the far zone can be deduced by applying the same techniques of GR. The considerations on the source are the standard ones for a weak source: small mass, slow velocity and negligible self-gravity. If $I_{ij}$ is the quadrupole moment given by the 00 component of the energy-momentum tensor, then it is found[9] that the leading contribution for the generation of gravitational waves has the same structure of Einstein's quadrupole formula of GR,

$$h_{ij}^{TT} = \frac{\kappa_{\rm H}}{4\pi\beta r} P_{ijkl}^{TT} \frac{d^2 I_{kl}(t - r/\sqrt{\beta})}{dt^2}\,, \tag{16}$$

where $\kappa_{\rm H}$ is the coupling constant arising in front of the Hořava action (which we set equal to one in Eq. (5), since that is a vacuum action). To get an exact matching with the quadrupole formula of GR, we must set the coupling constants $\kappa_{\rm H}$ and $\beta$ equal to their GR values, $\kappa_{\rm H} = 8\pi G_{\rm N}$ and $\beta = 1$.

We may apply the analysis of the parameterized-post-Newtonian (PPN) expansion for solar-system tests to the kinetic-conformal theory. It turns out that the theory reproduces the same values of the PPN parameters of GR, except for the parameters $\alpha_1^{\rm PPN}$ and $\alpha_2^{\rm PPN}$, whose deviations from the zero value indicate Lorentz-symmetry violation. For the kinetic-conformal Hořava theory these two constants are given by[9]

$$\alpha_2^{\rm PPN} = \frac{1}{8}\alpha_1^{\rm PPN} = \beta - 1 - \frac{\alpha}{2}\,. \tag{17}$$

The current observational bounds[12] on these parameters are $|\alpha_1^{\rm PPN}| < 10^{-4}$ and $|\alpha_2^{\rm PPN}| < 10^{-9}$. Relation (17) demands that the strong bound, which is the one on $\alpha_2^{\rm PPN}$, must be satisfied by both parameters. This condition is met if

$$\alpha = 2(\beta - 1) + \delta\,, \tag{18}$$

where $\delta$ represents the narrow observational window for the $\alpha_2^{\rm PPN}$ parameter, i. e. $|\delta| < 10^{-9}$.

We identify the proper geometry underlying non-relativistic string theory as 'String Newton-Cartan Gravity'. It has the distinguishing feature that one-dimensional foliation in Newton-Cartan geometry is replaced by a two-dimensional foliation on the target space. We discuss some basic properties of the string Newton-Cartan space-time, in particular it's behaviour under T-duality transformations. This leads to interesting non-relativistic conformal field theories at the boundary that have applications in condensed matter physics.

*Keywords*: Newton-Cartan gravity; Non-relativistic string theory.

## 1. Introduction

Assuming small spacetime curvature, the low-energy limit of superstring theory is described by a supergravity theory. Using this connection our knowledge about supergravity has teached us a lot about some basic properties of superstring theory such as T-duality, D-branes, exotic branes etc. Via it's embedding into string theory, supergravity in an AdS background has an intriguing holographic relation with a conformal field theory in one dimension lower. This latter relationship has also been investigated at the non-relativistic level by considering background geometries in the bulk that have non-relativistic isometries such as Lifshitz or Schrödinger symmetries. This leads to non-relativistic conformal field theories at the boundary that have applications in condensed matter physics.[a]

A different and less well studied corner of non-relativistic holography occurs when the gravity in the bulk itself becomes non-relativistic. It has been argued that the relevant non-relativistic gravity is an extension of Newton-Cartan (NC) gravity, i.e. the frame-independent formulation of Newtonian gravity. This new kind of holography leads to non-relativistic CFTs at the boundary with a different set of symmetries such as the (infinite-dimensional) Galilean conformal symmetries, see Ref. 1. We are especially interested in the possibility that the non-relativist gravity theory in the bulk is connected to a non-relativistic string theory in the same way that general relativity is related to relativistic string theory. This non-relativistic string theory could then perhaps be used as at starting point by itself, independent of the relativistic string theory, to study non-relativistic holography.

Independent of holography, it was realized in the condensed matter community that reparametrization invariance is not only relevant to gravity but also plays

[a]It has been found that the non-relativistic conformal field theories at the boundary couple to a Newton-Cartan geometry with twistless torsion in Ref. 13.

a crucial role in Effective Field Theories (EFTs), where one writes effective Lagrangians in an expansion organized according to the number of derivatives. Coupling an EFT to an arbitrary gravitational background enables one to study generic features of this EFT in an arbitrary frame. The application of non-relativistic gravity in this new context was pioneered by Son and coworkers in Ref. 2. The detailed understanding of how to couple a non-relativistic EFT to a general NC gravitational background can be obtained systematically by starting from a relativistic EFT in a general gravitational background that includes an auxiliary zero-flux vector field as in Ref. 3. By taking a special limit of this EFT in a frame-independent way, one automatically obtains a non-relativistic EFT in a Newton-Cartan background.

In the first part we recall how the kinematics of NC gravity follows from gauging a specific non-relativistic algebra. We extend this analysis to String NC gravity. In the second part we discuss the non-relativistic string theory that naturally couples to the String NC geometry. In particular, we discuss the T-duality properties of this new kind of geometry. At the end we give our conclusions.

## 2. Newton-Cartan Gravity

It is well-known that the symmetries connecting non-relativistic inertial frames are given by the following set of Galilei symmetries:

- time translations: $\delta t = \xi^0$,
- space translations: $\delta x^i = \xi^i$, $\quad i = 1, 2, 3$,
- spatial rotations: $\delta x^i = \lambda^i{}_j \, x^j$,
- Galilean boosts: $\delta x^i = \lambda^i t$.

Here $\xi^0, \xi^i, \lambda^i{}_j$ and $\lambda^i$ are the constant parameters associated with the time translation, space translations, spatial rotations and Galilean boosts, respectively. These symmetries are identical to the Poincaré symmetries except for the Galilean boosts which differ from the Lorentzian boosts in the sense that under Galilean boosts the spatial coordinates $x^i$ transform to the absolute time coordinate $t$, but $t$ does not transform back into the spatial coordinates $x^i$.

It turns out that gauging the Galilei algebra associated with the above symmetries is not sufficient to obtain NC gravity. One way to see this is to realize that the spin-connection fields associated with the spatial rotations and boost symmetries are dependent fields in General Relativity and one expects this to be the same in NC gravity. In General Relativity this is obtained by setting the torsion equal to zero which yields the 24 so-called conventional constraints needed to solve the 24 spin-connection fields associated with the Lorentz transformations. The problem with the Galilei algebra is that the curvature of time translations does not contain a spin-connection field and hence cannot be used for obtaining a conventional constraint. Therefore, there are not enough conventional constraints to solve for all spin-connections. One way to circumvent this issue is to work with a centrally extended Galilei algebra, called the Bargmann algebra. It turns out that

the curvature corresponding to the central charge transformations does contain the boost spin-connection fields. By setting this curvature to zero one acquires the 6 missing conventional constraints. Together with the 18 conventional constraints that follow from setting the curvature corresponding to the spatial translations equal to zero, one is now able to solve for the 12 spatial rotation connection fields $\Omega_\mu{}^{ab}$ ($\mu = 0, 1, 2, 3; a = 1, 2, 3$) and the 12 Galilean boost connection fields $\Omega_\mu{}^a$. The central charge introduced by the Bargmann algebra also has a physical interpretation. When coupled to matter, the U(1) central charge symmetry leads to a conserved Noether charge expressing the conservation of particle number. It also leads to the fact the the Schrödinger equation is necessarily complex providing a projective representation of the Galilei algebra.

We now consider the gauging of the Bargmann algebra, see Ref. 4. Our starting point is the set of commutation relations defining the Bargmann algebra

$$
\begin{aligned}
&[J_{ab}, P_c] = -2\delta_{c[a}P_{b]}\,, && [J_{ab}, G_c] = -2\delta_{c[a}G_{b]}\,,\\
&[G_a, H] = -P_a\,, && [G_a, P_b] = -\delta_{ab}Z\,,
\end{aligned}
\tag{1}
$$

where $\{H, P_a, J_{ab}, G_a, Z\}$ with $a = 1, 2, 3$ are the generators of time translation, space translations, spatial rotations, Galilean boosts and central charge transformation, respectively. In this gauging procedure we associate to every generator/symmetry a gauge field and gauge parameters that are arbitrary functions of spacetime together with the covariant curvatures, see Table 1 below. Note that we have left out the parameters corresponding to the time and space translations. Instead, we assume that all gauge fields transform as covariant vectors under general coordinate transformations with parameters $\xi^\mu(x)$. The two symmetries ($H$ and $P$ transformations versus general coordinate transformations) are related to each other via a so-called trivial or Zilch symmetry in Ref. 5.

Table 1. This table indicates for every symmetry of the Bargmann algebra the corresponding generators, gauge fields, local gauge parameters and covariant curvatures.

| symmetry | generators | gauge field | parameters | curvatures |
|---|---|---|---|---|
| time translation | $H$ | $\tau_\mu$ | – | $R_{\mu\nu}(H)$ |
| space translations | $P_a$ | $E_\mu{}^a$ | – | $R_{\mu\nu}{}^a(P)$ |
| Galilean boosts | $G_a$ | $\Omega_\mu{}^a$ | $\lambda^a(x^\nu)$ | $R_{\mu\nu}{}^a(G)$ |
| spatial rotations | $J_{ab}$ | $\Omega_\mu{}^{ab}$ | $\lambda^{ab}(x^\nu)$ | $R_{\mu\nu}{}^{ab}(J)$ |
| central charge transf. | $Z$ | $M_\mu$ | $\sigma(x^\nu)$ | $R_{\mu\nu}(Z)$ |

One can now show that by imposing the 24 conventional constraints

$$
R_{\mu\nu}{}^a(P) = R_{\mu\nu}(Z) = 0 \tag{2}
$$

the 24 connection fields $\Omega_\mu{}^{ab}$ and $\Omega_\mu{}^a$ can be solved in terms of independent gauge fiels . Furthermore, we impose the 6 geometric constraints

$$R_{\mu\nu}(H) = 2\partial_{[\mu}\tau_{\nu]} = 0 \qquad \rightarrow \qquad \tau_\mu = \partial_\mu \tau \,, \tag{3}$$

defining absolute time. Due to this constraint the time difference $\Delta T$ between two events becomes independent of the path $\mathcal{C}$ that the observer has traveled between these two events:

$$\Delta T = \int_{\mathcal{C}} \mathrm{d}x^\mu \tau_\mu = \int_{\mathcal{C}} \mathrm{d}\tau \,. \tag{4}$$

One thus ends up with three independent gauge-fields $\{\tau_\mu, E_\mu{}^a, M_\mu\}$ that transform under general coordinate transformations, with parameters $\xi^\mu$, as covariant vectors and under spatial rotations, Galilean boosts and central charge transformation as follows:

$$\begin{aligned} \delta\tau_\mu &= \xi^\lambda \partial_\lambda \tau_\mu + \partial_\mu \xi^\lambda \tau_\lambda \,, \\ \delta E_\mu{}^a &= \xi^\lambda \partial_\lambda E_\mu{}^a + \partial_\mu \xi^\lambda E_\lambda{}^a + \lambda^a{}_b \, E_\mu{}^b + \lambda^a \tau_\mu \,, \\ \delta M_\mu &= \xi^\lambda \partial_\lambda M_\mu + \partial_\mu \xi^\lambda M_\lambda + \partial_\mu \sigma + \lambda_a \, E_\mu{}^a \,. \end{aligned} \tag{5}$$

One may define the following Bargmann-invariant metrics

$$\tau_{\mu\nu} = \tau_\mu \tau_\nu \,, \qquad\qquad h^{\mu\nu} = E^\mu{}_a E^\nu{}_b \, \delta^{ab} \,, \tag{6}$$

one in the time direction and a separate one in the spatial directions. One cannot define a boost-invariant metric with upper indices in the time direction or lower indices in the spatial directions. A Galilean boost-invariant metric can be obtained by adding terms proportional to the central charge gauge field $M_\mu$ as follows:

$$H_{\mu\nu} = E_\mu{}^a E_\nu{}^b \delta_{ab} - 2\tau_{(\mu} M_{\nu)} \,. \tag{7}$$

However, in that case one ends up with a metric that is not invariant under the central charge gauge transformation.

Newton-Cartan gravity can be obtained as a non-relativistic limit of general relativity, much in the same way as the Bargmann algebra can be obtained as the Inönü-Wigner contraction of the direct product of the Poincaré algebra and a U(1) generator. The latter has the physical interpretation that, when coupled to matter, its Noether charge corresponds to the conservation of particles minus anti-particles. To describe this particular Inönü-Wigner contraction we consider the Poincaré algebra plus an additional U(1) generator $\hat{\mathcal{Z}}$ that commutes with all the Poincaré generators:

$$\big[\hat{P}_{\hat{A}}, \hat{M}_{\hat{B}\hat{C}}\big] = 2\,\eta_{\hat{A}[\hat{B}}\,\hat{P}_{\hat{C}]} \,, \quad \big[\hat{M}_{\hat{A}\hat{B}}, \hat{M}_{\hat{C}\hat{D}}\big] = 4\,\eta_{[\hat{A}[\hat{C}}\,\hat{M}_{\hat{D}]\hat{B}]} \quad \text{plus} \quad \hat{\mathcal{Z}} \,. \tag{8}$$

Here $\{\hat{P}_{\hat{A}}, \hat{M}_{\hat{A}\hat{B}}\}$ are the generators of spacetime translations and Lorentz transformations, respectively. We have indicated all relativistic generators with a hat to distinguish them from the non-relativistic case. The extra U(1) generator $\hat{\mathcal{Z}}$ is needed because the Bargmann algebra contains one generator more than the Poincaré algebra. Next, we decompose $\hat{A} = (0, a)$ and relate the Poincaré $\otimes$ U(1) generators $\{\hat{P}_0, \hat{P}_a\, \hat{M}_{a0}, \hat{M}_{ab}\}$ and $\hat{\mathcal{Z}}$ to the non-relativistic Bargmann generators $\{H, P_a, G_a, J_{ab}, Z\}$ as follows:

$$\hat{P}_0 = \frac{1}{2\omega}\, H + \omega\, Z\,, \qquad\qquad \hat{\mathcal{Z}} = \frac{1}{2\omega}\, H - \omega\, Z\,, \tag{9}$$

$$\hat{P}_a = P_a\,, \qquad \hat{M}_{ab} = J_{ab}\,, \qquad \hat{M}_{a0} = \omega\, G_a\,, \tag{10}$$

where we have introduced a contraction parameter $\omega$. In a second step, taking the limit $\omega \to \infty$, we obtain the Bargmann algebra including the following commutator containing the central charge generator $Z$:

$$\big[P_A, G_B\big] = \delta_{AB}\, Z\,. \tag{11}$$

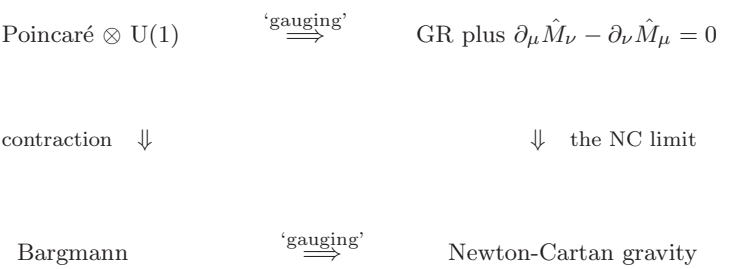

Fig. 1. This figure compares the Inönü-Wigner contraction of the Poincaré algebra times a U(1)with the non-relativistic limit of general relativity plus a zero flux gaugefield $\hat{M}_\mu$ discussed in the text.

The non-relativistic limit of general relativity, which is inspired by the above Inönü-Wigner contraction, is introduced as follows, see Figure 1. Using a second-order formulation of general relativity, we first introduce, on top of the Vierbein field, a vector field $\hat{M}_\mu$ with $\partial_{[\mu}\hat{M}_{\nu]} = 0$, see Ref. 3. Next, we relate the relativistic gauge fields $\{\hat{E}_\mu{}^{\hat{A}}, \hat{M}_\mu\}$ to the non-relativistic gauge fields $\{\tau_\mu, E_\mu{}^a, M_\mu\}$ of NC gravity as follows:

$$\hat{E}_\mu{}^0 = \omega\, \tau_\mu + \frac{1}{2\omega}\, M_\mu\,, \qquad \hat{M}_\mu = \omega\, \tau_\mu - \frac{1}{2\omega}\, M_\mu\,, \qquad \hat{E}_\mu{}^a = E_\mu{}^a\,. \tag{12}$$

In a second step we take the limit $\omega \to \infty$ in the relativistic transformation rules. In this way we obtain the correct non-relativistic transformation rules (5). The

same limit can be used to derive the NC gravity equations of motion from the Einstein equations. Note that the standard textbooks on general relativity usually go straight from General Relativity to Newtonian gravity skipping the general frame formulation of Newtonian gravity.

A striking feature of the non-relativistic limit we just defined is that it requires the introduction of the auxiliary gauge field $\hat{M}_\mu$. Another way to see the necessity of this additional gauge field for taking the limit is considering the action of a particle moving in a general relativistic gravitational background. In order to define a limit without fatal divergencies one needs to couple the particle not only to general relativity but also to the gauge field $\hat{M}_\mu$ via a so-called Wess-Zumino term. This brings us to the remarkable conclusion that the limit of general relativity we just defined is particular to particles. It will not work for other extended objects such as strings. This leads to the following question:

*If NC gravity couples to particles what is the non-relativistic gravity that couples to strings?*

We will answer this question in the next section.

## 3. String Newton-Cartan Gravity

A basic difference between particles and strings is that a particle naturally couples to a 1-form gauge field $\hat{M}_\mu$ whereas a string couples to a 2-form gauge field $\hat{M}_{\mu\nu}$. In order to cancel the leading divergence that occurs in the particle limit one needs to add a Wess-Zumino term to the particle kinetic term with

$$\hat{M}_\mu = \omega\tau_\mu + \cdots \tag{13}$$

In the case of strings the cancellation of the leading divergence requires that the 2-form gauge field $\hat{M}_{\mu\nu}$ starts as $\omega^2$ times something quadratic in $\tau_\mu$ but, due to the anti-symmetry of the 2-form, one cannot write down such an expression. One way to avoid this problem is to introduce *two* Vierbeine ${\tau_\mu}^A$ where $A = 0, 1$ refer to the two (timelike and spacelike) directions longitudinal to the string. One writes

$$\hat{M}_{\mu\nu} = \omega^2 {\tau_\mu}^A {\tau_\nu}^B \epsilon_{AB} + \mathcal{O}(\omega^0)\,. \tag{14}$$

The ${\tau_\mu}^A$ are two generalized clock functions that define a so-called string NC geometry. The basic difference with the particle case is that the relativistic index $\hat{A}$ is divided up differently in longitudinal directions $A$ and transverse directions $a$ as follows:

$$\text{particle:} \quad \hat{A} = (0, a) \;\text{ with }\; a = 1, \cdots, d \tag{15}$$

$$\text{string:} \quad \hat{A} = (A, a) \;\text{ with }\; A = 0, 1 \;\text{ and }\; a = 2, \cdots, d-1\,. \tag{16}$$

The string Galilei symmetries underlying this geometry are given by

| | |
|---|---|
| longitudinal translations | $H_A$ |
| transverse translations | $P_a$ |
| string Galilei boosts | $G_{Ab}$ |
| longitudinal Lorentz rotations | $M_{AB}$ |
| transverse spatial rotations | $J_{ab}$ |

In gauging the algebra corresponding to these symmetries one again encounters extensions that in this case are non-central:

$$[G_{Aa}, P_b] = 0 \qquad \rightarrow \qquad [G_{Aa}, P_b] = \delta_{ab} Z_A \tag{17}$$

and leads to non-central charge gauge fields $M_\mu{}^A$. To obtain irreducibility one needs to impose a set of conventional and geometric constraints. A difference with the particle case is that the zero torsion constraint now becomes a mixture of conventional and geometric constraint:

$$R_{\mu\nu}{}^A(H) = D_{[\mu}(\Omega)\tau_{\nu]}{}^A = 0. \tag{18}$$

For instance, in 4 spacetime dimensions, i.e. $d = 3$, the 12 curvature constraints (18) is a mixture of 4 conventional constraint that can be used to solve for the 4 components of longitudinal spin-connection fields

$$\Omega_\mu{}^{AB} = \epsilon^{AB}\Sigma_\mu \tag{19}$$

and 8 geometric constraints.

After gauging, one ends up with the independent string NC gauge fields $\{\tau_\mu{}^A, E_\mu{}^a, m_\mu{}^A\}$ that transform under the different symmetries as follows:

$$\begin{aligned} \delta\tau_\mu{}^A &= \Lambda^A{}_B \tau_\mu{}^B\,, \\ \delta E_\mu{}^a &= \Lambda^a{}_b\, E_\mu{}^b - \Sigma_A{}^a \tau_\mu{}^A\,, \\ \delta m_\mu{}^A &= D_\mu \sigma^A + \Sigma^A{}_a\, E_\mu{}^a\,. \end{aligned} \tag{20}$$

Furthermore, all gauge fields transform as covariant vectors under general coordinate transformations. These transformations rules are the generalization of the particle transformation rules (5) to strings and will play a prominent role as the symmetries on the non-relativistic Polyakov string we discuss in the next section.

We note that the string analogue of the longitudinal metric (6) and boost invariant metric (7) are given by

$$\text{longitudinal metric}: \qquad \tau_{\mu\nu} \equiv \tau_\mu{}^A \tau_\nu{}^B \eta_{AB}\,, \tag{21}$$

$$\text{boost invariant metric}: \qquad H_{\mu\nu} \equiv E_\mu{}^a E_\nu{}^b \delta_{ab} + \left(\tau_\mu{}^A m_\nu{}^B + \tau_\nu{}^A m_\mu{}^B\right)\eta_{AB}\,. \tag{22}$$

Like in the particle case, $H_{\mu\nu}$ is invariant under string Galilei boost transformations but transforms under the non-central charge gauge transformations with parameter $\sigma^A$.

## 4. The Non-relativistic Polyakov String

To understand the non-relativistic Polyakov string as the limit of the relativistic Polyakov string, it is instructive to first consider the particle case. Our starting point is a particle in a Polyakov formulation moving in the fields of general relativity and coupled to the extra gauge field $\hat{M}_\mu$ via a Wess-Zumino (WZ) term:

$$S_{\text{Pol.}} = -\tfrac{1}{2}\int d\tau\Big\{ -\frac{1}{e}\hat{E}_\mu{}^{\hat{A}}\dot{x}^\mu\hat{E}_\nu{}^{\hat{B}}\dot{x}^\nu\eta_{\hat{A}\hat{B}} + M^2 e - 2M\hat{M}_\mu\dot{x}^\mu\Big\}. \tag{23}$$

Here $e$ is the Einbein and $M$ a mass parameter. Substituing the parametrization (12) we obtain a potential leading divergence of order $c^2$:

$$S_{\text{Pol.}}(c^2) = -\tfrac{1}{2}c^2\int d\tau\frac{1}{e}\big[\tau_\mu\dot{x}^\mu - me\big]^2. \tag{24}$$

To circumvent this potential divergence, we introduce by hand a Lagrange multiplier $\lambda$ and rewrite the above term in the following equivalent form:

$$S_{\text{Pol.}}(c^2) = -\tfrac{1}{2}\int d\tau\frac{1}{e}\Big\{\lambda(\tau_\mu\dot{x}^\mu - me) - \frac{1}{4c^2}\lambda^2\Big\}. \tag{25}$$

Solving for $\lambda$ by using it's equation of motion one recovers the Lagrangian (24). The advantage of the Lagrangian (32) is that the quadratic divergence has disappeared. Note that this rewriting can only be done after making the expansion (12). Strictly speaking we can not consider the result we obtain as the limit of the original Polyakov Lagrangian (23).

Continuing in this way, we obtain the following Lagrangian for the non-relativistic Poyakov particle:

$$S_{\text{Pol.}}(\text{N.R.}) = -\tfrac{1}{2}\int d\tau\frac{1}{e}\Big\{\dot{x}^\mu\dot{x}^\nu H_{\mu\nu} + \lambda\big(\tau_\mu\dot{x}^\mu - me\big)\Big\}. \tag{26}$$

Note that the boost invariant metric $H_{\mu\nu}$ defined in eq. (7) occurs in the Lagrangian. The fact that this metric is not invariant under the central charge transformation leads to a total derivative in the Lagrangian. Solving for $e$ by using the equation of motion for $\lambda$ leads to the Lagrangian for the non-relativistic Nambu-Goto particle. Note that the resulting Nambu-Goto Lagrangian is non-linear in the longitudinal time coordinate $\tau_\mu\dot{x}^\mu$ but quadratic in the transverse coordinates that are contracted with the boost invariant metric $H_{\mu\nu}$. This is in contrast to the Lagrangian for the relativistic Nambu-Goto particle which is non-linear in *all* directions.

The Lagrangian (26) for the non-relativistic Polyakov particle has all the features of the non-relativistic Polyakov string. To derive the action for the non-relativistic

Polyakov string, the relativistic gauge fields are redefined as follows;

$$\hat{E}_\mu{}^A = \omega\tau_\mu{}^A + \frac{1}{\omega}\, m_\mu{}^A\,, \qquad\qquad \hat{E}_\mu{}^a = E_\mu{}^a\,, \tag{27}$$

$$\hat{M}_{\mu\nu} = \omega^2 \tau_\mu{}^A \tau_\nu{}^B\, \epsilon_{AB} + B_{\mu\nu} \tag{28}$$

and two Lagrange multipliers $\lambda$ and $\bar{\lambda}$ are introduced to avoid divergences when the limit is taken. We have used here the following definitions. First of all, we have defined a worldsheet metric $h_{\alpha\beta}$ that can be expressed in terms of worldsheet Zweibeine as follows:

$$h_{\alpha\beta} = e_\alpha{}^a e_\beta{}^b \eta_{ab}\,, \tag{29}$$

with $\alpha = 0, 1 (a = 0, 1)$ curved (flat) worldsheet indices.[b] Furthermore, for $e_\mu{}^a$ and $\tau_\mu{}^A$ we use the following lightcone notation:

$$e_\alpha \equiv e_\alpha{}^0 + e_\alpha{}^1\,, \qquad \bar{e}_\alpha \equiv e_\alpha{}^0 - e_\alpha{}^1\,, \tag{30}$$

$$\tau_\mu \equiv \tau_\mu{}^0 + \tau_\mu{}^1\,, \qquad \bar{\tau}_\mu \equiv \tau_\mu{}^0 - \tau_\mu{}^1\,. \tag{31}$$

On top of definitions above, by taking $\omega \to \infty$ limit of relativistic Polyakov action of a string that is coupled to both the target space metric $\hat{G}_{\mu\nu}$ and 2-form gauge field $\hat{M}_{\mu\nu}$, the non-relativistic Polyakov string action

$$S_{\text{Pol.}} = -\frac{T}{2}\int d^2\sigma \left[\sqrt{-h}\, h^{\alpha\beta}\, \partial_\alpha x^\mu \partial_\beta x^\nu H_{\mu\nu} + \epsilon^{\alpha\beta}\left(\lambda\, e_\alpha \tau_\mu + \bar{\lambda}\, \bar{e}_\alpha \bar{\tau}_\mu\right) \partial_\beta x^\mu\right]$$

$$- \frac{T}{2}\int d^2\sigma\, \epsilon^{\alpha\beta} \partial_\alpha x^\mu \partial_\beta x^\nu B_{\mu\nu} \tag{32}$$

is obtained. Using the equations of motion of the Lagrange multipliers $\lambda$ and $\bar{\lambda}$ one is able to solve for the worldsheet metric $h_{\mu\nu}$ in terms of the longitudinal metric $\tau_{\mu\nu}$ up to a scale factor:

$$h_{\alpha\beta} \sim \partial_\alpha x^\mu \partial_\beta x^\nu \tau_{\mu\nu}\,. \tag{33}$$

Substituting this solution back into the non-relativistic Polyakov Lagrangian (32) one obtains the Nambu-Goto formulation of the non-relativistic Polyakov string.

The non-relativistic Polyakov string defined by the Lagrangian (32) is a central result. The nice thing is that, although it was obtained as a kind of limit of the relativistic Polyakov string, one could use the Lagrangian (32) as an independent starting point to investigate the properties of non-relativitic string theory. Imposing the worldsheet conformal gauge

$$\sqrt{-h}\, h^{\alpha\beta} = \eta^{\alpha\beta} \tag{34}$$

and taking the flat spacetime background

$$\tau_\mu{}^A = \delta_\mu^A\,, \qquad E_\mu{}^a = \delta_\mu^a\,, \qquad M_\mu{}^a = 0 \tag{35}$$

[b]Note that we use the index $a$ both for flat worldsheet indices as well as for flat transverse target space indices. Whenever confusion could occur we will specify which index we mean.

one recovers the Lagrangian of the non-relativistic string theory of Ref. 6

$$S = -\frac{T}{2}\int d^2\sigma \left(\partial x^a\, \bar{\partial} x^b \delta_{ab} + \lambda\, \bar{\partial} X + \bar{\lambda}\, \partial \bar{X}\right) . \tag{36}$$

where

$$X = x_0 + x_1 \qquad \bar{X} = x_0 - x_1, \tag{37}$$

$$\partial = \partial_0 + \partial_1 \qquad \bar{\partial} = -\partial_0 + \partial_1. \tag{38}$$

We have generalized this Lagrangian to a string moving in an arbitrary non-relativistic gravitational background and, moreover, we have identified the geometry underlying the non-relativistic string as the string NC geometry discussed in section 2. We could now use this relation to study some of the properties of string NC geometry in the same way as we are doing in the relativistic case. One of these peculiar properties is the behaviour of the geometry under the so-called T-duality tranformations. In the next section we will derive the non-relativistic T-duality properties using the non-relativistic Polyakov Lagrangian (32) as our starting point. The non-relativistic limit introduced above is also applied to the Eintein-Hilbert action plus a term contains an auxiliary two-form and one-form gauge field and it produces the extended string Newton-Cartan gravity in Ref. 11.

## 5. T-duality

Before discussing the non-relativistic case, it is instructive to first go shortly over the relativistic case. Following Refs. 8, 9, 10, we assume that the geometry has a spacelike Killing vector $k^\mu$. Using adapted coordinates with isometry direction $y$

$$x^\mu = (y, x^i) \qquad\qquad k^\mu \partial_\mu = \partial_y \tag{39}$$

we rewrite the non-relativistic Polyakov Lagrangian (32) as the following parent action:

$$S_{\text{parent}} = \underbrace{S_{\text{Pol.}}(\partial_\alpha y \to v_\alpha)}_{\text{quadratic in } v_\alpha!} - T\int d^2\sigma \epsilon^{\alpha\beta}\tilde{y}\partial_\alpha v_\beta\,, \tag{40}$$

where we have replaced everywhere $\partial_\alpha y$ by a new field $v_\alpha$ and, moreover, have introduced a new Lagrange multiplier field $\tilde{y}$ who in a minute is going to play the role of the dual coordinate. The important point is that the Polyakov Lagrangian (32) is quadratic in $\partial y$ and, hence, the parent action as given in (40) is quadratic in $v_\alpha$.

Starting from the parent action (40) we can follow two approaches. One, we impose the equation of motion corresponding to the Lagrange multiplier $\tilde{y}$ leading to the Bianchi identiy for $v_\alpha$ whose solution is given by

$$v_\alpha = \partial_\alpha y\,. \tag{41}$$

Substituting this solution back into the action corresponding to the Polyakov Lagrangian (32) one re-obtains the Polyakov action we started from. Instead of doing

this, we can also solve for the equation of motion of $v_\alpha$. Since the first term in the parent action (40) is quadratic in $v_\alpha$ this leads to the following solution for $v_\alpha$:

$$v_\alpha = \epsilon_\alpha{}^\beta \partial_\beta \tilde{y}\,. \tag{42}$$

Substituting this solution back into the parent action (40) leads in the relativistic case to a Polyakov string moving in a dual geometric background. For instance, taking the ten-dimensional background to be a nine-dimensional Minkowski spacetime times a circle with radius $R$, after the duality transformation one ends up with the same geometry but now with R replaced by $1/R$:

$$R \quad \stackrel{T}{\to} \quad 1/R\,. \tag{43}$$

This is a special case of the so-called Buscher rules obtaned in Refs. 8, 9, 10.

We now wish to perform the same manipulations for the non-relativistic Polyakov string and derive the non-relativistic version of the Buscher rules. First of all, it matters whether we dualise in the longitudinal or transverse direction. This has to do with the fact that the term with the extra Lagrange multipliers $\lambda$ and $\bar{\lambda}$ only depends on the longitudinal embedding coordinates. These extra terms, which are absent in the relativistic case, can therefore only effect the longitudinal T-duality transformations. Following Ref. 7 we find the following results:

(1) The *longitudinal* spatial T-dual of the NR string is the Polyakov string moving in a general relativity background with a lightlike direction.

(2) The *transverse* spatial T-dual of the NR string is again a NR string but with a transverse spatial isometry direction given by the Buscher rules, i.e. a transverse circle with radius $R$ becomes a transverse circle with radius $1/R$.

## 6. Conclusions

We showed that the geometry underlying non-relativistic string theory is given by the string NC geometry as discussed in section 2. In section 4 we derived the action describing a non-relativistic Polyakov string moving in this string NC background. This led to the action (32) which should be the starting point for every effort to study non-relativistic string theory. As an example, we showed in this talk how the action (32) could be used to obtain the non-relativistic T-duality rules which gives information on how a non-relativistic string feels it's own geometry.

There are many other things one can study now, like, e.g., the calculation of the non-relativistic beta functions which would determine the consistent backgrounds in which the non-relativistic string can move. Our hope is that at the end we may use non-relativistic string theory as defined by the Lagrangian (32) to define non-relativistic holography and in this way learn something about the (non-perturbative) properties of non-relativistic conformal quantum field theories with (infinite-dimensional) Galilean conformal symmetries that could not be studied using general relativity in the bulk.

We present a systematic technique to expand the Einstein–Hilbert Lagrangian in inverse powers of the speed of light squared. The corresponding result for the non-relativistic gravity Lagrangian is given up to next-to-next-to-leading order. The techniques are universal and can be used to expand any Lagrangian theory whose fields are a function of a given parameter.

*Keywords*: Newton–Cartan geometry, non-relativistic gravity, post-Newtonian expansion.

## 1. Introduction

Recent developments have significantly improved our understanding of non-relativistic geometries such as Newton–Cartan geometry and their role in approximations and limits of relativistic theories such as general relativity, Chern–Simon theories and string theories. We will show how Newton–Cartan geometry and its torsionful generalization can be used to construct an order by order non-relativistic approximation of the Einstein–Hilbert Lagrangian. This will provide us with a non-relativistic gravity Lagrangian whose equations of motion describe Newtonian gravity and generalizations thereof that involve e.g. gravitational time dilation.

## 2. Expanding fields and Lagrangians

Consider a Lagrangian for a set of fields $\phi^I$ (with spacetime indices suppressed) that is a function of $c, \phi^I, \partial_\mu \phi^I$ where $\phi^I = \phi^I_{(0)} + c^{-2}\phi^I_{(1)} + \cdots$ with $c$ the speed of light. The explicit $c$ dependence is determined by the Lagrangian and is related to our choice of working with a set of fields whose $1/c^2$ expansion starts at order $c^0$. We will only consider even powers series in $c^{-1}$. Assuming the overall power of the Lagrangian is $c^N$ we define $\tilde{\mathcal{L}}(\sigma) = c^{-N}\mathcal{L}(c, \phi^I, \partial_\mu \phi^I)$ where $\sigma = c^{-2}$. We then Taylor expand $\tilde{\mathcal{L}}(\sigma)$ around $\sigma = 0$, i.e.

$$\tilde{\mathcal{L}}(\sigma) = \tilde{\mathcal{L}}(0) + \sigma \tilde{\mathcal{L}}'(0) + \frac{1}{2}\sigma^2 \tilde{\mathcal{L}}''(0) + O(\sigma^3)\,, \tag{1}$$

where the prime denotes differentiation with respect to $\sigma$, which satisfies

$$\frac{d}{d\sigma} = \frac{\partial}{\partial \sigma} + \frac{\partial \phi^I}{\partial \sigma}\frac{\partial}{\partial \phi^I} + \frac{\partial \partial_\mu \phi^I}{\partial \sigma}\frac{\partial}{\partial \partial_\mu \phi^I}\,. \tag{2}$$

Hence if we write

$$\mathcal{L} = c^N \tilde{\mathcal{L}}(\sigma) = c^N \left( \mathcal{L}_{\rm LO} + c^{-2} \mathcal{L}_{\rm NLO} + c^{-4} \mathcal{L}_{\rm NNLO} + O(c^{-6}) \right) , \tag{3}$$

it follows that the LO and NLO Lagrangians take the form

$$\mathcal{L}_{\rm LO} = \tilde{\mathcal{L}}(0) = \mathcal{L}_{\rm LO}(\phi^I_{(0)}, \partial_\mu \phi^I_{(0)}) , \tag{4}$$

$$\mathcal{L}_{\rm NLO} = \tilde{\mathcal{L}}'(0) = \frac{\partial \tilde{\mathcal{L}}}{\partial \sigma}\Big|_{\sigma=0} + \phi^I_{(1)} \frac{\delta \mathcal{L}_{\rm LO}}{\delta \phi^I_{(0)}} . \tag{5}$$

This shows that the equations of motion of the next-to-leading order (NLO) fields of the next-to-leading order Lagrangian are the equations of motion of the leading order (LO) fields of the leading order Lagrangian. A very similar calculation gives for the NNLO Lagrangian the expression

$$\begin{aligned} \mathcal{L}_{\rm NNLO} = {} & \frac{1}{2} \frac{\partial^2 \tilde{\mathcal{L}}}{\partial \sigma^2}\Big|_{\sigma=0} + \phi^I_{(1)} \frac{\delta}{\delta \phi^I_{(0)}} \frac{\partial \tilde{\mathcal{L}}}{\partial \sigma}\Big|_{\sigma=0} + \frac{1}{2} \phi^I_{(2)} \frac{\delta \mathcal{L}_{\rm LO}}{\delta \phi^I_{(0)}} + \frac{1}{2} \Bigg[ \phi^I_{(1)} \phi^J_{(1)} \frac{\partial^2 \mathcal{L}_{\rm LO}}{\partial \phi^I_{(0)} \partial \phi^J_{(0)}} \\ & + \left( \phi^I_{(1)} \partial_\mu \phi^J_{(1)} + \phi^J_{(1)} \partial_\mu \phi^I_{(1)} \right) \frac{\partial^2 \mathcal{L}_{\rm LO}}{\partial \phi^I_{(0)} \partial (\partial_\mu \phi^J_{(0)})} + \partial_\mu \phi^I_{(1)} \partial_\nu \phi^J_{(1)} \frac{\partial^2 \mathcal{L}_{\rm LO}}{\partial (\partial_\mu \phi^I_{(0)}) \partial (\partial_\nu \phi^J_{(0)})} \Bigg] . \end{aligned} \tag{6}$$

The term in square brackets is the second variation of the LO Lagrangian and is a quadratic form involving the Hessian of the LO Lagrangian. It can be shown that

$$\frac{\delta \mathcal{L}_{\rm NNLO}}{\delta \phi^I_{(1)}} = \frac{\delta \mathcal{L}_{\rm NLO}}{\delta \phi^I_{(0)}} . \tag{7}$$

Combining this with the fact that the equations of motion of $\phi^I_{(2)}$ of the NNLO Lagrangian give the equations of motion of the LO Lagrangian we see that the NNLO Lagrangian reproduces all of the equations of motion of the NLO Lagrangian.

## 3. Explicit dependence on speed of light of Einstein–Hilbert Lagrangian

In order to apply these ideas to the expansion of the Einstein–Hilbert (EH) Lagrangian we need to construct fields that start at order $c^0$. To this end we define

$$g_{\mu\nu} = -c^2 T_\mu T_\nu + \Pi_{\mu\nu} \qquad \text{and} \qquad g^{\mu\nu} = -\frac{1}{c^2} T^\mu T^\nu + \Pi^{\mu\nu} , \tag{8}$$

where $c^2 = \hat{c}^2/\sigma$ with $\hat{c}$ equal to the speed of light. The expansion is in $\sigma$ around zero which is the square of the dimensionless slope of the light cone in tangent space. We will set $\hat{c} = 1$ and expand around $1/c^2$. We can always impose the conditions

$$T_\mu \Pi^{\mu\nu} = 0 , \qquad T^\mu \Pi_{\mu\nu} = 0 , \qquad T_\mu T^\mu = -1 , \qquad \Pi_{\mu\rho} \Pi^{\rho\nu} = \delta^\nu_\mu + T^\nu T_\mu . \tag{9}$$

It will be convenient to use the following torsionful connection (instead of the usual Levi-Civita connection)

$$C^\rho_{\mu\nu} = -T^\rho \partial_\mu T_\nu + \frac{1}{2} \Pi^{\rho\sigma} \left( \partial_\mu \Pi_{\nu\sigma} + \partial_\nu \Pi_{\mu\sigma} - \partial_\sigma \Pi_{\mu\nu} \right) . \tag{10}$$

The covariant derivative $\overset{(C)}{\nabla}_\mu$ with respect to this connection obeys

$$\overset{(C)}{\nabla}_\mu T_\nu = 0\,, \qquad \overset{(C)}{\nabla}_\mu \Pi^{\nu\rho} = 0\,, \qquad \overset{(C)}{\nabla}_\mu T^\nu = \frac{1}{2}\Pi^{\nu\rho}\mathcal{L}_T \Pi_{\rho\mu}\,, \tag{11}$$

where $\mathcal{L}_T$ is the Lie derivative along $T^\mu$. The EH Lagrangian can be written as

$$\mathcal{L}_{\rm EH} = \frac{c^3}{16\pi G}\sqrt{-g}R = \frac{c^6}{16\pi G}\tilde{\mathcal{L}}(\sigma, T, \Pi, \partial)\,, \tag{12}$$

where $G$ is Newton's constant. The prefactor $c^3$, as opposed to the usual $c^4$, is due to the presence of $c$ in (8). The Lagrangian $\tilde{\mathcal{L}}$ which is at most order $c^0$ is

$$\tilde{\mathcal{L}} = \sqrt{-\det\left(-T_\alpha T_\beta + \Pi_{\alpha\beta}\right)}\left[\frac{1}{4}\Pi^{\mu\nu}\Pi^{\rho\sigma}T_{\mu\rho}T_{\nu\sigma} + \sigma\Pi^{\mu\nu}\overset{(C)}{R}_{\mu\nu} - \sigma^2 T^\mu T^\nu \overset{(C)}{R}_{\mu\nu}\right]. \tag{13}$$

In here $\overset{(C)}{R}_{\mu\nu}$ is defined with respect to the connection $C^\rho_{\mu\nu}$ and $T_{\mu\nu} \equiv \partial_\mu T_\nu - \partial_\nu T_\mu$.

## 4. Non-relativistic expansion of the metric

The fields $T_\mu$ and $\Pi_{\mu\nu}$, entering the metric, admit the following $1/c^2$ expansion

$$T_\mu = \tau_\mu + c^{-2}m_\mu + c^{-4}B_\mu + O(c^{-6})\,, \qquad \Pi_{\mu\nu} = h_{\mu\nu} + c^{-2}\Phi_{\mu\nu} + O(c^{-4})\,, \tag{14}$$

$$T^\mu = v^\mu + O(c^{-2})\,, \qquad \Pi^{\mu\nu} = h^{\mu\nu} + O(c^{-2})\,, \tag{15}$$

where the LO fields obey the following orthogonality and completeness relations

$$\tau_\mu v^\mu = -1\,, \qquad \tau_\mu h^{\mu\nu} = 0\,, \qquad v^\mu h_{\mu\nu} = 0\,, \qquad h^{\mu\rho}h_{\rho\nu} = \delta^\mu_\nu + v^\mu\tau_\nu\,. \tag{16}$$

This implies that the metric is expanded as

$$g_{\mu\nu} = -c^2\tau_\mu\tau_\nu + \bar{h}_{\mu\nu} + \frac{1}{c^2}\bar{\Phi}_{\mu\nu} + O(c^{-4})\,, \tag{17}$$

where we defined

$$\bar{h}_{\mu\nu} = h_{\mu\nu} - 2\tau_{(\mu}m_{\nu)}\,, \qquad \bar{\Phi}_{\mu\nu} = \Phi_{\mu\nu} - m_\mu m_\nu - B_\mu\tau_\nu - B_\nu\tau_\mu\,. \tag{18}$$

This is equivalent to metric expansions presented in the literature[1,2]. In the decomposition (8) we can perform local Lorentz transformations that act on $T_\mu$ and the vielbeine that form $\Pi_{\mu\nu}$. In the $1/c^2$ expansion these become local Galilean boosts (also known as Milne boosts) at leading order and NLO local boosts at NLO. These leave each order of the metric invariant. The quantities $\tau_\mu$, $\bar{h}_{\mu\nu}$ and $h^{\mu\nu}$ (the LO term of the inverse metric) are Milne boost invariant. The combination (18) in the metric at order $c^{-2}$ is invariant under both local Galilean and NLO local boosts.

The form of the expansions for $T_\mu$ and $\Pi_{\mu\nu}$ should be preserved in any coordinate system. This means that we must also expand the diffeomorphisms in powers of $1/c^2$. If under a diffeomorphism a tensor $X_{\mu\nu}$ changes as $\delta X_{\mu\nu} = \mathcal{L}_\Xi X_{\mu\nu}$ then we should write $\Xi^\mu = \xi^\mu + c^{-2}\zeta^\mu + O(c^{-4})$. All fields in the expansions are then tensors with respect to diffeomorphisms generated by $\xi^\mu$. The LO fields $\tau_\mu$ and $h_{\mu\nu}$

are invariant under the NLO diffeomorphisms $\zeta^\mu$, while the NLO fields transform according to

$$\delta m_\mu = \mathcal{L}_\zeta \tau_\mu = \partial_\mu \Lambda - \Lambda a_\mu + h^{\rho\sigma}\zeta_\sigma(\partial_\rho \tau_\mu - \partial_\mu \tau_\rho)\,, \tag{19}$$

$$\delta \Phi_{\mu\nu} = \mathcal{L}_\zeta h_{\mu\nu} = 2\Lambda K_{\mu\nu} + \check{\nabla}_\mu \zeta_\nu + \check{\nabla}_\nu \zeta_\mu\,, \tag{20}$$

where $\Lambda = \tau_\mu \zeta^\mu$ and $\zeta_\nu = h_{\nu\mu}\zeta^\mu$ and where $K_{\mu\nu} = -\frac{1}{2}\mathcal{L}_v h_{\mu\nu}$ is the extrinsic curvature and $a_\mu = \mathcal{L}_v \tau_\mu = v^\rho(\partial_\rho \tau_\mu - \partial_\mu \tau_\rho)$ is called the torsion vector. The derivative $\check{\nabla}_\mu$ is covariant with respect to the torsionful connection

$$\check{\Gamma}^\rho_{\mu\nu} = C^\rho_{\mu\nu}\big|_{\sigma=0} = -v^\rho \partial_\mu \tau_\nu + \frac{1}{2}h^{\rho\sigma}\left(\partial_\mu h_{\nu\rho} + \partial_\nu h_{\mu\rho} - \partial_\rho h_{\mu\nu}\right)\,. \tag{21}$$

The geometry is thus described by the LO fields $\tau_\mu$ and $h_{\mu\nu}$ and the subleading fields $m_\mu$ and $\Phi_{\mu\nu}$ are treated as gauge fields on this non-relativistic geometry. This setup is called type II Newton–Cartan geometry [3].

## 5. Non-relativistic expansion of the Einstein–Hilbert Lagrangian

We are now in a position to apply the results of section 2 to the case of the EH Lagrangian. Using (13) equation (4) becomes

$$\mathcal{L}_{\rm LO} = \frac{e}{4}h^{\mu\nu}h^{\rho\sigma}\tau_{\mu\rho}\tau_{\nu\sigma}\,, \tag{22}$$

where we defined $\tau_{\mu\nu} = \partial_\mu \tau_\nu - \partial_\nu \tau_\mu$ and $e = \left(-\det\left(-\tau_\mu\tau_\nu + h_{\mu\nu}\right)\right)^{1/2}$.

We can consider $\tau_\mu$, $h_{\mu\nu}$, $m_\mu$ and $\Phi_{\mu\nu}$ to be an independent set of quantities that can be varied independently. The total variation of $\mathcal{L}_{\rm LO}$ is then given by

$$\begin{aligned}\delta\mathcal{L}_{\rm LO} = e\left[\frac{1}{8}h^{\mu\nu}h^{\rho\sigma}\tau_{\mu\rho}\tau_{\nu\sigma}h^{\alpha\beta} - \frac{1}{2}h^{\mu\alpha}h^{\nu\beta}h^{\rho\sigma}\tau_{\mu\rho}\tau_{\nu\sigma}\right]\delta h_{\alpha\beta} \\ + e\left[-\frac{1}{4}h^{\mu\nu}h^{\rho\sigma}\tau_{\mu\rho}\tau_{\nu\sigma}v^\alpha + h^{\rho\sigma}a_\rho h^{\nu\alpha}\tau_{\nu\sigma} - e^{-1}\partial_\nu\left(e h^{\mu\nu}h^{\rho\alpha}\tau_{\mu\rho}\right)\right]\delta\tau_\alpha\,.\end{aligned} \tag{23}$$

We used here that $\delta h^{\mu\nu} = \left(v^\mu h^{\nu\rho} + v^\nu h^{\mu\rho}\right)\delta\tau_\rho - h^{\mu\rho}h^{\nu\sigma}\delta h_{\rho\sigma}$. Contracting the $\tau_\mu$ equation of motion with $\tau_\mu$ tells us that $h^{\mu\nu}h^{\rho\sigma}\tau_{\mu\rho}\tau_{\nu\sigma} = 0$. This is a sum of squares and so it implies the vanishing of the twist tensor $h^{\mu\nu}h^{\rho\sigma}\tau_{\mu\rho} = 0$ and thus that $\tau \wedge d\tau = 0$. This is a causality condition for a non-relativistic spacetime. The spacetime admits a global foliation given by a nowhere vanishing hypersurface orthogonal (clock) 1-form $\tau$. This is known as twistless torsional Newton–Cartan (TTNC) geometry [4].

From equation (13) we find that

$$\frac{\partial\tilde{\mathcal{L}}}{\partial\sigma}\Big|_{\sigma=0} = \sqrt{-\det\left(-T_\alpha T_\beta + \Pi_{\alpha\beta}\right)}\Pi^{\mu\nu}\overset{(C)}{R}{}_{\mu\nu}\big|_{\sigma=0} = e h^{\mu\nu}\check{R}_{\mu\nu}\,. \tag{24}$$

The NLO Lagrangian is of the form (5) and can thus be written as

$$\mathcal{L}_{\rm NLO} = e h^{\mu\nu}\check{R}_{\mu\nu} + \frac{\delta\mathcal{L}_{\rm LO}}{\delta\tau_\mu}m_\mu + \frac{\delta\mathcal{L}_{\rm LO}}{\delta h_{\mu\nu}}\Phi_{\mu\nu}\,, \tag{25}$$

where the Ricci tensor is defined with respect to the connection (21) as

$$\check{R}_{\mu\nu} = \check{R}_{\mu\rho\nu}{}^{\rho} = -\partial_\mu \check{\Gamma}^{\rho}_{\rho\nu} + \partial_\rho \check{\Gamma}^{\rho}_{\mu\nu} - \check{\Gamma}^{\rho}_{\mu\lambda}\check{\Gamma}^{\lambda}_{\rho\nu} + \check{\Gamma}^{\rho}_{\rho\lambda}\check{\Gamma}^{\lambda}_{\mu\nu}\,. \tag{26}$$

In section 2 we have shown that the equations of motion of the NNLO Lagrangian include all the equations of motion of the NLO Lagrangian. Furthermore, as can be seen from (6), the equations of motion of the NNLO fields will reproduce the equations of motion of the LO Lagrangian, i.e. they will impose the TTNC condition. If we are only interested in those equations of motion that involve at most NLO but not NNLO fields then we can ignore the variations of $\tau_\mu$ and $h_{\mu\nu}$ that lead to equations of motion for the NNLO fields. Using the TTNC condition on shell it can be seen that the only $\tau_\mu$ and $h_{\mu\nu}$ variations that do not involve NNLO fields are $\tau_\mu \frac{\delta}{\delta\tau_\mu}$ and $h_{\mu\rho}h_{\nu\sigma}\frac{\delta}{\delta h_{\mu\nu}}$. As far as these variations and those of the other fields are concerned we might as well implement the TTNC condition off shell. We thus conclude that an action for the LO and NLO fields can be obtained by computing the NNLO Lagrangian with TTNC off shell. The TTNC condition itself can always be obtained by adding a Lagrange multiplier of the form $\frac{1}{2}B_\mu \frac{\delta \mathcal{L}_{\text{LO}}}{\delta\tau_\mu}$ where $B_\mu$ is a NNLO field.

We will call the NNLO Lagrangian with TTNC imposed off shell the non-relativistic gravity (NRG) Lagrangian. Using (6) it can be shown to take the form

$$\begin{aligned}\mathcal{L} = e\Bigg[&-v^\mu v^\nu \check{R}_{\mu\nu} - 2m_\nu \check{\nabla}_\mu \left(h^{\mu\rho}h^{\nu\sigma} - h^{\mu\nu}h^{\rho\sigma}\right) K_{\rho\sigma} + \Phi h^{\mu\nu}\check{R}_{\mu\nu} + \frac{1}{4}h^{\mu\rho}h^{\nu\sigma}F_{\mu\nu}F_{\rho\sigma} \\ &-\Phi_{\rho\sigma}h^{\mu\rho}h^{\nu\sigma}\left(\check{R}_{\mu\nu} - \check{\nabla}_\mu a_\nu - a_\mu a_\nu - \frac{1}{2}h_{\mu\nu}h^{\kappa\lambda}\check{R}_{\kappa\lambda} + h_{\mu\nu}e^{-1}\partial_\kappa\left(eh^{\kappa\lambda}a_\lambda\right)\right)\Bigg]\,,\end{aligned} \tag{27}$$

where $\Phi = -v^\mu m_\mu$ is the Newtonian potential and where $F_{\mu\nu} = \partial_\mu m_\nu - \partial_\nu m_\mu - a_\mu m_\nu + a_\nu m_\mu$. When comparing with (6) we see that the first term in (27) agrees with $\frac{1}{2}\frac{\partial^2\tilde{\mathcal{L}}}{\partial\sigma^2}\big|_{\sigma=0}$. The terms linear in $\Phi_{\mu\nu}$ and $m_\mu$ agree with $\phi^I_{(1)}\frac{\delta}{\delta\phi^I_{(0)}}\frac{\partial\tilde{\mathcal{L}}}{\partial\sigma}\big|_{\sigma=0}$. The terms containing NNLO fields in (6) are not present here because we used TTNC off shell. Finally the second order variation of the LO Lagrangian with respect to $\tau_\mu$ is still nontrivial even when we use TTNC off shell and this leads to the field strength squared terms in (27) on the last line. Note that there are no terms quadratic in $\Phi_{\mu\nu}$ because all derivatives with respect to $h_{\mu\nu}$ of the LO Lagrangian give zero upon using the TTNC condition. The equation of motion of $\Phi_{\mu\nu}$ agrees with the equation of motion of $h_{\mu\nu}$ when varying (25) and the $m_\mu$ equation of motion of (27) agrees with the $\tau_\mu$ equation of motion of (25).

There is only one term containing $\Phi = -v^\mu m_\mu$, the Newtonian potential. To find Newtonian gravity and its generalization to TTNC geometries requires computing the variations $\tau_\mu\frac{\delta}{\delta\tau_\mu}$ and $h_{\mu\nu}\frac{\delta}{\delta h_{\mu\nu}}$[3]. If one would like to continue expanding to higher orders then we would need to compute the full NNLO Lagrangian without using TTNC off shell.

In non-relativistic gravity $\tau$ is of the form $\tau = NdT$ where $N$ is a non-relativistic lapse function and $T$ is some time function. This means that gravitational time dilation is a non-relativistic phenomenon[2,5]. For example the Tolman–Oppenheimer–Volkov solution for a fluid star is a solution of NRG coupled to a fluid[6,7]. As a result

the classical tests of general relativity: gravitational redshift, perihelion precession and bending of light are also passed by non-relativistic gravity[5].

We can rewrite (27) in terms of manifest Milne boost invariant tensors as

$$\mathcal{L} = e\Big[-\hat{v}^\mu\hat{v}^\nu\bar{R}_{\mu\nu} + \hat{\Phi}h^{\mu\nu}\bar{R}_{\mu\nu} - \bar{\Phi}_{\rho\sigma}h^{\mu\rho}h^{\nu\sigma}\Big(\bar{R}_{\mu\nu} - \bar{\nabla}_\mu a_\nu - a_\mu a_\nu - \frac{1}{2}h_{\mu\nu}h^{\kappa\lambda}\bar{R}_{\kappa\lambda} + h_{\mu\nu}e^{-1}\partial_\kappa\left(eh^{\kappa\lambda}a_\lambda\right)\Big)\Big], \tag{28}$$

where $\hat{v}^\mu = v^\mu - h^{\mu\nu}m_\nu$ and $\hat{\Phi} = -v^\mu m_\mu + \frac{1}{2}h^{\mu\nu}m_\mu m_\nu$. In here the Ricci tensors are defined with respect to the Milne boost invariant connection

$$\bar{\Gamma}^\rho_{\mu\nu} = -\hat{v}^\rho\partial_\mu\tau_\nu + \frac{1}{2}h^{\rho\sigma}\left(\partial_\mu\bar{h}_{\nu\rho} + \partial_\nu\bar{h}_{\mu\rho} - \partial_\rho\bar{h}_{\mu\nu}\right). \tag{29}$$

The NRG Lagrangian is uniquely fixed by all its gauge symmetries[3].

It would be interesting to make contact with the post-Newtonian approximation by finding a convenient way of expressing the higher orders of the $1/c^2$ expansion of the EH Lagrangian and more generally to see if this off shell and covariant approach can be used for interesting approximations to general relativity. To this end it might be useful to employ a first order formulation[8,9].

In this talk, we review the construction of two three-dimensional non-relativistic pure supergravity theories. One of these yields a supersymmetrization of Newton-Cartan gravity. The other one is a Chern-Simons theory with different bosonic equations of motion and matter couplings than Newton-Cartan gravity. We comment on the prospect of using these theories to construct non-relativistic supersymmetric field theories in curved backgrounds, that can be amenable to exact non-perturbative analysis via localization techniques.

*Keywords*: Supergravity; Newton-Cartan gravity.

## 1. Introduction

Ever since its inception in Ref. 1, supergravity (sugra) has played an important role in string theory, cosmology and high energy particle physics. Apart from its phenomenological use, sugra has also been instrumental as a tool to study strongly coupled and non-perturbative aspects of Quantum Field Theory (QFT). For example, the anti-de Sitter/Conformal Field Theory (AdS/CFT) correspondence allows one to rephrase the calculation of quantities in $d$-dimensional strongly coupled CFTs as computations in weakly coupled dual $(d+1)$-dimensional sugra theories. Another development where sugra is used in the study of non-perturbative QFT, concerns the construction of supersymmetric QFT in curved space-times. Such QFTs have the advantage that localization techniques often allow quantities such as the partition function to be calculated exactly (see Ref. 2 for a recent collection of reviews). Here, sugra techniques give a particularly convenient and insightful way to obtain the Lagrangians and supersymmetry transformation rules of these theories as a rigid limit of matter-coupled off-shell sugra, as has been shown in Ref. 3.

Sugra is most often discussed in the relativistic regime, that is suitable for high energy physics. In light of the above mentioned applications, it is clear that also non-relativistic (NR) sugra can be useful to study strongly coupled NR effective field theories that appear in Condensed Matter physics in the context of e.g. the Fractional Quantum Hall Effect or quantum critical points. NR versions of the AdS/CFT correspondence have been proposed, in which strongly coupled NR CFTs are given a dual gravity description.[4–6] Most of the ensuing work has focused on non-supersymmetric versions of these dualities. Including supersymmetry can shed

more light on the validity of such conjectured correspondences and this is where NR sugra can show its applicability. Similarly, if one can extend the results of Ref. 3 to the NR realm, one can use NR sugra as a tool to construct supersymmetric NR QFTs in curved space-times, that are amenable to exact analysis using localization techniques.

Despite the fact that relativistic sugra is by now more than 40 years old, NR versions thereof have only recently appeared in the literature. The first non-trivial pure sugra theory that incorporates only NR gravitational and spin-3/2 fields was constructed in Ref. 7. This is a three-dimensional on-shell theory and its equations of motion correspond to a supersymmetric version of Newton-Cartan (NC) gravity, Cartan's diffeomorphism covariant reformulation of the laws of Newtonian gravity.[8] A peculiar feature of NR gravity is that one can formulate different theories, with different local space-time symmetries and equations of motion, that nevertheless are of the same order of derivatives. This is unlike relativistic gravity, where the only possibility for local space-time symmetries is given by Lorentz symmetry, leading to General Relativity as the unique theory of gravity at the two-derivative level. Indeed, a three-dimensional NR gravity theory, that is different from NC gravity, was considered as a Chern-Simons (CS) theory in Ref. 10. The sugra version of this theory was then constructed as a super-CS theory in Ref. 9.

In this talk, we will give a brief overview of the construction and structure of the sugra theories of Refs. 7 and 9. We will then also comment on ongoing and future research regarding the steps that need to be taken to apply these theories to studies of non-perturbative aspects of NR field theories.

## 2. Three-dimensional Newton-Cartan and Extended Bargmann supergravity

### 2.1. *Three-dimensional Newton-Cartan supergravity*

A three-dimensional sugra version of NC gravity can be constructed by gauging a suitable NR supersymmetry algebra. The algebra chosen in Ref. 7 is the three-dimensional $\mathcal{N} = 2$ super-Bargmann algebra.[11] The bosonic part of this algebra is given by the Bargmann algebra, that consists of time and space translations, spatial rotations, NR boosts and a central charge that is associated to mass conservation. The first step of the gauging procedure then consists of associating gauge fields to every generator of the superalgebra and reading off the gauge transformation rules and covariant field strengths from the structure constants of the superalgebra in Ref. 11. See Table 1 for the notation used here.

The bosonic fields $\tau_\mu$, $e_\mu{}^a$ and $m_\mu$ transform under local rotations, boosts and the central charge such that they can be interpreted as the time-like and space-like Vielbeine and the central charge gauge field of the Vielbein formulation of NC geometry.[12,13] The two fields $\omega_\mu{}^{ab}$, $\omega_\mu{}^a$ can be interpreted as supersymmetric versions of the rotation and boost spin connections of NC geometry, once the following

Table 1. Gauging the $\mathcal{N}=2$ super-Bargmann algebra

| symmetry | generators | gauge field | parameters | curvatures |
|---|---|---|---|---|
| time translations | $H$ | $\tau_\mu$ | $\zeta(x^\nu)$ | $\hat{R}_{\mu\nu}(H)$ |
| space translations | $P_a$ | $e_\mu{}^a$ | $\zeta^a(x^\nu)$ | $\hat{R}_{\mu\nu}(P_a)$ |
| boosts | $G_a$ | $\omega_\mu{}^a$ | $\lambda^a(x^\nu)$ | $\hat{R}_{\mu\nu}(G_a)$ |
| spatial rotations | $J_{ab}$ | $\omega_\mu{}^{ab}$ | $\lambda^{ab}(x^\nu)$ | $\hat{R}_{\mu\nu}(J_{ab})$ |
| central charge transf. | $M$ | $m_\mu$ | $\sigma(x^\nu)$ | $\hat{R}_{\mu\nu}(M)$ |
| two supersymmetries | $Q_\alpha^\pm$ | $\psi_{\mu\pm}$ | $\epsilon_\pm(x^\nu)$ | $\hat{\psi}_{\mu\nu\pm}$ |

so-called 'conventional' constraints are imposed

$$\hat{R}_{\mu\nu}(P^a) = 2\partial_{[\mu}e_{\nu]}{}^a - 2\omega_{[\mu}{}^{ab}e_{\nu]b} - 2\omega_{[\mu}{}^a\tau_{\nu]} - \bar{\psi}_{[\mu+}\gamma^a\psi_{\nu]-} = 0\,, \tag{1}$$

$$\hat{R}_{\mu\nu}(M) = 2\partial_{[\mu}m_{\nu]} - 2\omega_{[\mu}{}^a e_{\nu]a} - \bar{\psi}_{[\mu-}\gamma^0\psi_{\nu]-} = 0\,. \tag{2}$$

Solving these constraints to express $\omega_\mu{}^{ab}$, $\omega_\mu{}^a$ in terms of the other fields, one finds that the resulting expressions transform as expected from NC spin connections.

At this point, one is left with the independent fields $\tau_\mu$, $e_\mu{}^a$, $m_\mu$ and $\psi_{\mu\pm}$. The commutator of two local supersymmetries should then close on these fields in order for them to define a NR sugra multiplet. The conventional constraints ensure that the supersymmetry algebra properly closes on $e_\mu{}^a$ and $m_\mu$. In order for this to work on $\tau_\mu$ however, one needs to impose the extra constraint

$$\hat{R}_{\mu\nu}(H) = 2\partial_{[\mu}\tau_{\nu]} - \frac{1}{2}\bar{\psi}_{[\mu+}\gamma^0\psi_{\nu]-} = 0\,. \tag{3}$$

This is the supercovariantization of the so-called 'zero torsion' or 'foliation' constraint that is often imposed in NR gravity, as it expresses the notion of absolute time in a coordinate independent way.

For consistency, one then needs to require that this constraint is invariant under supersymmetry, leading to two additional constraints

$$\hat{R}_{\mu\nu}(H) = 0 \quad \Rightarrow \quad \hat{\psi}_{\mu\nu+} = 0 \quad \Rightarrow \quad \hat{R}_{\mu\nu}(J_{ab}) = 0\,. \tag{4}$$

The constraint $\hat{\psi}_{\mu\nu+} = 0$ ensures algebra closure on $\psi_{\mu+}$. For the superalgebra to close on $\psi_{\mu-}$, one needs to impose two more constraints

$$e^\mu{}_a e^\nu{}_b\hat{\psi}_{\mu\nu-} = 0\,, \qquad \gamma^\mu\tau^\nu\hat{\psi}_{\mu\nu-} = 0\,, \tag{5}$$

where $e^\mu{}_a$, $\tau^\mu$ are projective inverses of $e_\mu{}^a$ and $\tau_\mu$. The last of these constraints can be interpreted as an equation of motion for a NR spin-3/2 field. This interpretation is confirmed by its supersymmetry variation that is given by a supersymmetric version of the covariant Poisson equation, that is the analog of the Einstein equations in NC gravity. At this point, one is then left with a set of independent fields $\tau_\mu$, $e_\mu{}^a$, $m_\mu$, $\psi_{\mu\pm}$ that form a consistent NR on-shell sugra multiplet. This multiplet can be called 'on-shell Newton-Cartan' since it only realizes the superalgebra once the supersymmetric NC equations of motion hold.

### 2.2. *Extended Bargmann supergravity*

One of the drawbacks of ordinary NC supergravity described above, is that there is no simple action principle (involving just the fields given above) known that leads to the NC equations of motion. This complicates discussions of matter couplings and attempts to e.g. construct supersymmetric QFTs in curved space-times by generalizing Ref. 3. Moreover, as noted in eq. 4, on-shell NC sugra implements a foliation constraint $\hat{R}_{\mu\nu}(H) = 0$ from which it follows that also $\hat{R}_{\mu\nu}(J_{ab}) = 0$. These two constraints imply that the theory's space-time manifold is foliated in an absolute time and flat spatial slices, severely limiting the possible backgrounds that could be obtained via a generalization of Ref. 3. Adding matter is unlikely to change this, as matter coupling in NC gravity does not change these constraints.

As mentioned in the introduction, there exists a different three-dimensional NR gravity theory, that is a CS theory with gauge algebra given by a central extension of the Bargmann algebra encountered in the previous subsection.[14] In Ref. 9, it was shown that adding matter density in this theory sources the constraint that implies that the spatial slices are flat, so that matter coupling can now lead to interesting NR curved backgrounds. A sugra generalization might thus serve as a good starting point to generalize the construction of Ref. 3 to NR QFTs.

Such a sugra generalization was constructed in Ref. 9, as a super-CS theory based upon a novel superalgebra that admits a non-degenerate supertrace. With respect to Table 1, this algebra contains 2 extra generators: a bosonic generator $S$ with associated gauge field $s_\mu$ and field strength $\hat{R}_{\mu\nu}(S)$ and a fermionic generator $R$ with associated gauge field $\rho_\mu$ and field strength $\hat{\rho}_{\mu\nu}$. The action is easily constructed following the CS recipe and is given by

$$S = \frac{k}{4\pi}\int \mathrm{d}^3x\epsilon^{\mu\nu\rho}\Big(e_\mu{}^a\hat{R}_{\nu\rho}(G_a) - m_\mu\hat{R}_{\nu\rho}(J) - \tau_\mu\hat{R}_{\mu\nu}(S) + \bar{\psi}_{\mu+}\hat{\rho}_{\nu\rho} + \bar{\rho}_\mu\hat{\psi}_{\nu\rho+} + \bar{\psi}_{\mu-}\hat{\psi}_{\nu\rho-}\Big)\,, \tag{6}$$

where $k$ is the CS coupling constant and $\hat{R}_{\mu\nu}(J) = \frac{1}{2}\epsilon^{ab}\hat{R}_{\mu\nu}(J_{ab})$. Varying this action with respect to $\omega_\mu{}^a$, $\omega_\mu{}^{ab}$ reproduces the conventional constraints 1, that allow one to express these spin connections in terms of the other fields. Variation with respect to $s_\mu$ yields the foliation constraint 3. Since one has an action at hand, matter coupling can be done by adding a suitable matter action, minimally coupled to this sugra background. In such a minimally coupled matter action, the field $m_\mu$ couples to the matter density. Since $m_\mu$ couples to $\hat{R}_{\mu\nu}(J_{ab})$ in the gravitational action 6, one sees that the inclusion of matter can indeed source the curvature $\hat{R}_{\mu\nu}(J_{ab})$ of spatial sections, as advertised.

## 3. Towards non-relativistic supersymmetric field theories in curved space-times

The method of Ref. 3 to obtain supersymmetric QFTs in curved backgrounds starts from matter-coupled off-shell sugra. This has several technical advantages. Firstly,

the off-shell character of the sugra multiplet cleanly separates between dynamical matter fields and sugra background fields. It further allows one to systematically classify all possible backgrounds on which supersymmetry can be defined. This is done by looking for background values for the metric and auxiliary fields of the off-shell sugra multiplet for which the Killing spinor equations, obtained by putting the gravitino supersymmetry transformations equal to zero, have non-trivial solutions. The auxiliary fields can then be physically interpreted as couplings of the supercurrent multiplet to the background geometry.

Both NR sugra multiplets discussed in the previous section are on-shell. In order to maintain the above mentioned technical advantages, it would be desirable to extend these multiplets to off-shell ones. This question has been addressed for the on-shell NC multiplet in Refs. 15, 16. The multiplets constructed in these references are off-shell, in the sense that one no longer needs the second of eqs. 5 to obtain algebra closure. At present, there is however no completely off-shell formulation of the multiplets presented above known, for which algebra closure is guaranteed without the imposition of extra constraints. One always needs to impose the foliation constraint or a so-called twistless torsional (see Ref. 18) generalization thereof. The last constraint of eqs. 4 is modified to include auxiliary field contributions. It would be interesting to investigate how to couple matter to these multiplets. Likewise, it would be interesting to carry out an analysis of the Killing spinor equations, following from these multiplets, to see whether they can support non-trivial curved supersymmetric backgrounds.[17]

The lack of completely off-shell multiplets indicates that an alternative approach to obtaining NR supersymmetric field theories in curved space-times can be useful. In this regard, it is noteworthy that four-dimensional Lorentzian backgrounds on which supersymmetry can be defined exhibit a null Killing vector.[19,20] It is known that dimensional reduction along null isometries leads to NR theories.[12,21] This suggests that three-dimensional NR supersymmetric field theories on curved backgrounds can be obtained by dimensional reduction of relativistic ones over null directions. This approach is currently pursued in work in progress, on which we hope to report soon.[22]

## Acknowledgments

The authors are grateful to the organizers of the MG15 meeting and the organizers of the 'Newton-Cartan gravity' parallel session at the MG15 meeting for the opportunity to present the work described here.

We review how the large $c$ expansion of General Relativity leads to an effective theory in the form of Twistless Torsional Newton-Cartan gravity. We show how this is a strong field expansion around the static sector of General Relativity and illustrate this through two examples.

*Keywords*: Nonrelativistic gravity; Strong gravity; Newton-Cartan geometry.

## 1. Introduction

Weak field and/or nonrelativistic approximations of General Relativity (GR) have various applications, see e.g. Ref. 1 for an introduction. These approximations are typically worked out in an adapted coordinate system. To the author's knowledge a covariant expansion of GR in the (inverse) speed of light $c$ was not systematically studied before the work of Dautcourt[2] in the '90s. In that work it is assumed that the coefficient of $c^2$ in the relativistic connection vanishes and with this assumption the leading and subleading orders of the expansion reproduce Newtonian and post-Newtonian gravity respectively, see also Ref. 3. Because the formalism is manifestly covariant one reproduces (post-)Newtonian gravity in a covariant formalism, so called Newton-Cartan (NC) gravity. The analysis of Ref. 2 leaves however two questions: 1) why this assumption on the connection? 2) how come a large $c$ expansion automatically leads to a small $G_{\mathrm{N}}$ result? Indeed, as was recently shown[4], these two questions are closely related: relaxing the assumption on the connection introduces (nonrelativistic) strong gravitational effects, in particular time dilation. Working out the expansion in full detail one obtains at leading order a generalization of Newtonian gravity, where this effect of time dilation is encoded as a torsion in the NC connection.[a]

## 2. Review of the large $c$ expansion

In the large $c$ expansion[2–4] one starts from an expansion of the metric and its inverse in (even[b]) powers of $c^{-1}$:

$$g_{\mu\nu} = \sum_{i=-1}^{\infty} \overset{(2i)}{g}_{\mu\nu} c^{-2i} \qquad g^{\mu\nu} = \sum_{i=0}^{\infty} \overset{(2i)}{g}{}^{\mu\nu} c^{-2i}. \tag{1}$$

[a] Since this talk was presented some further related work appeared[5,6].

[b] It is consistent to consider only even powers of $c$, odd powers are allowed to appear however and including them is interesting[7].

The key physical input – that time is related to space through a factor $c$ – translates to the assumption that $\overset{(-2)}{g}_{\mu\nu}$ is of rank 1 and negative, so we can write

$$\overset{(-2)}{g}_{\mu\nu} = -\tau_\mu \tau_\nu . \tag{2}$$

One needs to impose the condition that $g_{\mu\nu}$ and $g^{\mu\nu}$ are each others inverse. For the leading term of the inverse metric this implies it is purely spatial, i.e. a rank three symmetric tensor orthogonal to the time direction:

$$\overset{(0)}{g}{}^{\mu\nu} = h^{\mu\nu} \qquad \text{with} \qquad h^{\mu\nu}\tau_\nu = 0. \tag{3}$$

At subleading order one finds that[4]

$$\overset{(0)}{g}_{\mu\nu} = -2\hat{\Phi}\tau_\mu\tau_\nu + \hat{h}_{\mu\nu} \qquad \overset{(2)}{g}{}^{\mu\nu} = -\hat{\tau}^\mu\hat{\tau}^\nu + \hat{\beta}^{\mu\nu} \tag{4}$$

where $\tau_\nu\hat{\tau}^\nu + \hat{h}_{\mu\rho}h^{\rho\nu} = \delta^\nu_\mu \qquad \hat{\tau}^\rho\hat{\tau}^\sigma\hat{h}_{\rho\sigma} = 0 \qquad \tau_\mu\hat{\beta}^{\mu\nu} = 0.$

Expanding the metric compatibility equation for the relativistic covariant derivative naturally leads to the nonrelativistic connection[4]

$$\begin{aligned}\overset{(nc)}{\Gamma}{}^\lambda_{\mu\nu} = \frac{1}{2}h^{\lambda\rho}\Big(\partial_\mu\hat{h}_{\rho\nu} + \partial_\nu\hat{h}_{\mu\rho} - \partial_\rho\hat{h}_{\mu\nu} + 2\partial_\rho\hat{\Phi}\tau_\mu\tau_\nu - 4\hat{\Phi}(\tau_\mu\partial_{[\nu}\tau_{\rho]} + \tau_\nu\partial_{[\mu}\tau_{\rho]})\Big) \\ + \hat{\tau}^\lambda\partial_\mu\tau_\nu .\end{aligned} \tag{5}$$

This connection is compatible with the Newton-Cartan structure, i.e. $\overset{(nc)}{\nabla}_\mu h^{\nu\lambda} = 0$ and $\overset{(nc)}{\nabla}_\mu\tau_\nu = 0$, but has torsion $\overset{(nc)}{\mathrm{T}}{}^\lambda_{\mu\nu} = 2\hat{\tau}^\lambda\partial_{[\mu}\tau_{\nu]}$.

One can now insert the expansion (1) into the relativistic Ricci tensor and expand it in turn in powers of $c^{-2}$. Equating each term to zero will provide an expansion of the vacuum Einstein equations[c]. At leading order the Einstein equation is equivalent to

$$\tau_{[\mu}\partial_\nu\tau_{\lambda]} = 0\,. \tag{6}$$

The geometric interpretation of the equation (6) is two-fold: first it implies that $\tau_\mu$ defines a foliation and hence a global time direction, second it implies that the torsion of the connection (5) is twistless[8], and the related geometry is referred to as Twistless Torsional Newton Cartan (TTNC) geometry.

The next to leading order Einstein equation provides an equation for this torsion:

$$h^{\lambda\rho}(\overset{(nc)}{\nabla}_\lambda\hat{a}_\rho - \hat{a}_\lambda\hat{a}_\rho) = 0\,, \qquad \text{where } \hat{a}_\mu = \mathcal{L}_{\hat{\tau}}\tau_\mu\,. \tag{7}$$

At next to next to leading order the expanded relativistic Ricci tensor provides an equation for the Ricci tensor of the Newton-Cartan connection (5), see Ref. 4 for the actual expression, we'll here simply refer to it as the 'Ricci equation'. The component of this Ricci equation proportional to $\tau_\mu\tau_\nu$ provides the Poisson equation for the Newtonian potential $\Phi$. The Ricci equation together with (7) provide a system of equations for the fields determining the TTNC geometry and for this reason we'll refer to the theory formed by these equations as TTNC gravity.

[c]See Ref. 4 for the contributions of the energy momentum tensor.

In summary, up to next to next to leading order in a $c^{-2}$ expansion GR is effectively described by TTNC gravity.

## 3. TTNC gravity as an expansion around static GR

One of the defining features of NC geometry is that it is covariant under 4 dimensional diffeomorphisms. But since in TTNC there is a well defined time direction – specified by $\tau_\mu$ – on which all observers agree, this 4 dimensional diffeomorphism covariance is somewhat artificial. Indeed, from a physical point of view it might be more natural to introduce an explicit time coordinate $t$, such that $\tau_\mu = e^{\lambda(t,x)}\delta^t_\mu$, the most general form allowed by (6). This choice of time breaks 4 dimensional diffeomorphisms to 3 dimensional time dependent diffeomorphisms.[d] It has the advantage that it removes a number of unphysical components of the fields and makes the physical field content more explicit. After this partial gauge fixing the expansion (2, 3, 4) can be rewritten as

$$\begin{aligned} ds^2 = &-c^2\, e^{\lambda} dt^2 + e^{-\lambda} h_{ij} dx^i dx^j - 2e^{\lambda} dt(\Phi dt - C_i dx^i) \\ &+ c^{-2}\left((e^{-\lambda}\beta_{ij} - e^{\lambda} C_i C_j) dx^i dx^j + B_i dt dx^i + \Sigma dt^2\right) + \mathcal{O}(c^{-4}). \end{aligned} \tag{8}$$

The physical fields are then a scalar $\lambda$, a spatial 3-metric $h_{ij}$, the Newtonian potential $\Phi$, a vectorfield $C_i$ and a symmetric 3-tensor $\beta_{ij}$[e]. This formulation makes manifest the connection between the NC torsion and the time-like warpfactor of GR, both determined by $\lambda$. Contrary to the Newtonian potential $\Phi$, which is the contribution to the warp factor at zeroth order the potential $\lambda$ appears at the higher order $c^2$, it encodes a strong gravitational effect that is absent in the weak field post-Minkowskian approximation.

The TTNC gravitational equations, (7) and the Ricci equation, take the following form in this formulation ($K_{ij} = 2\partial_{[i}C_{j]}$ , $G_i = -\partial_i\Phi - e^{-\frac{1}{2}\lambda}\partial_t(e^{\frac{1}{2}\lambda}C_i)$):

$$\nabla_i \partial^i \lambda = 0 \qquad\qquad R_{ij} = \frac{1}{2}\partial_i\lambda\partial_j\lambda \tag{9}$$

$$\frac{1}{2}\nabla^j\left(e^{2\lambda}K_{ij}\right) = -h^{jk}\nabla_{[j}\dot{h}_{i]k} - \frac{1}{2}(h^{jk}\dot{h}_{jk} - \dot{\lambda})\partial_i\lambda - \partial_i\dot{\lambda} + \dot{h}_{ij}\partial^j\lambda \tag{10}$$

$$-e^{\frac{3}{2}\lambda}\nabla^i(e^{\frac{1}{2}\lambda}G_i) = T[\ddot{\lambda}, \ddot{h}, \partial\phi, \nabla\beta]. \tag{11}$$

The first important point to note is the hierarchical nature of the above equations. The first two equations (9) form an independent closed system of equations for $h_{ij}(t,x)$ and $\lambda(t,x)$ wich determines their spatial dependence but leaves the time dependence free. The third equation (10) is an equation that determines the spatial dependence of $C_i(t,x)$ and takes the time derivatives of $h_{ij}$ and $\lambda$ as input sources. The last equation (11) is an equation containing $\Delta\Phi$ and can thus be identified with

[d] See e.g. Ref. 9 for some details on the precise relation between the 4d diffeomorphisms, Milne boosts and 3d time dependent diffeomorphisms.

[e] Note that the fields $B_i$ and $\Sigma$ will not appear in the equations to the order of the expansion we consider in this work.

the Newtonian Poisson equation, interestingly it contains second time derivatives of $h_{ij}$ and $\lambda$, and spatial derivatives of $C_i$ as sources[f].

Secondly one observes[g] that the equations (9) are essentially the static Einstein equations. Indeed any static metric can be written in the form $ds^2 = -c^2\, e^{\tilde{\lambda}(x)} dt^2 + e^{-\tilde{\lambda}(x)} \tilde{h}_{ij}(x) dx^i dx^j$ and for such an ansatz the vacuum Einstein equations reduce to equations of the form (9). The key difference between (9) and the static Einstein equations is that contrary to $\tilde{\lambda}$ and $\tilde{h}_{ij}$ the fields $\lambda$ and $h_{ij}$ are time-dependent. We come to the conclusion that $\lambda$ and $h_{ij}$ correspond to solutions of the static Einstein equations with any integration constants replaced by arbitrary functions of time. Such time-dependent deviations from static solutions then source the equations for the higher order fields, starting a series of corrections. One thus sees that the large $c$-expansion is an expansion around the static sector of GR. In particular any static solution[h] of GR will also be an exact (i.e. contrary to infinite series) solution of the effective TTNC gravity theory (by putting all fields other than $\lambda$, $h_{ij}$ to zero). This makes very concrete how the large $c$-expansion is an extension of Newtonian gravity that also contains strong gravitational effects: indeed all the non-linearities of the static sector of GR are included.

## 4. Non-static examples

This interpretation of the large $c$-expansion as an expansion around the static sector of GR can best be explored in some non-static examples.

### 4.1. *Kerr black hole*

The Kerr black hole is a good starting point as it is no longer static but still stationary. The metric[i] contains two physical parameters $M = m\mathrm{G_N}c^{-2}$ $a = J(mc)^{-1} = Ac^{-1}$. We consider the 'strong field'[4] expansion $c \to \infty$ with $M$ and $A$ fixed. Comparing with (8) one finds

$$\lambda = \log\left(1 - \frac{2M}{r}\right) \qquad h_{ij}dx^i dx^j = dr^2 + \left(1 - \frac{2M}{r}\right) r^2 d\Omega^2 \tag{12}$$

$$C_i dx^i = 2\frac{AM}{r}\sin^2\theta \left(1 - \frac{2M}{r}\right)^{-1} d\phi \qquad \Phi = \frac{A^2 M}{r^3}\left(1 - \frac{2M}{r}\right)^{-1} \cos^2\theta. \tag{13}$$

[f]Note that we refrained from spelling out these source terms explicitely here. They can be obtained from Ref. 4 and as was pointed out there one can remove $\beta_{ij}$ from (11) by a gauge transformation. A better, gauge-independent, understanding has emerged from work[5] that appeared after this talk was presented: at one lower order there will appear an additional equation for $\beta_{ij}$ not including other new fields. Together with the equation (11) this will form a closed system determining the spatial dependence of $\Phi$ and $\beta_{ij}$.

[g]This was pointed out by J. Raeymaekers.

[h]The example of the Schwarzschild black hole was worked out in Ref. 4 and extends to other examples such as Tolmann-Oppenheimer-Volkov fluid stars[10].

[i]We follow the notation of Ref. 11.

This example – of which one can check that it solves (9-11) – shows the Kerr black hole as a nonrelativistic expansion around the Schwarzschild black hole, which is a solution to (12)[4]. The non-zero rotation of Kerr – i.e. $A$ – translates to a non-zero $C_\phi$ and $\Phi$. Note that the fields above only express the first terms in an infinite expansion of the Kerr metric. For these first terms to be a good approximation of the relativistic metric one needs the condition

$$r \gg r_+ + \frac{A^2}{Mc^2} + \mathcal{O}(c^{-4})\,, \tag{14}$$

which means that at a distance $\frac{A^2}{Mc^2}$ from the outer horizon the nonrelativistic approximation breaks down. Interestingly the strong field expansion remains valid for large radii where gravity becomes weak and where it overlaps with the post-Newtonian expansion obtained by keeping $m$ and $J$ fixed as $c \to \infty$. This suggests that the TTNC effective theory is a resummation of the post-Newtonian series.

### 4.2. *Oppenheimer-Snyder collapse*

Realistic dynamic situations can be far from stationary, and so it is interesting to explore what additional effects can appear in their large $c$-expansion. To this aim we shortly present some aspects of the nonrelativistic expansion of the Oppenheimer-Snyder solution[12] which describes the collapse of a ball of dust. This solution depends on two parameters: $r_0$, the initial radius of the ball and $M = m\mathrm{G_N}c^{-2}$, its total mass. It is composed of two metrics – an FRW universe inside the ball and the Schwarzshild metric outside – glued together along the worldtube of the ball's surface. This surface follows a radial geodesic in the Schwarschild geometry, see figure 1, and can be described through the curve $r_{\mathrm{match}}(t)$, with $r$ and $t$ the standard Schwarzschild coordinates.

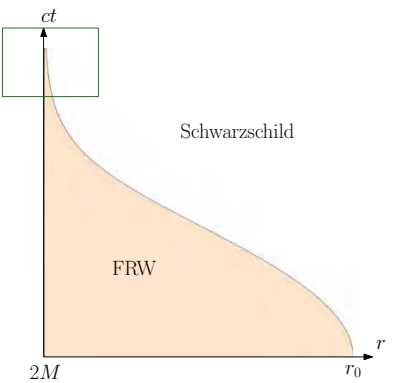

Fig. 1. Space-time of a collapsing ball of dust.

Again we'll be interested in a 'strong field'[4] expansion, where we keep $r_0$ and $M$ fixed as $c \to \infty$, and one finds

$$r_{\text{match}}(t) \approx 2M \left(1 + 2\sqrt{\frac{r_0}{2M} - 1}\, e^{-\frac{ct}{2M}} + \mathcal{O}(e^{-\frac{ct}{M}})\right). \tag{15}$$

Note that the expansion here is of a very different type than the standard Newtonian expansion which holds far away from the ball of dust, just after the collapse has started. In (15) we are close to the event where the ball forms a horizon, both in space and time, the green box in figure 1. There gravity is strong and non-Newtonian, still it is nonrelativistic. That this is the case follows from the well-known – but ever intriguing – fact that an outside observer never sees a horizon form. For such an observer the radial velocity of the shell goes asymptotically to zero again at late times, making it describable by non-relativistic physics. Interestingly though we see that the form of the first correction in (15) is non-perturbative in large $c$. It appears that to describe the nonrelativistic gravitational fields of such a collapsing ball one would need a transseries extension of the ansatz (1).

## Acknowledgments

The author thanks J. Hartong, J. Raeymaekers, and B. Vercnocke for useful discussions and comments. This work was partially supported by the Boğaziçi University Research Fund under grant number 17B03P1 and TUBITAK grant 117F376.

# Constraints on chameleon dark energy model from SN Ia and BAO observations

Stefano Bellucci*

*INFN - Laboratori Nazionali di Frascati, 1-00044, Frascati Rome, Italy*
** E-mail: Stefano.Bellucci@lnf.infn.it*

Behnaz Fazlpour

*Department of Physics, Babol Branch, Islamic Azad University Babol, Iran*
*E-mail: b.fazlpour@umz.ac.ir*

We have used data sets from Type Ia supernova (SN Ia) and Baryon Acoustic Oscillations (BAO) to place constraints on a chameleon model of dark energy in which tachyon scalar field plays the role of chameleon field. In our analysis the exponential and non-exponential forms for the non-minimal coupling function and tachyonic potential have been assumed.

*Keywords*: Dark energy; Chameleon model; Observational constraints.

## 1. Tachyonic chameleon model

A scalar field with non-minimal coupling to the matter is known as a chameleon field[1,2]. Although, this type of scalar field is heavy in the laboratory environment, on cosmological scale where the matter density is small, the chameleon is light enough to play the role of dark energy.

A chameleon scalar field has many remarkable cosmological features as they pointed out by many authors. For instance, when it couples to an electromagnetic field[3] in addition to the fluid then the fine tuning of the initial condition on the chameleon may be resolved[4]. Chameleon field can also successfully explain a smooth transition from a deceleration to an acceleration epoch for our universe[5]. The scalar field that plays the role of chameleon could be a Brans-Dicke scalar field with interesting cosmological consequences such as explaining the current accelerated expansion of the universe[5–7]. Koury in[8] has summarized some important features of the chameleon field theories. Moreover, phase-space analysis of chameleon scalar field where a quintessence field acts as a chameleon has been investigate in[9]. We have also studied the dynamics of chameleon model where tachyon field plays the role of chameleon[10]. We have utilized the dynamical system tools to obtain the critical points of such theory and showed its interesting cosmological behaviour.

In the present work we apply combined datasets of Type Ia Supernova (SN Ia) and Baryon Acoustic Oscillations to test the tachyonic chameleon model and constrain its parameters. We use $\chi^2$ minimization technique to find the best fit values of the model parameters and to plot the likelihood contours for them.

Tachyonic chameleon model of dark energy is described by the following action

$$S = \int d^4x\sqrt{-g}\Big[\frac{R}{16\pi G} - V(\phi)\sqrt{1-\partial_\mu\phi\partial^\nu\phi} + f(\phi)\mathcal{L}_m\Big], \tag{1}$$

where $g$ is the determinant of the metric tensor $g_{\mu\nu}$, $R$ is the Ricci scalar and $G$ is the bare gravitational constant. $f(\phi)$ is the coupling function between scalar field and the matter. $\mathcal{L}_m$ is the matter Lagrangian and $V(\phi)$ is also the tachyon potential.

Variation of action (1) with respect $g_{\mu\nu}$ in FRW background

$$ds^2 = dt^2 - a^2(dr^2 + r^2d\theta^2 + r^2sin^2\theta d\phi^2), \tag{2}$$

gives the following Friedman equations:

$$3H^2 = \rho_m f + \frac{V(\phi)}{\sqrt{1-\dot{\phi}^2}}, \tag{3}$$

$$2\dot{H} + 3H^2 = -\gamma\rho_m f + V(\phi)\sqrt{1-\dot{\phi}^2}, \tag{4}$$

where $\rho_m$ and $p_m$ are the matter energy density and pressure respectively where $p_m = \gamma\rho_m$.

On the other hand, variation of (1) with respect to the scalar field yields to

$$\ddot{\phi} + (1-\dot{\phi}^2)(3H\dot{\phi} + \frac{V'}{V}) = (1-3\gamma)(1-\dot{\phi}^2)^{\frac{3}{2}}\frac{\rho_m f'}{V}, \tag{5}$$

where a prime stands for derivative with respect to the $\Phi$.

In addition, the continuity equation reads,

$$(\rho_m f)^{\cdot} + 3H(1+\gamma)\rho_m f = -(1-3\gamma)\rho_m\dot{f}. \tag{6}$$

Since, tachyonic chameleon dark energy model exhibits some interesting cosmological implication from dynamical system point of view [10], investigation of such scenario using observational cosmology and constraining the model parameters according to the latest data is not only interesting but also necessary.

## 2. Observational constraints

In this section, we will fit the model parameters with recent observational data from Type Ia Supernova (SN Ia) and Baryon Acoustic Oscillations (BAO) observations.

The total $\chi^2$ for combined data analysis is given by:

$$\chi^2 = \chi^2_{\rm SN} + \chi^2_{\rm BAO}, \tag{7}$$

where

$$\chi^2_{\rm SN} = A - \frac{B^2}{C} \tag{8}$$

$$A = \sum_i \frac{\left[\mu_{\rm obs}(z_i) - \mu_{\rm th}(z_i;\mu_0 = 0)\right]^2}{\sigma_i^2}\,, \tag{9}$$

$$B = \sum_i \frac{\mu_{\rm obs}(z_i) - \mu_{\rm th}(z_i;\mu_0 = 0)}{\sigma_i^2}\,, \tag{10}$$

$$C = \sum_i \frac{1}{\sigma_i^2}\,. \tag{11}$$

$\mu_{obs}$ and $\mu_{th}$ represent the observed and theoretical distance modulus respectively. $\sigma_i$ is also the uncertainly in the distance modulus.

We use (8) for minimization of $\chi^2$ for 580 recent data points of SN Ia [11].

$\chi^2_{\rm BAO}$ is also given by

$$\chi^2_{\rm BAO} = \left(x^{\rm th}_{i,\rm BAO} - x^{\rm obs}_{i,\rm BAO}\right)\left(C^{-1}_{\rm BAO}\right)_{ij}\left(x^{\rm th}_{j,\rm BAO} - x^{\rm obs}_{j,\rm BAO}\right), \tag{12}$$

where the indices $i, j$ are in growing order in $z$, as in Table 1. The WiggleZ collaboration [12] has measured the baryon acoustic scale at three different redshifts, while SDSS and 6DFGS surveys provide data at lower redshift [13].

Table 1. The BAO data used in our analysis.

| | 6dF | SDSS | | WiggleZ | | |
|---|---|---|---|---|---|---|
| $z$ | 0.106 | 0.2 | 0.35 | 0.44 | 0.6 | 0.73 |
| $d_z$ | 0.336 | 0.1905 | 0.1097 | 0.0916 | 0.0726 | 0.0592 |
| $\Delta d_z$ | 0.015 | 0.0061 | 0.0036 | 0.0071 | 0.0034 | 0.0032 |

In addition, $C^{-1}_{\rm BAO}$ was obtained from the covariance data [12] as follows:

$$C^{-1}_{\rm BAO} = \begin{pmatrix} 4444 & 0 & 0 & 0 & 0 & 0 \\ 0 & 30318 & -17312 & 0 & 0 & 0 \\ 0 & -17312 & 87046 & 0 & 0 & 0 \\ 0 & 0 & 0 & 23857 & -22747 & 10586 \\ 0 & 0 & 0 & -22747 & 128729 & -59907 \\ 0 & 0 & 0 & 10586 & -59907 & 125536 \end{pmatrix}. \tag{13}$$

### 2.1. *Four different classes*

Two important functions in the model (1) are the chameleon field potential $V(\phi)$ and coupling function $f(\phi)$. We perform our analysis based on this fact that whether these functions are exponential (power-law) or not. Thus we have four categories given by the following cases,

*case I*: exponential coupling function and power-law potential

$$f(\phi) = f_0 e^{\alpha\phi},$$
$$V(\phi) = V_0\phi^{\beta}. \tag{14}$$

*case II*: exponential potential and a power-law $f(\phi)$

$$f(\phi) = f_0\phi^{\alpha},$$
$$V(\phi) = V_0 e^{\beta\phi}. \tag{15}$$

*case III*: power-law $f(\phi)$ and $V(\phi)$

$$f(\phi) = f_0\phi^{\alpha},$$
$$V(\phi) = V_0\phi^{\beta}. \tag{16}$$

*case IV*: Exponential $f(\phi)$ and $V(\phi)$

$$f(\phi) = f_0 e^{\alpha\phi},$$
$$V(\phi) = V_0 e^{\beta\phi}. \tag{17}$$

We are interested in constraining model parameters $\alpha$ and $\beta$ together with the present values of the density parameters. The best-fit values of $\alpha$, $\beta$ and $\Omega_{m_0}$ in addition to $\chi^2_{min}$ (the minimum value of chi-square) for each cases are presented in Table 2, separately. We have also plotted the likelihood contours for different combinations of the parameters for $1\sigma$ , $2\sigma$ and $3\sigma$ confidence levels in Figures 1-4 in cases $I$ to $IV$ respectively. For simplicity reasons we set $f_0 = V_0 = 1$. As one can see in these figures this model is in agreement with observations.

Table 2. The value of $\chi^2_{min}$ and the best fit values of model parameters $\Omega_{m_0}$, $\alpha$ and $\beta$.

| | $\chi^2_{min}$ | $\Omega_{m_0}$ | $\alpha$ | $\beta$ |
|---|---|---|---|---|
| case$I$ | 584.08 | 0.29 | -1.53 | 1.96 |
| case$II$ | 584.08 | 0.270 | 1.18 | 0.44 |
| case$III$ | 584.08 | 0.30 | 1.23 | -0.44 |
| case$IV$ | 584.09 | 0.31 | -1.58 | 2.25 |

## 3. Conclusion

Tachyonic chameleon dark energy model has the ability to alleviate the coincidence problem via the mechanism of scaling attractors[10]. In this paper we have used the latest observational data to constrain the parameters of this model. Two important functions in our analysis are tachyonic potential $V(\phi)$ and non-minimal coupling function $f(\phi)$ in action (1). In general we have considered two types of these functions i.e power-law and exponential forms.

We have fitted data from Type Ia supernova (SN Ia) and Baryon Acoustic Oscillation (BAO) to constrain the present matter density parameter $\Omega_{m_0}$, the parameter $\alpha$ in functional form of $f(\phi)$ (the non-minimal coupling function $f$ is of the form $f(\phi) \propto e^{\alpha\phi}$ or $f(\phi) \propto \phi^{\alpha}$) and the parameter $\beta$ in $V(\phi)$ (tachyonic potential is assumed to be $V(\phi) \propto e^{\beta\phi}$ or $V(\phi) \propto \phi^{\beta}$). For exponential $f(\phi)$ and power-law $V(\phi)$ we have seen that positive $\alpha$ and negative $\beta$ are favoured by the data while for power-law $f(\phi)$ and exponential $V(\phi)$ both $\alpha$ and $\beta$ should be positive in order to our model be compatible with observations. On the other hand, when $f(\phi)$ and $V(\phi)$ are both power-law functions of scalar field a positive value of $\alpha$ and a negative value of $\beta$ are favoured while when these functions are both in exponential forms then $\alpha$ is negative and $\beta$ is a positive constant. We remark that in all four cases the value of present matter density parameter $\Omega_{m_0}$ is very close to the desired value.

In summay, the scenario of the tachyonic chameleon dark energy is compatible with observations, for all examined scalar field potential and non-minimal coupling functions.

Density perturbations in the cosmic microwave background within general $f(R, \phi)$ models of gravity are presented. The general dynamical equations for the tensor and scalar modes in any $f(R, \phi)$ gravity model are provided. An application of the equations to the (varying power)-law modified gravity toy-model is then given. Based on the latest observations of the density perturbations in the sky, the model requires inflation to occur at an energy scale less than the GUT-scale ($10^{14}$ GeV). The density perturbations obtained from observations are recovered naturally, with very high precision, and without fine tuning the model's parameters.

*Keywords*: Modified gravity; Inflation; Density perturbations; (Varying power)-law model.

## 1. Introduction

Some of the great problems of modern cosmology are the problem of dark energy, the problem of dark matter and the problem of the early Universe. A widely pursued axis of research to solve these problems consists in modifying general relativity (GR). The easiest way to modify GR is to replace the Ricci scalar $R$ in the gravitational action by an arbitrary function of $R$ and/or to add a possible extra degree of freedom for spacetime, besides the metric, in the form of a scalar field $\phi$. Such modified GR models are known as $f(R, \phi)$ gravity models. In order to understand the motivation behind the peculiar (varying power)-law model, let us briefly draw a timeline of some of the well-known models of $f(R, \phi)$ modified gravity.

## 2. A brief history of $f(R, \phi)$ gravity

Here is a very simplified sketch of the various $f(R, \phi)$ models and their evolution in time.

*This talk is based on the published paper 1.

$$S \sim \int \mathrm{d}^4x\sqrt{-g}R \quad \text{Hilbert (1915).}$$

$$S \sim \int \mathrm{d}^4x\sqrt{-g}\left(\phi R - \frac{\omega(\phi)}{\phi}\partial_\mu\phi\partial^\mu\phi - V(\phi)\right) \quad \begin{cases}\text{Thiry (1948), Jordan (1955),}\\ \text{Brans-Dicke (1961),}\\ \text{Bergman (1968),}\\ \text{Nordtveldt (1970),}\\ \text{Wagoner (1970),}\\ \text{O'Hanlon (1972),}\\ \text{Horndeski (1974, complicated),}\\ \text{Bekenstein (1977),}\\ \text{Barker (1978).}\end{cases}$$

$$S \sim \int \mathrm{d}^4x\sqrt{-g}f(R) \quad \text{Buchdahl (1970).}$$

$$S \sim \int \mathrm{d}^4x\sqrt{-g}\left(\alpha_0 + \alpha_1 R + \alpha_2(R^2 - 4R_{\mu\nu} + R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}\right) \quad \text{Lovelock (1971).}$$

$$S \sim \int \mathrm{d}^4x\sqrt{-g}\left(R + \frac{R^2}{6M_P^2}\right) \quad \text{Starobinski (1980).}$$

$$S \sim \int \mathrm{d}^4x\sqrt{-g}\left(R + f_1R^2 + f_2R_{\mu\nu}R^{\mu\nu} + f_3R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}\right) \quad \text{Stelle's gravity (1980).}$$

$$S \sim \int \mathrm{d}^4x\sqrt{-g}\left(R + RF_1(\Box)R + R_{\mu\nu}F_2(\Box)R^{\mu\nu} + C_{\mu\nu\rho\rho}F_3(\Box)C^{\mu\nu\rho\sigma}\right) \quad \begin{cases}\text{Biswas-}\\ \text{Gerwick-}\\ \text{Koivisto}\\ \text{(1980).}\end{cases}.$$

The tensor $C_{\mu\nu\rho\sigma}$ consists of the more complicated invariant $\frac{1}{3}R^2 - 2R_{\mu\nu}R^{\mu\nu} + R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma}$. These expressions arise from the study of the quantum trace anomaly. A pragmatic trend has appeared more recently, however, which consists in trying out an arbitrary function of $f(R)$ inside the Lagrangian such that it could a priori be Taylor-expanded in $R$: $f(R) = \alpha_0 + \alpha_1 R + \alpha_2 R^2 \ldots$ Such models are called $f(R)$ gravity. Below is a list of the most studied ones,

$$f(R) = R - \frac{c}{(R-\Lambda_1)^n} + b(R-\Lambda_2)^m \qquad \text{Nojiri \& Odintsov (2003),}$$

$$f(R) = R + \alpha\ln\left(\frac{R}{\mu^2}\right) + \beta R^m \quad \text{Nojiri \& Odintsov (2004).}$$

$$f(R) = R + \gamma R^{-n}\left(\frac{R}{\mu^2}\right)^m \quad \text{Meng \& Wang (2004).}$$

$$f(R) = \frac{\alpha R^{2n} - \beta R^n}{1 + \gamma R^n} \quad \text{Nojiri \& Odintsov (2007).}$$

The various powers in these models are constrained by solar-system observations one one hand, and the need to reproduce both the early expansion of the universe and the late-time cosmic acceleration on the other. Some models, however, require different (real and fractional) values for the powers whether one applies them to reproduce inflation or the late-time expansion. This suggests that one might as well let the power of the Ricci scalar in the gravitational action to vary in space and time, so that it would adjust itself depending on the epoch in the evolution of the Universe and on the cosmological environment. This leads to a (*varying power*)law model, in which the power of the Ricci scalar is a spacetime-dependent scalar field:

$$S \sim \int \mathrm{d}^4x\sqrt{-g}\left[R - \frac{\mu^2}{2}\left(\frac{R}{\mu^2}\right)^{\phi}\right]. \tag{1}$$

An important remark to make here is that, unlike $f(R)$ gravity models, the redefinitions $\partial_R f = \phi$ and $(2f - R\partial_R f)/3 = dV/d\phi$ do not transform the (varying power)-law model into GR with a scalar field. this is due to the high non-linearity of the model. On the other hand, a Weyl transformation $g_{\mu\nu} \to \phi^2 g_{\mu\nu}$, followed by the field redefintion $\phi^2 \sim \sigma^{-1}$, does transform the model into a Brans-Dicke like theory, in which matter also acquires a coupling with the scalar field $\sigma$, though.

## 3. Scalar modes in any $f(R, \phi)$ model

Start from the field equations of an $f(R, \phi)$ model.[2] Then, perturb the equations using $g_{\mu\nu} = \bar{g}_{\mu\nu} + h_{\mu\nu}$, with $\bar{g}_{\mu\nu} = diag(-1, a^2, a^2, a^2)$ is the Friedmann-Lemaître-Robertson-Walker (FLRW) background metric and $|h_{\mu\nu}| \ll 1$, as well as $\phi = \bar{\phi} + \delta\phi$. Then, choose the Newtonian gauge $\mathrm{d}s^2 = -(1+2\Phi)\mathrm{d}t^2 + a^2(t)(1-2\Psi)\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j$. The dynamical equation for the gravitational potentials $\Psi$ and $\Phi$ is,[1]

$$\begin{aligned}
&\ddot{\Phi} + \ddot{\Psi} + \left(H - \frac{2\ddot{\phi}}{\dot{\phi}} + \frac{3\dot{f}_{,R}}{f_{,R}}\right)(\dot{\Phi} + \dot{\Psi}) - \left(4\dot{H} - \frac{4\ddot{f}_{,R}}{f_{,R}} + \frac{6\dot{f}_{,R}}{f_{,R}}\frac{\ddot{\phi}}{\dot{\phi}}\right)\Phi \\
&+ \left[6\dot{H} + 6H^2 + H\left(\frac{4\dot{f}_{,R}}{f_{,R}} - \frac{2\ddot{\phi}}{\dot{\phi}}\right) - \frac{f - 2\Box f_{,R}}{f_R} - \frac{\ddot{f}_{,R}}{f_{,R}} + \frac{2\dot{f}_{,R}}{f_{,R}}\frac{\ddot{\phi}}{\dot{\phi}} - \frac{\dot{\phi}^2}{f_{,R}} - \frac{\nabla^2}{a^2}\right](\Phi + \Psi) = 0.
\end{aligned} \tag{2}$$

## 4. Tensor modes in any $f(R, \phi)$ model

In order to extract the tensor modes equation, perturb the FLRW background, $\mathrm{d}s^2 = -(1+2\Phi)\mathrm{d}t^2 + \left[a^2(t)(1-2\Psi)\delta_{ij} + h_{ij}\right]\mathrm{d}x^i\mathrm{d}x^j$ and impose the transverse gauge, $\partial_i h^i_j = 0$, with also $h^i_i = 0$. The transverse modes' equation is,[1]

$$\left[\partial_0^2 - \left(H - \frac{\dot{f}_{,R}}{f_{,R}}\right)\partial_0 + 4H^2 - \frac{f - 2\Box f_{,R}}{f_{,R}} - \frac{\nabla^2}{a^2}\right]h_{ij} = 0. \tag{3}$$

## 5. The (varying power)-law model

The action of the model is,[3]

$$S = \frac{M_P^2}{16\pi}\int \mathrm{d}^4x\sqrt{-g}\left[R - (\partial\phi)^2 - m^2\phi^2 - \frac{\mu^2}{2}\left(\frac{R}{\mu^2}\right)^{\phi}\right], \tag{4}$$

where $M_P$ is the Planck mass and $m$, whose order of magnitude is not constrained by the model, is the scalar field's mass. The energy scale $\mu$ is determined by observation and it is found that it should be $\sim 10^{14}$ GeV. At the beginning of inflation $R \sim \mu^2$, so that the action approximates to $S \sim \int \mathrm{d}^4x\sqrt{-g}(R-(\partial\phi)^2)$. At late times, $R \ll \mu^2$, so that the action approximates to, $S \sim \int \mathrm{d}^4x\sqrt{-g}(R-(\partial\phi)^2-m^2\phi^2-\frac{1}{2}\mu^2(R/\mu^2)^{\phi})$, in which the last term could be identified with a cosmological constant, while the scalar field could be identified with dark matter. Thanks to the effective potential,

$$V(R,\phi) = \frac{m^2}{2}\phi^2 + \frac{\mu^2}{4}\left(\frac{R}{\mu^2}\right)^{\phi}, \tag{5}$$

of the scalar field, the mass of the latter is found to depend on the curvature of the environment.[3] In addition, the radiative corrections show that $m_{\mathrm{eff}}$ could be huge for very low curvatures.[3,4]

It turns out that this model easily finds a very nice application for investigating the early Universe.[1] The slow-roll parameters of the model are,

$$\epsilon \equiv \frac{|\dot{H}|}{H^2} \ll 1, \qquad \eta \equiv \frac{|\dot{\phi}|}{H} \ll 1. \tag{6}$$

In usual inflationary models, where the Hubble parameter is given by $H^2 \sim V(\phi)$, the analogue of the $\eta$-condition is $\dot{\phi}^2/H^2 \ll 1$, which, thanks to the scalar field's equation of motion, is just equivalent to the $\epsilon$-condition in (6). However, in the model (4) the Hubble parameter is not simply given by $H^2 \sim V(\phi)$ and, therefore, no condition should *a priori* be imposed on $\dot{\phi}$. However, it turns out that the $\eta$-condition is automatically satisfied throughout all the duration of an inflation. The latter starts in this model at an energy scale $\mu$ and ends at another energy scale not very far off. The end of inflation occurs at that energy scale for which either both or one of the slow-roll parameters in (6) ceases to be small and negligible. It is found that both slow-roll conditions (6) are satisfied up to the scale $R/\mu^2 \sim 10^{-0.05}$. The number of $e$-folds $N$ in this model can be deduced via the formula,[1]

$$N \simeq \frac{13}{4}\ln\left(\frac{\ln\rho_f}{\ln\rho_i}\right). \tag{7}$$

For example, if one assumes inflation to have ended at the energy scale of $\rho \simeq 10^{-0.05}$, then one should allow inflation to start at the energy scale of $\rho \simeq 10^{-10^{-8}}$, in which case one finds, $N \simeq 50$.[1] To have a bigger number of $e$-folds one needs to push back the starting of inflation to scales which are even closer to the $\mu$-scale, if not exactly equal to $\mu$.

### 5.1. *Scalar modes in the (varying power)-law model*

Using the scalar modes equations (2), one easily extracts for the model the following $\alpha_s$, $\nu_s$ and $\beta$ are given by,[1]

$$\alpha_s = \frac{4}{11} - \frac{3\epsilon}{22} + \frac{1501\eta}{968}, \quad \nu_s^2 = \frac{225}{121} + \frac{285\epsilon}{121} + \frac{145555\eta}{21296},$$
$$\beta = 1 + \frac{13\eta}{22}. \tag{8}$$

### 5.2. *Tensor modes in the (varying power)-law model*

Using the tensor modes equations (3), one easily extracts for the model the following $\alpha_t$, $\nu_t$,[1]

$$\alpha_t = \frac{1}{2} - \frac{\eta}{4} \qquad \text{and} \qquad \nu_t^2 = \frac{9}{4} + 3\epsilon - \frac{11\eta}{4}. \tag{9}$$

### 5.3. *The power spectra in the (varying power)-law model*

At Hubble-crossing one finds,[1]

$$r \simeq \eta_*^2, \tag{10}$$

where $\eta_*$ is the slow-roll parameter in (6) evaluated at the Hubble crossing. The scalar and tensor tilts $n_s$ and $n_t$ can be computed from the scalar and tensor power spectra $\mathcal{P}_\mathcal{R}$ and $\mathcal{P}_h$, respectively, as,[1]

$$n_s - 1 = \left.\frac{d\ln\mathcal{P}_\mathcal{R}}{d\ln k}\right|_{k=k_*} = 2 + 2\alpha_s - 2\nu_s, \tag{11}$$

$$n_t = \left.\frac{d\ln\mathcal{P}_h}{d\ln k}\right|_{k=k_*} = 2 + 2\alpha_t - 2\nu_t. \tag{12}$$

One can compute the values of $r$, $n_s$ and $n_t$ in (10), (11) and (12), respectively, for various energy scales comprised between the energy scales $\rho \sim 10^{-10^{-8}}$ and $\rho \sim 10^{-0.05}$. One easily finds that the scale for the Hubble crossing that matches the best with observations is comprised between $\rho \sim 10^{-0.008}$ and $\rho \sim 10^{-0.01}$ for which the values of $r$, $n_s$, and $n_t$ found using expressions (8) and (9) for $\alpha_s$, $\nu_s$, $\alpha_t$ and $\nu_t$ are: $r \in [0.00035, 0.00055]$, $n_s \in [0.965, 0.972]$, and $n_t \in [0.031, 0.040]$.[1]

The specific scale that agrees best with the observed values is found to be $\rho \sim 10^{-0.009}$. Indeed for this scale a computation using again expressions (8) and (9) for $\alpha_s$, $\nu_s$, $\alpha_t$ and $\nu_t$ gives the following results:[1]

$$r \simeq 0.00044, \quad n_s \simeq 0.969, \quad n_t \simeq 0.036. \tag{13}$$

Here, one uses the value of the scalar tilt to find the best match. In fact, the value of the ratio $r$ is only known by its upper boundary value which is $r < 0.1$[5]. Notice that the tensor tilt here is positive in contrast to usual single-field inflationary models

where it comes out negative. The other major difference is that the model predicts a very small value for the tensor-to-scalar ratio $r$.

One can also deduce the energy scale for inflation required by the model after making use of the relation between the scalar power spectrum $\mathcal{P}_{\mathcal{R}}$ and its amplitude $A_S$. The latest observations show that the amplitude of the scalar power spectrum at the Planck pivot scale $k_*$ is $A_S \sim 2 \times 10^{-9}$.[5] This implies that the inflation scale according to the model should be around $\sim 10^{14}\,\mathrm{GeV}$.

## 6. Conclusion

The (varying power)-law model cannot be motivated from particle physics. It has only two free parameters, though, and does not require any fine-tuning. It might unify dark energy, dark matter and the early expansion of the Universe.

# Dark matter with pressure as an alternative to dark energy

Orlando Luongo* and Marco Muccino

*Istituto Nazionale di Fisica Nucleare, Laboratori Nazionali di Frascati, 00044 Frascati, Italy*
**E-mail: orlando.luongo@lnf.infn.it*

We revise the cosmological concordance paradigm assuming dark matter shows non-vanishing pressure. We propose a Lagrangian for matter field with a Lagrange multiplier as constraint. In addition, we add a symmetry breaking effective potential accounting for the classical cosmological constant problem. To face out the fine-tuning issue, we investigate two phases: before and after transition due to the symmetry breaking. Investigating the conserved Noether current due to the *shift symmetry*, we show that our Lagrangian does not depend upon the scalar field $\varphi$ before and after transition. We propose that during the transition the dark matter sector cancels out the effects due to quantum field vacuum energy. This process induces a positive increase of Helmotz's free-energy which naturally leads to a negative pressure, which turns out to be constant since the sound speed naturally vanishes. The order of magnitude of the pressure is determined by visible matter only or by the bare cosmological constant. The numerical bounds over the pressure and matter densities are in agreement with current observations, alleviating the coincidence problem. Finally assuming a thermal equilibrium between the bath and our effective matter fluid, we estimate the mass associated to the dark matter candidate. Our bounds seem to be compatible with the most recent predictions over WIMP masses for fixed spin and temperature.

*Keywords*: The cosmological constant problem; dark energy; dark matter.

## 1. Introduction

It is now a controversial and debatable fact that the cosmic speed up is induced by a vacuum energy cosmological constant $\Lambda$. Quantum fluctuations lead to a huge amount of energy which severely differs from observations. Although $\Lambda$ is the most accepted possibility, it does not represent the unique alternative to describe present-time acceleration[1]. What cancels $\Lambda$ out leads to the well-known *cosmological constant problem* and may suggest the $\Lambda$CDM model could be theoretically incomplete[2], requiring stunning revisions[a].

In the standard paradigm, cold dark matter and baryons are pressureless. We here show that assuming an effective a scalar field Lagrangian for matter with *non-vanishing pressure* it is possible to address the cosmological constant problem if a cancellation mechanism is included. The underlying idea is to assume that during

[a]It is commonly believe that the introduction of *dark energy* represents a possible strategy. As the Universe expands the net fluid gets less dense, whereas $\Lambda$ remains constant over time. Dropping this out, dark energy leads to an evolving equation of state. However, although appealing, this scenario does not explain why quantum fluctuations are not included into Einstein's energy-momentum tensor. Nonetheless, our $\Lambda$-dominated Universe fixes the cosmological constant magnitude to be overwhelmingly close to matter, providing a further issue: *the coincidence problem*.

an early-time phase transition, dark matter pressure counterbalances the effects of $\Lambda$, leaving as unique contribute the pressure of baryons[b], as the transition ends[3].

In this paper, we discuss: 1) under which conditions pressure can be negative without putting it by hand, 2) which mechanism cancels $\Lambda$ out, 3) which predictions on dark matter candidates can be obtained and 4) how thermodynamics and small perturbations fix bounds on our model. Since we show our process does not set $\Lambda$ to zero, but partially removes it in a natural way, we end up there is no need of dark energy and/or modified gravity contributions to accelerate the Universe today. We only invoke that baryons may have non-zero pressure or that the bare cosmological constant can be the only byproduct as the transition ends.

The paper is structured as follows: In section II we discuss the effective field representation of our model. In section III, we discuss thermodynamics and small perturbations. Afterwards we show the predictions of our model in section IV and finally we conclude with our final remarks and perspectives, in section V.

## 2. Effective field representation of matter with pressure

Let us invoke a few number of basic hypotheses and possible clues on the problems plaguing the concordance paradigm: 1) dark energy does not evolve and its existence is not due to quantum fluctuations, but only to *one matter fluid* with non-vanishing pressure, 2) the coupling between matter and $\Lambda$ can produce a mechanism of cancellation for quantum fluctuations, 3) a phase transition enables the aforementioned cancellation, 4) the whole energy is constrained through a Lagrange multiplier, i.e. the fluid flows along geodesics, but with non-zero pressure, 5) thermodynamics *naturally* fixes an *emergent negative pressure* capable of accelerating the Universe. In this respect, the model is thought to degenerate with the $\Lambda$CDM paradigm, although providing different predictions[4].
This suggests

$$\mathcal{L} = K\left(X,\varphi\right) + \lambda Y\left[X,\nu\left(\varphi\right)\right] - V^{\text{eff}}\left(X,\varphi\right) \tag{1}$$

where the scalar field $\varphi$ is associated to *matter only* and $X = \frac{1}{2}g^{\alpha\beta}\nabla_\alpha\varphi\nabla_\beta\varphi$. Here, $\nu(\varphi)$ plays the role of the specific inertial mass and $V^{\text{eff}}$ takes arbitrary forms which produce a symmetry breaking transition. Assuming thermal equilibrium, the simplest possibility is: $V^{\text{eff}}(X,\varphi) = V_0 + \frac{\chi}{4}\left(\varphi^2-\varphi_0^2\right)^2 + \frac{\chi}{2}\varphi_0^2\varphi^2\frac{T^2(X)}{T_c^2}$, with $T_{\text{c}} = \varphi_0\sqrt{\chi/\bar{g}}$ the critical temperature.
The corresponding equations of motion are

$$Y = 0\,, \tag{2}$$

$$\mathcal{L}_\varphi - \nabla_\alpha\left(\mathcal{L}_X\nabla^\alpha\varphi\right) = 0\,, \tag{3}$$

$$T_{\alpha\beta} = \mathcal{L}_X\nabla_\alpha\varphi\nabla_\beta\varphi - \left(K - V^{\text{eff}}\right)g_{\alpha\beta}\,, \tag{4}$$

[b]For the sake of completeness, our model leaves open the possibility that the effective contribution to the net pressure is due to the bare cosmological constant, leaving baryons to be pressureless and dark matter to have a primordial non-vanishing pressure term.

and immediately one gets:

$$\rho\left(\lambda, X, \varphi\right) = 2X\mathcal{L}_X - \left(K - V^{\text{eff}}\right) , \tag{5}$$

$$P\left(X, \varphi\right) = K - V^{\text{eff}} . \tag{6}$$

Non-dissipative fluids are puzzled through the Carter's covariant formulation, in which coordinates of each matter space serve as labels, distinguishing fluid element worldlines[5]. Each scalars can be viewed as Stückelberg fields and are framed with four scalar fields. Hence, all thermodynamic properties are encoded via precise action's symmetries. Below we discuss which symmetries can be used for our purposes[6].

## 3. Thermodynamics and small perturbations

Providing the cosmological principle, the global shift symmetry[7] applies as

$$\varphi \to \varphi + c^0 , \tag{7}$$

with $c^0$ an arbitrary constant, on the zero-component of our fluid only.

To account for perfect fluid thermodynamics we use the first principle, the Gibbs-Duhem relation and the Helmotz free-energy density and we infer that if the Helmotz free energy variation is positive, i.e. $df > 0$, one gets $-PdV > 0$, or alternatively that $P < 0$. Immediately one finds: the internal energy $u = \rho = 2X\mathcal{L}_X - \left(K - V^{\text{eff}}\right)$, the enthalpy $h = u + P = 2X\mathcal{L}_X$, and the Gibbs free-energy $g = f + P = 0$.

It is remarkable to stress that before transition the effective potential remains constant, although after transition: the effective potential becomes a function of $X$, i.e. invariant under global shift symmetry. The study of our model during transition is beyond the purposes of this work, thus we limit our analysis when we are in proximity of minima. Therefore, invoking the Noether's theorem, from the matter Lagrangian part we find a first conserved current:

$$\mathcal{J}_1^\alpha = \sqrt{2X}\left(K_X + \lambda Y_X\right) v^\alpha . \tag{8}$$

while from the potential part only, we define another conserved current:

$$\mathcal{J}_2^\alpha = -\sqrt{2X} V_X^{\text{eff}} v^\alpha . \tag{9}$$

Hence one can see that

$$\mathcal{J}^\alpha \equiv \mathcal{J}_1^\alpha + \mathcal{J}_2^\alpha = \sqrt{2X}\mathcal{L}_X v^\alpha = s^\alpha . \tag{10}$$

The former coincides with the entropy density current $s_\alpha = s v_\alpha$.

It is easy to see that the fluid is irrotational and insentropic and, in the conformal Newtonian gauge, the density perturbations are functions of the $X$ and of the Lagrange multiplier perturbations, whereas pressure perturbations depend only on $\delta X$. We easily obtain:

$$\delta\rho = A(X)\delta X + 2X\lambda Y_{X\nu}\delta\nu + 2XY_X\delta\lambda , \quad \delta P = B(X)\delta X . \tag{11}$$

where $A(X) = (2X\mathcal{L}_X)_X - K_X$ and $B(X) = K_X$. After some manipulations, the entropy perturbation shift, $\Delta = \left(\frac{\delta P}{\delta \rho} - c_{\rm s}^2\right)\frac{\delta \rho}{P} = -\frac{D(X)\delta\nu + E(X)\delta\lambda}{P}$ leads to $c_{\rm s}^2 \equiv 0$ and $P = \text{const}$, i.e. showing a vanishing adiabatic sound speed[8–10]. The functions $D(X)$ and $E(X)$, in particular, are:

$$D(X) = 2X\lambda Y_{X\nu} c_X^2 \,, \tag{12}$$

$$E(X) = 2X\lambda Y_X c_X^2 \,. \tag{13}$$

## 4. Solving the cosmological constant problem

Shortly summarizing the cosmological constant problem is due to the ambiguity over the two possible choices of the off-set $V_0$, which leads to profoundly different physical puzzles[11]. The two possibilities are:

1) $V_0 = -\chi\varphi_0^4/4$. This implies that as the transition finishes $V^{\rm eff} = 0$. We have:

$$P_1 = \begin{cases} K & \text{(BT)} \\ K + \chi\varphi_0^4/4 & \text{(AT)} \end{cases} , \tag{14}$$

$$\rho_1 = \begin{cases} 2X\lambda Y_X - K & \text{(BT)} \\ 2X\lambda Y_X - K - \chi\varphi_0^4/4 & \text{(AT)} \end{cases} , \tag{15}$$

with $K < -\chi\varphi_0^4/4$.

2) $V_0 = 0$. Now we have that before the transition: $V^{\rm eff} = 0$. One has:

$$P_2 = \begin{cases} K - \chi\varphi_0^4/4 & \text{(BT)} \\ K & \text{(AT)} \end{cases} , \tag{16}$$

$$\rho_2 = \begin{cases} 2X\lambda Y_X - K + \chi\varphi_0^4/4 & \text{(BT)} \\ 2X\lambda Y_X - K & \text{(AT)} \end{cases} , \tag{17}$$

so $K < 0$.

In both the aforementioned cases, one has that $K$ is negative, but with different magnitudes. On the one hand, it is possible to demonstrate that $V_0 = 0$ corresponds to the ΛCDM model, plagued by the issues of coincidence and fine tuning. On the other hand, we propose that:

$$K_{\rm DM} \approx -\chi\varphi_0^4/4 \,, \tag{18}$$

$$K_{\rm BM} \ll K_{\rm DM} \,, \tag{19}$$

and easily one infers

$$P_1 \approx \begin{cases} K_{\rm DM} & \text{(BT)} \\ K_{\rm BM} & \text{(AT)} \end{cases} , \tag{20}$$

$$\rho_1 \approx \begin{cases} (\rho_{\rm DM} + \rho_{\rm BM})(1+z)^3 - K_{\rm DM} & \text{(BT)} \\ (\rho_{\rm DM} + \rho_{\rm BM})(1+z)^3 - K_{\rm BM} & \text{(AT)} \end{cases} , \tag{21}$$

where $\rho_{\rm BM} = 2X\lambda_0 Y_{{\rm BM},X}$, $\rho_{\rm DM} = 2X\lambda_0 Y_{{\rm DM},X}$ and $a = \frac{1}{1+z}$.

### 4.1. *The mechanism for cancelling Λ out*

The mechanism of cancellation is defined in Eq. (21). It elides vacuum energy contribution through dark matter. In fact, $\chi > 0$ implies that $K_{\rm DM}$ has opposite sign with respect to vacuum energy. It remains the question: Which fluid contributes to accelerate the Universe today? The answer is at the end of transition: the Universe accelerates *because of the presence of a negative baryonic pressure or in terms of a bare cosmological constant which remains non-zero.* Since the pressure is constant, the corresponding *emergent cosmological constant* is represented by a fluid whose equation of state evolves by $\omega^{-1} \propto \rho$, mimicking a dark fluid, but with no coincidence and fine-tuning[3].

The mechanism works only if dark matter constituents are appropriately chosen. In the simplest case of thermal equilibrium, the energy density of all bosons (b) and fermions (f) becomes

$$\epsilon_{\rm BT} = \left[\Omega_{\rm r}\left(\frac{T_{\rm p}}{T_0}\right)^4 + \Omega_{\rm m}\left(\frac{T_{\rm p}}{T_0}\right)^3 + \Omega_\Lambda\right]\epsilon_{\rm c} + \epsilon_{\rm v}\,, \tag{22}$$

where $\Omega_{\rm r} = (9.16 \pm 0.19) \times 10^{-5}$ is the radiation density parameter, and $\epsilon_{\rm c} = \rho_{\rm c} c^2$, where $\rho_{\rm c} = 3H^2/(8\pi G)$ is the Universe critical density, in which $H$ is the Hubble parameter and $G$ the gravitational constant. The plasma temperature is $T_{\rm p} = (6.6559 \pm 0.0019) \times 10^{14}\ K$.

In the standard picture, primordial dark matter interactions are due to annihilation of a heavier particle $Q$ with its antiparticle $\bar{Q}$. Assuming a mass $M$ and a production of two lighter particles, say $q$ and $\bar{q}$, it is licit to invoke symmetry between $Q$ and $\bar{Q}$ and so: $n_Q \equiv n_{\bar{Q}} \equiv n$, leading to the Boltzmann equation for the evolution of $n$ under the form $\frac{1}{a^3}\frac{d\left(a^3 n\right)}{dt} = -\langle \varkappa v\rangle \left(n^2 - n_{\rm eq}^2\right)$, where $n_{\rm eq}$ is the equilibrium number density and $\langle \varkappa v\rangle$ the thermally averaged cross-section.

Standard treatments[3] on the form of such particles show that the mass interval is $\leq 2$ TeV. These constituents enter the standard puzzle and represent the ones enabling the mechanism to work. Summarizing the model produces intriguing outcomes which have been reported in the list below

$$P = \text{const (always)} \Rightarrow c_{\rm s}^{\rm DM} \equiv c_{\rm s}^{\rm BM} \equiv 0\,, \tag{23}$$

$$P < 0 \text{ (from thermodynamics)}\,, \tag{24}$$

$$T = \text{const (during the transition)}\,, \tag{25}$$

$$P_{\rm DM} \gg P_{\rm BM}\ ,\ P_{\rm DM} \approx \epsilon_{\rm v}\,, \tag{26}$$

$$\rho_\Lambda \equiv P_{\rm DM}\ (\rm BT)\,, \tag{27}$$

$$\rho_\Lambda \equiv P_{\rm BM}\ (\rm AT)\,, \tag{28}$$

$$0.5 \lesssim Mc^2/\text{TeV} \lesssim 1.7\ \text{(Cold Dark Matter)}\,, \tag{29}$$

$$0.81 \leq \langle \varkappa v\rangle/(10^{-26}\text{cm}^3\text{s}^{-1}) \leq 2.42\,. \tag{30}$$

## 5. Conclusions

We demonstrated that there exists only one *perfect, irrotational, and isentropic fluid*, composed by baryons and cold dark matter. If matter is not purely pressureless, a coupling to $\Lambda$ induces a phase transition in which the quantum fluctuations may be removed by means of matter pressure. In particular, the corresponding thermodynamics of our matter fluid *naturally* suggests an emergent negative pressure, which turns out to be constant. This guarantees, from small perturbations, that the sound speed vanishes, degenerating with the $\Lambda$CDM model. Soon after the transition, we can have two possibilities: the emergent cosmological constant is given by the (negative) pressure of baryons only or by the bare cosmological constant which may dominate over baryon pressure. In both cases, the fine-tuning and coincidence issues are overcome and the $\Lambda$CDM effects are mimed in terms of a dark fluid with constant pressure but non-constant density. To address this mechanism to work at thermal equilibrium, we predict the dark matter constituents to lie inside the interval $0.5 \lesssim M \lesssim 1.7$ TeV. This leaves open the possibility to detect in laboratory additional heavier bosons. However, the mass value is strongly influenced by several factors. If non-equilibrium is invoked, for example, its magnitude is expected to change. Future developments will take into account the consequences of our model on structure formation and during early phases of Universe's evolution.

We discuss constraints to some nonminimally (NMC) coupled curvature-matter models of gravity by means of Solar System experiments.

First we discuss a NMC gravity model which constitutes a natural extension of $1/R^n$ gravity to the nonminimally coupled case. Such a NMC gravity model is able to predict the observed accelerated expansion of the Universe. Differently from the $f(R) = 1/R^n$ gravity case, which is not compatible with Solar System observations, it turns out that this NMC model is a viable theory of gravity.

Then we consider a further NMC gravity model which admits Minkowski spacetime as a background, and we derive the $1/c$ expansion of the metric. The nonrelativistic limit of the model is not Newtonian, but contains a Yukawa correction. We look for trajectories around a static, spherically symmetric body. Since in NMC gravity the energy-momentum tensor of matter is not conserved, then the trajectories deviate from geodesics. We use the NMC gravity model to compute the perihelion precession of planets and we constrain the parameters of the model from radar observations of Mercury.

*Keywords*: Extended theories of gravity; nonminimal coupling; PPN formalism; Mercury precession.

## 1. Introduction

We consider the possibility of constraining some nonminimally coupled (NMC) curvature-matter models of gravity[1] by means of Solar System experiments. The action functional involves two functions $f^1(R)$ and $f^2(R)$ of the Ricci curvature $R$. The function $f^1(R)$ is a nonlinear term which is analogous to $f(R)$ gravity, and the function $f^2(R)$ yields a NMC between the matter Lagrangian density and curvature. For other NMC gravity theories and their applications, see for instance[2–4].

NMC gravity has been applied to several astrophysical and cosmological problems such as dark matter[5,6], cosmological perturbations[7], post-inflationary reheating[8] or the current accelerated expansion of the Universe[9].

First we discuss the application of a perturbative method due to Chiba, Smith and Erickcek[10] to the NMC gravity model by Bertolami, Frazao and Paramos[9],

which constitutes a natural extension of $1/R^n$ gravity to the non-minimally coupled case. Such a NMC gravity model is able to predict the observed accelerated expansion of the Universe. Differently from the $f(R) = R + 1/R^n$ gravity case, which predicts the value $\gamma = 1/2$ for the PPN parameter $\gamma$, so that the $f(R)$ model is not compatible with Solar System observations, it turns out[11] that the NMC gravity model cannot be constrained, for specific choices of the functions $f^1(R)$ and $f^2(R)$, by the perturbative method considered by Chiba *et al.*[10], so that it remains, in this respect, a viable theory of gravity.

Then we consider a further NMC gravity model[12,13], which admits Minkowski spacetime as a background, and we derive the $1/c$ expansion of the metric assuming the functions $f^1(R)$ and $f^2(R)$ analytic at $R = 0$. The nonrelativistic limit of the model is not Newtonian, but contains a Yukawa correction. A parameterized post-Newton plus Yukawa (PPNY) approximation of the NMC model of gravity can be computed. We consider the metric around a static, spherically symmetric body and we look for trajectories of a test body around the spherical body. Since in NMC gravity the energy-momentum tensor of matter is not conserved, then the trajectories deviate from geodesics. We use the NMC gravity model to compute the perihelion precession of planets. Eventually we constrain the parameters of the model from radar observations of Mercury, including data from the NASA orbiter MESSENGER (MErcury Surface, Space ENvironment, GEochemistry and Ranging) spacecraft.

## 2. The NMC gravity action functional

The action functional of NMC gravity is given by[1]

$$S = \int \left[\frac{1}{2} f^1(R) + [1 + f^2(R)]\mathcal{L}_m\right] \sqrt{-g} d^4x,$$

where $f^1(R), f^2(R)$ are functions of the spacetime curvature $R$, $g$ is the metric determinant, $\mathcal{L}_m = -\rho c^2$ is the Lagrangian density of matter, and $\rho$ is mass density.

The function $f^2(R)$ yields a NMC between geometry and matter, and the class of $f(R)$ gravity theories is recovered in the case $f^2(R) = 0$. General Relativity (GR) is recovered by taking:

$$f^1(R) = 2\kappa(R - 2\Lambda), \quad f^2(R) = 0, \quad \kappa = c^4/16\pi G,$$

where $G$ is Newton's gravitational constant and $\Lambda$ is the Cosmological Constant.

The first variation of the action functional with respect to the metric yields the field equations

$$\left(f^1_R + 2f^2_R\mathcal{L}_m\right) R_{\mu\nu} - \frac{1}{2} f^1 g_{\mu\nu} = \nabla_{\mu\nu}\left(f^1_R + 2f^2_R\mathcal{L}_m\right) + \left(1 + f^2\right) T_{\mu\nu}, \qquad (1)$$

where $f^i_R = df^i/dR$ and $\nabla_{\mu\nu} = \nabla_\mu\nabla_\nu - g_{\mu\nu}g^{\sigma\eta}\nabla_\sigma\nabla_\eta$. Such equations will be solved by perturbative methods.

## 3. A model for the accelerated expansion of the Universe

We consider the NMC gravity model proposed by Bertolami, Frazao and Paramos[9] to account for the observed accelerated expansion of the Universe:

$$f^1(R) = 2\kappa R, \qquad f^2(R) = \left(\frac{R}{R_n}\right)^{-n}, \quad n > 0, \tag{2}$$

where $n$ is an integer and $R_n$ is a constant. This NMC gravity model constitutes a natural extension to the non-minimally coupled case of the $1/R^n$ model proposed by Carroll *et al.*[14] as an instance of $f(R)$ model.

Matter is described as a perfect fluid with negligible pressure[15] with Lagrangian density $\mathcal{L}_m = -\rho c^2$. We assume that the metric, which describes the spacetime around the Sun, is a perturbation of a flat Friedmann-Robertson-Walker (FRW) metric with scale factor $a(t)$:

$$ds^2 = -\left[1 + 2\Psi(r,t)\right] dt^2 + a^2(t) \left(\left[1 + 2\Phi(r,t)\right] dr^2 + r^2 d\Omega^2\right), \tag{3}$$

where $|\Psi(r,t)| \ll 1$ and $|\Phi(r,t)| \ll 1$. The NMC gravity model Eq. (2) yields a cosmological solution with a negative deceleration parameter $q < 0$, and the scale factor $a(t)$ of the background metric follows the temporal evolution $a(t) = a_0 \left(t/t_0\right)^{2(1+n)/3}$, where $t_0$ is the current age of the Universe[9].

In the perturbative approach developed by Chiba *et al.*[10] for $f(R)$ gravity, the Ricci curvature of the perturbed spacetime is expressed as the sum

$$R(r,t) = R_0(t) + R_1(r,t),$$

where $R_0$ denotes the scalar curvature of the background FRW spacetime and $R_1$ is the perturbation due to the Sun. The extension of the perturbative method of Chiba *et al.*[10] to NMC gravity consists in the following steps[11]. We assume that functions $f^1(R)$ and $f^2(R)$ admit a Taylor expansion around $R = R_0$, and we linearize the field equations (1) under two conditions:

(i) terms nonlinear in $R_1$ can be neglected in the Taylor expansion of $f^1, f^2$;
(ii) the following inequality

$$|R_1(r,t)| \ll R_0(t), \tag{4}$$

is satisfied both around and inside the Sun.

We compute the functions $\Psi$ and $\Phi$ of the metric Eq. (3), then we find an expression of the parameter $\gamma$ of the PPN (Parameterized Post-Newtonian) formalism[16]. Eventually the validity of the condition (4) is checked a posteriori.

The condition (4) means that the curvature $R$ of the perturbed spacetime remains close to the cosmological value $R_0$ inside the Sun. In GR such a property of the curvature is not satisfied inside the Sun. However, for some $f(R)$ theories condition (4) can be satisfied and that leads to a violation of a constraint on PPN parameter $\gamma$ from Solar System tests of gravity. For instance, the $1/R^n$ $(n > 0)$ gravity model[14] satisfies condition (4)[10,17].

The perturbative solution of the field equations (1) yields the following expression for the PPN parameter $\gamma = -\Phi(r)/\Psi(r)$ [11]:

$$\gamma = \frac{1}{2}\left[\frac{1 + f_0^2 + 4f_{R0}^2 R_0 + 12\Box f_{R0}^2}{1 + f_0^2 + f_{R0}^2 R_0 + 3\Box f_{R0}^2}\right],$$

where $f_0^2 = f^2(R_0)$ and $f_{R0}^2 = df^2/dR(R_0)$. When $f^2(R) = 0$ we find the known result $\gamma = 1/2$ which holds for $f(R)$ gravity theories which satisfy the condition $|R_1| \ll R_0$ [10]. The $1/R^n$ $(n > 0)$ gravity theory [14], where $f(R)$ is proportional to $(R + \text{constant}/R^n)$, is one of such theories that, consequently, have to be ruled out by Cassini measurement [18].

For the NMC gravity model (2), though $|R_1| \ll R_0$ for $n \gg 1$, the solution for $R_1$ inside the Sun shows that non-linear terms in the Taylor expansion of $f^2(R)$ cannot be neglected [11]:

$$f^2(R) = f_0^2\left[1 - n\frac{R_1}{R_0} + \frac{n(n+1)}{2}\left(\frac{R_1}{R_0}\right)^2 - \frac{1}{6}n(n+1)(n+2)\left(\frac{R_1}{R_0}\right)^3\right] + O\left(\left(\frac{R_1}{R_0}\right)^4\right).$$

Hence assumption (i) is contradicted, implying the lack of validity of the perturbative regime. Eventually, by such a contradiction argument the model (2) cannot be constrained by the extension to a NMC of the perturbative method by Chiba *et al.* [10], so that the model (2) remains, in this respect, a viable theory of gravity [11].

## 4. Planetary precession

We now consider a NMC gravity model where the functions $f^1(R)$ and $f^2(R)$ are assumed analytic at $R = 0$ [13], so that they admit the Taylor expansions:

$$f^1(R) = 2\kappa \sum_{i=1}^{\infty} a_i R^i, \qquad a_1 = 1, \qquad f^2(R) = \sum_{j=1}^{\infty} q_j R^j.$$

If $a_i = 0$ for any $i > 1$ and $q_j = 0$ for any $j$, then the action of GR is recovered.

The model admits Minkowski spacetime as a background, and the $1/c$ expansion of the metric can be computed [13], assuming a general distribution of matter with mass density, pressure and velocity. The nonrelativistic limit of the model turns out to be non-Newtonian, but contains also a Yukawa correction. The coefficients $a_2, a_3, q_1, q_2$ are used to compute the metric at the order $O(1/c^4)$ for the $0-0$ component, and are considered as parameters of the NMC gravity model. A parameterized post-Newton plus Yukawa (PPNY) approximation of the NMC model of gravity can be computed [13].

Here we report the result [13] for the metric in vacuum around a static, spherically symmetric body (Sun) with uniform mass density ($g_{0i} = 0$):

$$\begin{aligned} g_{00} &= -1 + 2\frac{GM_S}{rc^2}\left(1 + \alpha e^{-r/\lambda}\right) + \frac{2}{c^4}F(r), \\ g_{ij} &= \left[1 + 2\frac{GM_S}{rc^2}\left(1 - \alpha e^{-r/\lambda}\right)\right]\delta_{ij}, \end{aligned} \tag{5}$$

where $M_S$ is the mass of the spherical body, $F(r)$ is a radial potential, and $\lambda, \alpha$ are the range and strength of the Yukawa potential which depend on the parameters of the NMC gravity model[13]:

$$\lambda = \sqrt{6a_2}, \qquad \alpha = \frac{1}{3}(1-\theta) + \frac{GM_S}{c^2 R_S}\theta\left[\theta\left(\frac{\mu}{2}-1\right) - \frac{2}{3}\nu\right]\left(\frac{\lambda}{R_S}\right)^2 + \ldots, \tag{6}$$

where $R_S$ is the radius of the spherical body, $\theta, \mu, \nu$ are the following dimensionless ratios: $\theta = q_1/a_2$, $\mu = a_3/a_2^2, \nu = q_2/a_2^2$, and dots ... denote smaller contributions[13]. Formula (6) has been obtained for $\lambda \gg R_S$.

Using the metric (5) the effect of NMC gravity on the orbit of a planet is computed. In NMC gravity the energy-momentum tensor is not covariantly conserved[1]:

$$\nabla_\mu T^{\mu\nu} = \frac{f_R^2}{1+f_2}(g^{\mu\nu}\mathcal{L}_m - T^{\mu\nu})\nabla_\mu R \neq 0 \qquad \text{if } f^2(R) \neq 0,$$

consequently, the trajectories deviate from geodesics:

$$\frac{d^2x^\alpha}{ds^2} + \Gamma^\alpha_{\mu\nu}\frac{dx^\mu}{ds}\frac{dx^\nu}{ds} = \frac{f_R^2(R)}{1+f^2(R)}g^{\alpha\beta}R_{,\beta}. \tag{7}$$

Moreover, geodesics are different from GR. The formula for perihelion precession of a planet has been computed[13] for $\lambda \gg L$, where $L$ is the *semilatus rectum* of the unperturbed orbit. Here we report the leading term in the formula[13]:

$$\begin{aligned}\delta\phi_P = {} & \frac{6\pi GM_S}{Lc^2} + (1-\theta)^2\frac{\pi}{3}\left(\frac{L}{\lambda}\right)^2 e^{-L/\lambda} \\ & + (1-\theta)\frac{\pi GM_S}{3Lc^2}\theta\left[3\theta\left(\frac{\mu}{2}-1\right) - 2\nu\right]\left(1-\frac{L}{\lambda}\right)\left(\frac{L}{R_S}\right)^3 + \ldots,\end{aligned} \tag{8}$$

where the terms in the first row are the GR precession and the nonrelativistic Yukawa precession, respectively, and the term in the second row is the leading contribution from the NMC relativistic correction. Dots ... denote smaller contributions[13]. Eq. (8) reduces to the GR expression if $\theta = 1$.

Using Eq. (8), bounds on PPN parameters from the Cassini experiment[18] and fits to planetary data, including data from Messenger spacecraft[19] orbiting around Mercury, it follows that the additional perihelion precession due to NMC deviations from GR, in the case of Mercury orbit, is bounded by[13]

$$-5.87537 \times 10^{-4} < \delta\phi_P - 42.98'' < 2.96635 \times 10^{-3}.$$

These inequalities define an admissible region in the four-dimensional parameter space with dimensionless coordinates $\theta, \mu, \nu, R_S/\lambda$. Exclusion plots obtained by slicing the admissible region with two-dimensional planes can be drawn[13].

The admissible region in three-dimensional parameter subspace with coordinates $(\theta, \mu, \nu)$, for $0 < |1-\theta| \ll 1$ and a given $\lambda \gg L$, can be approximated by the region enclosed within the degenerate quadric surfaces

$$\nu = \frac{3}{4}\mu - \frac{3}{2} - 9\left(\frac{R_S}{L}\right)^3 \frac{\varepsilon_i}{(1-L/\lambda)(1-\theta)}, \qquad i = 1, 2,$$

where

$$\varepsilon_1 \frac{6\pi G M_S}{Lc^2} = -5.87537 \times 10^{-4}, \qquad \varepsilon_2 \frac{6\pi G M_S}{Lc^2} = 2.96635 \times 10^{-3}.$$

The intersection of the three-dimensional admissible subregion with a plane $\theta = constant$, with $0 < |1 - \theta| \ll 1$, is a strip enclosed between two lines in the $(\mu, \nu)$ plane. The intersections with the planes $\mu = constant$ and $\nu = constant$ are regions enclosed by pairs of hyperbolae[13].

Eventually, the BepiColombo mission to Mercury should allow for a reduction on the above bounds by approximately one order of magnitude[20].

Our proposal is suggested by the presence of still open problems in Astrophysics and Cosmology. In fact the Standard Cosmological Model, even if in agreement with the experiments on several Phenomena, features strange structure, with the presence of the "Magic" Contribute of Dark Matter and Dark Energy that reaches 96% of the total. At a closer glance the principal open problems in Astrophysics and Cosmology are:

*i.* In the observed Universe the matter prevails on antimatter even if both are always created together;
*ii.* CMB is not anisotropic nor inhomogeneous enough to be compatible with the Big Bang model without the introduction of a still unknown interaction driving the inflation;
*iii.* Given the gravity we expect a negative acceleration of the expansion. On the contrary that seems to accelerate;
*iv.* The gravitational field of Galaxies, clusters and even of the Solar system seems much stronger that the one due to the visible matter.

At present the possible suggested solutions are:

*i.* The mechanism suggested by Sakarov for matter/antimatter asymmetry is connected to CPV but experimentally this phenomenon is far too weak;
*ii.* Models have been proposed to justify inflation by supersymmetric vacuum energy and SSB but at present no evidence for supersymmetry has been found yet;
*iii.* Dark Energy has been introduced by hand in order to give a motivation to the accelerated expansion of the Universe;
*iv.* Dark Matter has been introduced in order to give a motivation to the observed discrepancies between theory and measurements of the orbital speed of the stars of the external part of the galaxies.

This situation is far from being satisfactory from the point of view of the elegance:

*i.* As many hypothesis as problems;

*ii.* Most of them just put by hand into the theory;
*iii.* Dark Matter and Dark Energy hypotheses are artificial.

The hypothesis that antimatter could have a different coupling to the gravitational field has fascinated physicists since the discovery of the first antiparticles. Several authors and one of the authors of this paper, Hajdukovic, have shown that the possible gravitational repulsion between matter and antimatter could offer at least a partial explanation for this number of cosmological problems, including those connected to dark matter and dark energy [1–15] with this single hypothesis. At present, the state-of-the-art is not very different from the framework summarized in the article by Nieto et al. in 1991 [16]. Limits on repulsive gravity have been calculated based on measurements [17] and [18]. A relatively large number of experiments on the gravitational interaction of antimatter have been proposed and even started, e.g. AEGIS [19], ALPHA [20], ATRAP [21], and GBAR [22]. Our proposal is very simple and is completely model independent. It is inspired by Good's argument [28]. We in fact propose to study a possible dependence of CP violation on the gravitational interaction in the Ks-KL system in space. The magnitude of any difference between the CP violation parameter, measured in orbit and that measured on Earth's surface would give important indication on the nature of the gravitational interaction between matter and antimatter as well as provide evidence for a quantum gravitational effect. In this paper we outline a new approach to the problem capable of providing a measurement taking advantage from the presence of energetic cosmic protons at the level of the LEO orbit around the Earth.

The rate of incoming protons in a LEO has, in fact, been measured [29] and [30], and when integrated on the target of the proposed orbiting detector, can reach as many as $2.2x10^4$ protons per second. The energy of the cosmic protons ranges from a few MeV to ∼200 GeV with the maximum flux around 1 GeV and several smaller local maxima at 5, 13, and 31 GeV.

We simulated the interaction of this spectrum of protons with several kinds of targets in order to extimate the KL and Ks production (Figures 1 and 2). We simulated the position of the decay vertex as well, downstream of a Wolframium target.

In the Figures 3 and 4 it is evident that a simple cut at the moment allows to depress the contamination of Ks in the measured events.

This means that the incident proton spectrum is energetic enough for the production of kaons allowing for a measurement of

$$R = \frac{\Gamma(\mathrm{K_L} \to \pi^+\pi^-)}{\Gamma(\mathrm{K_L} \to \pi^+\pi^-\pi^0)} \tag{1}$$

which is quadratic in $\varepsilon$. The mean gravitational field strength in a Low Earth Orbit (LEO) is about 10% less than the one on the Earth's surface. If CP violation depends linearly on the gravitational field [1] and [2] we expect a 10% effect to translate into a 20% effect on R. On a GEO orbit the intensity of the of the Earth's

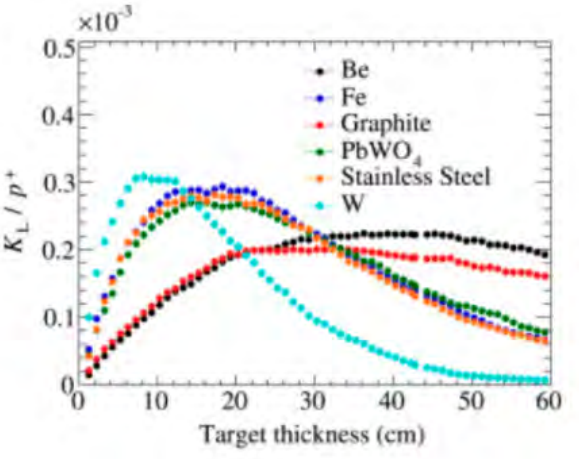

Fig. 1. KL production as simulated on different targets from cosmic proton spectrum as measured by AMS satellite[33,35].

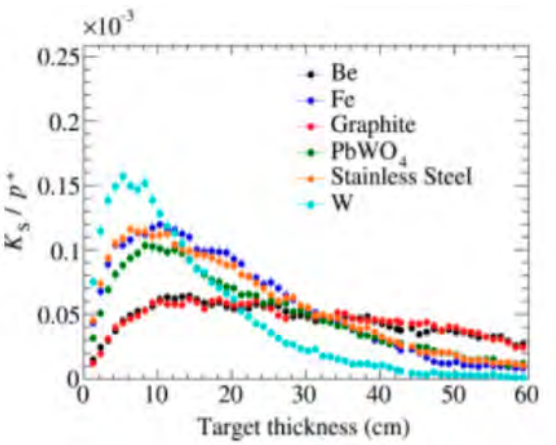

Fig. 2. KS production as simulated on different targets from cosmic proton spectrum as measured by AMS satellite[33,35].

gravitational field is of the order of few percent configuring an even better experimental condition. We suggest the use of a dedicated Satellite on a LEO orbit with a payload aimed at performing a particle physics experiment in orbit.

As can be seen in Figure 5 it includes active target, magnetic spectrometer, tracker and calorimeter. We estimate that on a square target of 70 cm of side, about $1.4x10^4$ protons per second will impact, and produce the neutral Kaons. The total number of K mesons decays over a space mission lifetime ($> 2$ years) will yield the required physical measurement of $12.5x10^5$ $K_L$ decays necessary to make a 5 $\sigma$ measurement of a 20% variation of R.

The first step to complete physical theories is to contemplate on the axiomatic character of the principles. This principle of relativity was formulated by Galileo and used by Newton to derive the laws of motion, and later was placed by Einstein at the center of the Special Theory and the General Relativity. This work considers the general principle of relativity as an expression of the inherent characteristic of the most important quantity in physics - the energy - that states that the energy is constant and is independent of the type or speed of movement of an object. The energy of an object is expressed as one entity that equals the sum of two energy expressions with different character. One of these two terms is denoted as the exposed energy with a kinetic character and represents the magnitude of the field of an object. This new definition of the energy offers several perspectives that are valid for both the classical and relativistic physics and provides insights beyond these two as: i) it leads to a coherent and complete model that relates the energy with the momentum and the force, ii) enables to construct the lagrangian that can be used to derive the equations of motion without artifices, iii) offers an original viewpoint on the dark matter and dark energy that is coherent with recent developments. Einstein was the first to deny the separate existence of gravitation and electromagnetism and has implied that the goal of a unified theory would be to explain the existence and to calculate the properties of matter. He revolutionized the use of the principles of symmetry in deriving the physical laws. It is known that the classical and quantum domain do not overlap and one would not expect the same governing symmetry principles in both domains. To calculate the properties of matter we employ spatial parameters that are related with the energy state of an object and the force that it exhibits. The mechanism assumes the common origin of different forces at the highest energy level. These spacetime parameters can be used to derive the electric and gravitational forces through a single mechanism that respects the LT dimensional analysis using neither the electrical charge nor the gravitational constant.

*Keywords*: Special relativity; exposed energy; gravitational force; non-gravitational forces; spacetime parameters; Planck scale.

## 1. Introduction

Newton and Einstein in his early efforts in formulating special relativity did not recognize the energy as an inherent characteristic of the object and this is the major reason why they postulated the expressions of the momentum in both the classical and relativistic physics. The aim of the construction of the fundamental theories is the complete understanding of the matter and its interactions. The steps to follow

in the formulation of fundamental theories would be: i) the matter, ii) fundamental quantities, iii) invariants, iv) the principle, v) mathematical apparatus, vi) the conservation laws. The matter is associated with the energy that is strongly related to the fundamental quantities of mass-space-time. The dynamic interaction of these quantities leads to consistent patterns, or constants of nature such as the constant of the speed of light c, Planck constant h, Sommerfeld constant $\alpha$ etc. These constants lead to the formulation of the principles that stand at the top of the theories. This approach allows to remove the axiomatic character of the principles, which according to the Method are considered simply as a representation of the character of the fundamental quantities. So, the fact that the speed of light is constant constitutes a postulate of the special theory, is just an unnecessary promotion to a undeserved rank. The speed of light being a constant is just a result of the fact that the ratio between the lengthscale and timescale parameters is always a constant. The energy dictates the behaviour of the space and time parameters, and their behaviour produces an important constant in physics: the constant of the speed of light. At this point we have arrived at the fourth step of the newly proposed scheme: the principle. The principle is associated by a mathematical apparatus that reflects the essence of the principle from a quantitative perspective. The scheme is concluded with the formulation of the conservation laws that determine the range of the applicability in practice of the principle that is put at the front of the theories. Placing the energy at the top of the hierarchical structure makes unnecessary the postulation of the expression of the physical quantities. Here we define the exposed energy that can be considered as the measurable energy of an object, or also as a term that is analoguous to the kinetic energy term. We define also the expression for the unexposed energy that is analoguous to the energy stored in the internal degrees of freedom of an object, or can be considered as the amount of the energy that cannot be measured experimentally. The exposed energy can be used to describe the overall interaction of an object and we can derive all the expressions of physical quantities from it. The expression for the momentum is not postulated but is directly obtained by taking the derivative of the exposed energy (of the kinetic term) with respect to the velocity for both the classical and relativistic physics. Taking the derivative of this quantity with respect to the velocity yields the expression of the momentum which for small velocities is the same as in the classical mechanics and relativistic physics.

Over time, through great efforts physicists have been able to construct elegant models of interaction of matter. Now the challenge is to unify these models as much as possible and to have a complete picture [1]. Sometimes, if not frequently, we may need to be more creative than analytical. Einstein was the first that used the principles of symmetry to derive the constraints to the dynamical laws. He wanted to include electromagnetism to the general relativity and was very persistent in the task. The major difficulty is to provide a common explanation to both gravity and quantum mechanics. The quantum effects become dominant only at smaller

lengthscales, whereas gravitation is dominant at large lengthscales and it would be unexpected to have a single symmetry principle at both domains.

De Broglie was the first that associated a space parameter to an object and on one of his works dating 1964 he calls for a reinterpretation of the wave mechanics and states that there is a need to postulate a relation between the wave and the corpuscle[2]. In a unique work that applies topological methods to cosmology, Bartini uses a unique model that a particle with a small inner radius (gravitational radius) can undergo an inversion to the larger outer radius (classical radius)[3]. He then proceeds to derive all the physical constants as a function of two parameters only.

Here in this work we present the following major points: (i) the association of an object with a field that is a function of the object's mass only, allows one to define spacetime parameters with a quantum character, and (ii) the spacetime parameters are used to determine all the parameters of an object including the potential energy that the object creates, from which the force emerges. Using these spatial parameters the force exerted by an object as a function of mass only is derived, thus dropping the gravitational constant, the Coulomb's constant and the concept of the charge. These spatial parameters are modified by the Lorentz factor and at the highest energy level are equal to the Planck length and it is at this specific point where the quantum foam-like medium is excited[4].

## 2. Definition of the Exposed Energy

The principles upon which the physical theories are constructed, rather than having an axiomatic character, are statements that describe the character of the most important fundamental quantity: the inherent character of the energy. The major principle should emphasize the constant character of energy and that is described as the sum of the internal energy (distributed among the internal degrees of freedom) and the exposed energy (defined here in this work and has kinetic character). The central idea emphasizes that as a force is exerted on an object, there is no change in its mass or its total energy but only a transformation of the internal energy into the exposed energy. The object changes only its attributes such as inertia, an attribute that should not be confused with the mass or the energy.

$$E_{exp} = mc^2 \left[ 1 - \sqrt{1 - \frac{v^2}{c^2}} \right] \tag{1}$$

An object with a defined mass and energy transforms its energy as the velocity changes. The part of the energy that is transformed is defined in this work as the exposed energy as in Eqn. (1), whereas the other part is called the unexposed energy and expressed as in Eqn. (2).

$$E_{unexp} = mc^2 \left[ \sqrt{1 - \frac{v^2}{c^2}} \right] \tag{2}$$

The sum of these two energies is a constant quantity which is called the total energy of an object, $E = E_{exp} + E_{unexp} = mc^2$. The exposed energy for small speeds converges to the expression of the kinetic energy in classical physics: $E = \frac{1}{2}mv^2$.

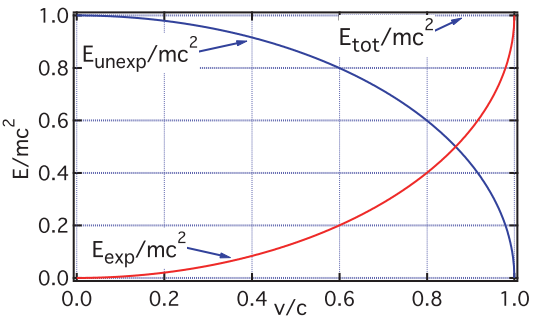

Fig. 1. The exposed (red) and unexposed (blue) energy as a function of velocity and their corresponding momentum.

The interpretation of the two newly defined energies is that the exposed energy has a kinetic character and relates to the experimentally measurable quantities. So if one massive object has a small speed then the effects that it exhibits are small, whereas for higher speed the measurable quantities increase. In this respect, the total percentage of the whole mass of the universe that is called the standard mass is very small because of the low exposed energy, or because of its relatively low kinetics. According to this interpretation, there is no need to include the dark matter as a constituent of the mass of the universe. Careful analysis of recent experimental data is raising serious questions on the existence of dark matter[5]. As the universe undergoes expansion the lengthscale increases and thus the energy scale decreases, and this decrease results in the lowering of the exposed energy. As the exposed energy decreases the experimentally measurable mass of the Universe decreases.

## 3. Derivation of the Equations of Motion

One can find the expression for the momentum by taking the derivative of the exposed energy – that represents the field of a material object as Einstein envisioned — with respect to the velocity and that is valid for relativistic and classical physics.

$$p = \frac{dE_{exp}}{dv} = \frac{mv}{\sqrt{1 - \frac{v^2}{c^2}}} \tag{3}$$

If one takes the derivative of the momentum with time, one finds the expression of the force for both classical mechanics and relativistic mechanics.

$$F = \frac{dp_{exp}}{dv} = \frac{ma}{(1 - \frac{v^2}{c^2})^{3/2}} \tag{4}$$

Once we find this force, one can calculate the work done on an object by integrating the force with the distance and one finds: $W = \int F dx = (\gamma - 1)mc^2 = KE$.

The exposed energy can be used in the formulation of the Lagrangian from which the equations of motion for both classical and relativistic mechanics are derived.

$$L = mc^2 \left[ 1 - \sqrt{1 - \frac{v^2}{c^2}} \right] - V(x) \tag{5}$$

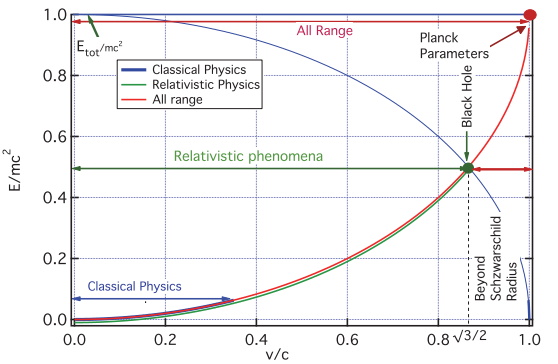

Fig. 2. The exposed and unexposed energy used to determine classical physics (blue), relativistic physics (green) and quantized geometrodynamics domain (red).

The expression for the energy used here in this work never diverges to infinity. The expression for the momentum that is postulated by Newton and then by Einstein is found here by taking the derivative of the energy. A hierarchical functional scale of the expressions of energy-momentum-force is constructed. The lagrangian described by Eqn. (5) is valid for the classical physics depicted in Figure 2 in blue (not to scale), and is also valid for the relativistic physics shown in green up to the intersection point of the exposed energy with the unexposed energy. In the literature one may find the Lagrangian expressed in the form as $L = -\frac{mc^2}{\gamma}$, where $\gamma = \frac{1}{\sqrt{1-\beta^2}}$. This expression may be criticized as the Lagrangian is commonly a relation of kinetic energy and this quantity cannot be a negative quantity. The Lagrangian reported as in Eqn (5) does not include a negative energy term and

the term is a bounded value that is between 0 and $mc^2$. The Lagrangian in polar coordinates can be expressed as below.

$$L = mc^2 \left[ 1 - \sqrt{1 - \frac{\dot{r}^2 + r^2\dot{\theta}^2}{c^2}} \right] - V(r) \tag{6}$$

The intersection point of the exposed energy with the unexposed energy is at $v = \frac{\sqrt{3}}{2} = 0.866c$ and this point determines the upper limit that an object can be described using general relativity. All the observed black holes have rotational speed smaller than this critical value. The highest speed observed is that of the black hole found in the center of the NGC 1365 galaxy with a reported value of 0.84c[6]. An object beyond this critical point cannot be analyzed without revealing its singularity. The intersection of the curves corresponds to the point where an object has its Schwarzschild radius or lengthscale parameter. After the intersection point, which would be beyond the black hole radius, all the space parameters have a quantum character and the calculations are done using the quantized geometrodynamics as formulated by Wheeler[4]. In the next section we will also show that beyond this limit an object can reach the highest energy level that would correspond to the Planck parameters.

The exposed energy increases as shown in the figure above and higher energy levels are associated with smaller lengthscales and at the highest energy level an object's spatial parameter correspond to the Planck parameters. This perspective is in line the idea of doubly-special relativity[7].

## 4. Wave Mechanics and Associating Space Parameters for Objects

Here we propose the use of mcr=$\alpha\hbar$ to find space parameters for any object. A similar formulation is the Compton wavelength, which plays an important role in determining the Compton shift and appears in Klein-Gordon equation. The equation allows parameterization of the minimum (corresponding to largest lengthscale) and the maximum energy state (smallest lengthscale) of objects in nano- and macroscale.

$$r^m_{max} = \frac{\alpha\hbar}{mc} \tag{7}$$

Using these space parameters, all the other parameters including the force can be determined. The equation to find the space parameters that determines the inertia of mass (gravitational radius) exhibits an inversion represented by replacing the mc by the $1/Mc$ term and resulting in $(1/Mc)r^M_{max} = 2\pi\alpha\hbar$. The equations for the minimum and maximum radii exhibit a symmetry with respect to a critical mass, such as the minimum radii for lighter masses (m) can be found using the same expression that finds the maximum radii for heavier masses (M).

$$(1/mc)r^m_{min} = 2\pi\alpha\hbar \tag{8}$$

Similarly we can write: $r_{min}^{M} = \frac{\alpha\hbar}{Mc}$. Quantum effects become evident in small dimensions and the parameter that determines whether the quantum effects are dominant or not, undergoes modifications as the mass of an object changes. The product of minimum and maximum radii for all the masses considered is equal to the square of a critical length scale that is equivalent to the Planck length.

The radius or the length scale found in Eqn. 7 is two orders smaller, or 1/137 of the Compton wavelength (scale where quantum effects become dominant). The length scales employed here can be thought as parameterizing tools for different energy scales.

The equations used for the lighter masses are equivalent to the representation of the real domain, whereas the equations for the heavier masses are equivalent to the representation of the reciprocal domain and this can be seen by the use of the inverse of 'mc' to derive $r_{max}$. An equivalent interpretation of the reciprocal space can be found in the literature denoted as the hologram approach[9]. In that interpretation, the reality is considered to be the projection of the three dimensional reality on a two dimensional screen with spatial frequency equal to the Planck length[10]. The imaging of reality on image planes is in the reciprocal domain whether done through a lens (requiring the Fourier optics analysis) or through a pinhole. An object exhibits its maximum gravitational radiation associated with the maximum force when it has its minimum length scale (with quantum character) and the product of these two quantities is equal to the total energy of an object denoted by $F_{max} r_{min} = mc^2$.

$$F_{max}^{m} = \frac{mc^2}{r_{min}} = \frac{c}{\alpha h} \tag{9}$$

This maximum value of the force is associated with a space parameter that is in the same order with the Planck lengthscale: $\lambda_{real}$. For heavier masses one finds: $F_{max}^{M} = \frac{Mc^2}{r_{min}^{M}} = \frac{M^2c^3}{\alpha\hbar}$. To calculate the force as a function of some real experimentally measurable distance ($r_{real} > \lambda_{real}$) one can use the inverse distance squared relation: $F_{max}\lambda_{real}^2 = F(r)r_{real}^2$. Finally we obtain one expressions for the force that is mass independent ($m < m_{crit}$) and one expression that is proportional to $m^2$ ($m > m_{crit}$). Using the expressions of $r_{min}^{m}$ and $r_{min}^{m}$, one can obtain space parameter $\lambda_{real}$ that is of the order of the Planck length: $r_{min}^{m} r_{max}^{m} = 2\lambda_{real}^2$. The mechanism that shows how the variables are linked is essential.

$$2\lambda_{real}^2 = r_{max} r_{min} = \frac{\alpha\hbar}{mc} mc(2\pi\alpha\hbar) \rightarrow \lambda_{real} = \sqrt{\pi}\alpha\hbar = (1.36)(10^{-36})m$$

If we control $r_{max}^{m}$ for the electron ($m_e < m_{crit}$), and $r_{max}^{M}$ for the black hole in the NGC 1365 galaxy ($m_{BH} > m_{crit}$)[6]:

$$r_{max}^{elec} = \frac{\alpha\hbar}{mc} = \frac{(1/137)(1.054)(10^{-}34)}{(9.1)(10^{-}31)(3)(10^{8})} = (2.8)(10^{-15})m$$

$$r_{max}^{BH} = mc(2\pi\alpha\hbar) = 2(10^{36})(3)(10^{8})\pi\frac{(1.054)(10^{-34})}{137} = (1.4)(10^{9})m$$

The maximum lengthscales that are found for the electron and for the black hole correspond to the lowest energy point. The radius would then decrease with the Lorentz factor as the energy is increased through the same factor. So, if we multiply the maximum radius of the Black hole with the Lorentz factor evaluated at $v = \sqrt{3}/2c$ one finds the Schwarzschild radius $r_{max}\sqrt{1 - v^2/c^2} = (0.7)(10^9)m$. This is the correct radius reported for this black hole confirming the use of the spatial parameters. The radius of the black hole will keep decreasing beyond the Schwarzschild radius as the speed increases and will converge to the Planck radius at the highest energy level. At this point of highest energy level, an object exerts its maximum force (see the expression for $F^m_{max}$ and $F^M_{max}$) on its surface assuming that all of its mass is contained within a Planck length. These units help one to express the gravitational field flux using $F_{max}\lambda^2_{real} = F(r)r^2_{real} = constant$, and the force decreases with the square of the distance. The determination of the maximum radius, minimum radius (equivalent to Planck length) and real physical parameter of an object makes the use classical radius and Schwarzschild radius redundant.

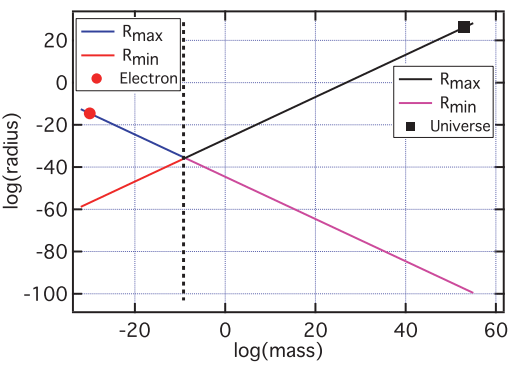

Fig. 3. Space parameters (radii) vs mass.

According to our approach, an object exhibits the maximum force (that is inversely proportional to the square of the physical distance) when it attains its maximum exposed energy and at that point the object has its smallest physical parameters, which are equal to the Planck length. We use the term physical distance so that it is not confused with the minimum and maximum space parameters that have a different character (scaling parameters) rather than a physical character. The space parameters that have the quantum character are used only to determine the energetic state of the object.

### 4.1. *Newton gravitational constant and electrostatic force*

Gravitational constant is the force between two objects each of a mass of 1 kg at a distance of 1 meter. At first we calculate the minimum radius of the object using

the expressions of $r^M_{min}$, $F^M_{max}$.

$$r_{min} = \frac{\alpha\hbar}{mc} = \frac{(7.297)(10^{-3})(1.054)(10^{-34})}{(1.3)(10^8)} = 2.563 \times 10^{-45} m$$

The second step relates the maximum force with the smallest lengthscale according to $F_{max} r_{min} = mc^2$ and resulting to $F_{max} = 3.5 \times 10^{61} kg\ m/sec^2$.

The maximum force corresponds to lengthscale of $(1.36)(10^{-36})$ m and decreases with the square of the distance. As the distance increases from $r_{min}$ to 1 meter, one finds:

$$F = F_{max} \frac{\lambda^2_{real}}{r^2}$$

The result is 98% of the gravitational constant G. If we use the expressions of $r^m_{min}$, $F^m_{max}$ for the electron ($m < m_{crit}$), to determine the force between two electrons at a distance of 1 meter we find a force that is equal numerically to the Coulomb force. $F = \frac{c}{\hbar\alpha} \frac{\lambda^2_{real}}{r^2} = \frac{3(10^8)(137)}{6.6(10^{-34})} \frac{(1.36\times10^{-36})^2}{1^2} = 1.14 \times 10^{-28}$N

$$ke^2 = 9(10^9)(1.6 \times 10^{-19})^2 = 2.3 \times 10^{-28} N$$

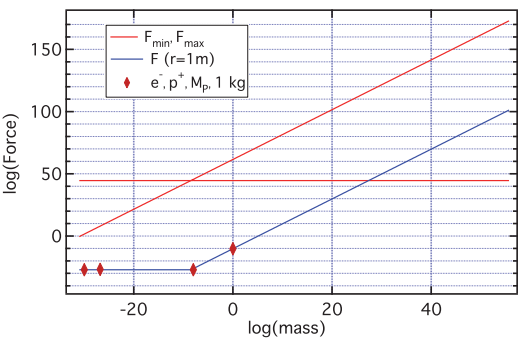

Fig. 4. $F_{min}$ and $F_{max}$ vs mass (in red). $F(r)$ at $r = 1m$ (in blue). Four markers (in red) are forces between two electrons, two protons, two objects with a mass equal to the Planck mass and two objects with mass of 1 kg (equal to gravitational constant $G = 6.53 \times 10^{-11}$).

The calculation of the forces presented here are based on principle that agree with LT dimensional analysis, and this way we show that both the gravitational and nongravitational forces can be derived using a single mechanism. We use spatial parameters with quantum character because they are equivalent to the Compton length and De Broglie wavelength. Below we show the relation between the force as a function of the mass only. An interesting observation is that the force is independent of the mass for objects lighter than the Planck's mass. Using the above formula one can calculate a force of around $10^2 N$ between two nucleons at a distance of $r \approx 10^{-15}$m. Using the model presented in this work that relates all the forces at

the smallest lengthscale one can find the gravitational and nongravitational force. It is known that gravitation coverges to the magnitude of the other forces at the smallest lengthscales. We found the forces using only the mass and did not use three parameters (k, e, G), thus eliminating the difference between the gravitational and nongravitational forces.

## 5. Conclusions

We established the idea that the correct expression of energy (the exposed energy) helps derive the expressions of other physical quantities (momentum and force). Using the exposed energy in the Lagrangian formalism the equations of motion for both the relativistic and classical physics were derived. This expression provides the insight that the experiments measure only the exposed energy and thus a lower mass. A lower mass as the system expands, which can be predicted using the exposed energy may be one of the alternatives to the dark matter and to the modified Newtonian dynamics (MOND)[8]. The major problem of MOND is that it cannot predict the lower mass in the system being analyzed. The exposed energy also provides a model on how to predict the upper limit of the spin of the black holes, and also the gravitational flux beyond the Schwarzschild radius.

Here in this work spatial parameters are used to derive important parameters for elementary particles and for celestial objects. These parameters exhibit an inversion at a mass that is analogous with the Planck mass. The calculation of the gravitational constant and of the electrostatic force between two elementary particles were provided as two examples to confirm the validity of the proposed mechanism. The same set of equations was used to determine the Schwarzschild radii of the black holes. The derivation of the gravitational force employs a mathematical step – denoted here as the reciprocal domain of the spatial domain – that is equivalent to the approach used by several researchers to describe the holographic representation of three dimensional reality. The need for such a set of spacetime parameters with a quantum character can help the researchers to measure other important parameters of matter. The rare equality between the physical and quantum spacetime parameters may have hindered our path to complete the full picture. For example, the accepted radius of the electron ($\approx 10^{-15}m$) is equal to $(1/137)\lambda_C$, where $\lambda_C$ is the Compton wavelength. In the case of the electron, classical radius corresponds to its physical size, but this is not always the case for the other elementary particles.

*E-mail: vfaraoni@ubishops.ca*

Orlando Luongo

*INFN-Laboratori Nazionali di Frascati, Frascati, Italy*
*E-mail: Orlando.Luongo@lnf.infn.it*

The parallel session AT7 of the 15th Marcel Grossmann Meeting held in Rome, Italy on July 1-7, 2018 is summarized. In particular, we briefly discuss each talk, highlighting the principal results and the most intriguing perspectives.

*Keywords*: Alternative theories of gravity; dark energy; dark matter; particle physics.

## 1. Introduction

The parallel session AT7, "Theories of gravity: alternatives to the cosmological and particle standard models" was devoted to alternative scenarios to the standard models of cosmology and particle physics. It run on Monday, July 2 and Tuesday, July 3, 2018 and included nineteen speakers. There was no poster session. There were several motivations for holding this session at the 15th Marcel Grossmann Meeting. To begin with, in the standard model of cosmology the $\Lambda$-Cold Dark Matter ($\Lambda$CDM) model based on Einstein's General Relativity, dark energy is introduced completely *ad hoc* in order to explain the present acceleration of the universe. This standard model requires also the introduction of dark matter dominating (by far) ordinary baryonic matter but yet undetected in the laboratory, and it suffers from phenomenological problems. The simplest explanation to account for the cosmic speed up lies on considering a vacuum energy cosmological constant, whose origin comes from quantum fluctuations at early times. Modifying gravity may give an interplay between cosmology and quantum field theory and represents a possible alternative, albeit a wide number of proposals have been presented in recent years. Likewise, the standard model of particle physics is unable to incorporate all of the current particle phenomenology and proposed dark matter candidates. Further, the model cannot match cosmological observations in terms of expected vacuum energy and it seems to be unable to predict the required cosmological constant or any dark energy terms. In this respect, cosmology and particle physics come together

in the early universe and, surprisingly, also in theories and models of the present, accelerating universe. The main target of present-time researches is to have a self-consistent scheme which incorporates quantum field theory and general relativity in a unique scenario.

Session AT7 was designed in a wide framework to include several topics related to these problems, and spanning alternative theories of gravity and cosmology, alternatives to the ΛCDM model, quantum field theory applied to gravity, extensions of the standard model of particle physics, and dark energy and dark matter from a particle physics point of view. This session represents the interplay between, and the efforts to match, particle physics and cosmology, giving particular emphasis to the role played by particle quantum field theory in the early and the late universe.

## 2. Cosmology and dark energy

Stefano Bellucci presented a contribution entitled *Constraints on chameleon dark energy model from SN Ia and BAO observations*. He considered a scalar field, known as chameleon, *i.e.*, a scalar field non-minimally coupled to matter. Such a chameleon field not only can be heavy enough in the laboratory tests so that the local gravity constraints are fulfilled but also it can be light enough at cosmological scales and considered as a dark energy candidate. In his talk Bellucci used the latest observational data to constrain the parameters of the tachyonic chameleon model of dark energy. Two important functions in the analysis were considered, *i.e.*, the tachyonic potential $V$ and the non-minimal coupling function $f$ between the scalar field and matter. In general Bellucci and collaborators considered two types of these functions, *i.e.*, power-law and exponential forms. They fitted data from Type Ia supernova (SN Ia) and Baryon Acoustic Oscillations (BAO) to obtain constraints on the present matter density parameter and the free parameters in the functional form of the functions $f$ and $V$, thus showing that the scenario is compatible with observations[1].

Hernando Quevedo discussed *geometrothermodynamic cosmology* by applying the formalism of geometrothermodynamics to derive a fundamental thermodynamic equation. In conjunction with the Friedmann equations, this was used to construct a cosmological model. The main features of this scenario are an early phase with thermodynamic interaction, corresponding to inflation, and a late phase without thermodynamic interaction, equivalent to the standard ΛCDM model[2].

Orlando Luongo presented *Speeding up the universe using dust with pressure*. He showed that the standard cosmological model can be *updated* assuming a mechanism which cancels vacuum energy out. This enables the universe to accelerate today without the need of some sort of "quantum fluctuating" cosmological constant. To do so, he suggested that standard matter, *i.e.*, baryons and cold dark matter, can show a non-vanishing pressure. Soon after a spontaneous symmetry breaking, one recovers two cases: the first, *i.e.*, the ΛCDM model, is disfavored with respect to the second case, *i.e.*, an effective dark fluid approach, in which the universe

accelerates with a fine-tuned emergent cosmological constant. To model the matter fluid able to realize the above mechanism, he introduced a Lagrangian composed of a Lagrange multiplier and a generalized kinetic term. Further, to account for the phase transition the model presumes a fourth order potential, in which the scalar field is the one associated to matter only. Evaluating the Helmoltz free energy, it is possible to constrain the sign of the pressure, instead of postulating exotic dark energy terms. Further, once the shift symmetry is invoked on the field, the associated Noether currents show that the entropy density is conserved and particle production does not contribute, in proximity of each minima. Luongo showed the net fluid is therefore irrotational invoking the Carter-Lichnerowicz equations. From small perturbations, after cumbersome algebra, he showed that the pressure turns out to be constant as the entropy shift suggests. In such a way, the adiabatic sound speed vanishes, in agreement with previous dark fluid approaches. As a byproduct, the numerical bounds on the pressure and matter densities fulfill modern observations and, under the hypothesis of thermal equilibrium, the dark matter candidate turns out to be a highly massive WIMP particle whose mass lies in the interval[3] $0.5 - 1.7$ TeV.

Behnaz Fazlpour talked about *Cosmological constraints on tachyonic teleparallel dark energy model*. She started from teleparallel gravity, reviewing that it is an equivalent formulation of general relativity in which instead of the Ricci scalar $R$, one uses the torsion scalar $T$ for the Lagrangian density. She showed that by adding a quintessence scalar field, and allowing a non-minimal coupling to gravity, the so-called teleparallel dark energy emerges as a natural fact. It has been proposed in hher slides, and it was found, that such a non-minimally coupled quintessence theory has a richer structure than other approaches based on general relativity. The work employs tachyonic teleparallel dark energy in which a tachyon scalar field is responsible for dark energy. She focused on constraining this model with the most recent observations of Type Ia supernova (SN Ia) and Baryon Acoustic Oscillations measurements and she showed that the scenario is compatible with observations[4].

Ali Banijamali presented *Dynamics and observational constraints on a scalar-tensor model with Gauss-Bonnet coupling*. He discussed the dynamics of a scalar-tensor model of dark energy in which the scalar field, playing the role of dark energy, is non-minimally coupled to the Gauss-Bonnet invariant in four dimensions. He showed how to use the dynamical system approach to extract the critical points, finding scaling attractor solutions with the property that the ratio of the dark energy and dark matter density parameters are comparable. These solutions may alleviate the coincidence problem in cosmology and may give an explanation of it. Further, constraints on the free parameters of the model have been computed using different sources of cosmological data. In this respect, the viability of the model has been explored combining different data sets, among all Type Ia supernova (SN Ia) and Baryon Acoustic Oscillations[5].

Antonino Marciano talked about *Emergent inflation from a Nambu-Jona-Lasinio mechanism in gravity with non-dynamical torsion*. He discussed a new scenario of early universe inflation emerging from a Nambu-Jona-Lasinio mechanism in the presence of non-dynamical torsion, which couples to Standard Model fermions. Without introducing new scalar fields, in this model inflation emerges from a four-fermion interaction induced by the torsion. The role of the inflaton field is played by a (nonminimally coupled) composite field of Standard Model particles arising from a curved space Nambu-Jona-Lasinio mechanism. Definite predictions for gravitational waves in this inflationary model were also presented[6].

## 3. $f(R)$, $f(\phi, R)$, and metric-affine gravity

The class of $f(\phi, R)$ theories of gravity (where $R$ is the Ricci scalar and $\phi$ is a gravitational scalar field) is very large. Fayçal Hammad discussed scalar and tensor perturbations in this general class, talking about *Density Perturbations in $f(R, \varphi)$-Gravity with an Application to the (Varying Power)-Law Model*. Within the specific model of varying power-law modified gravity, he computed tensor-to-scalar ratio, scalar tilt, and tensor tilt. In order to be compatible with current cosmological observations, this model requires inflation to occur at an energy scale less than the GUT energy scale. It was claimed that the observed density perturbations are obtained without fine tuning.

Restricting to the (still very broad) class of $f(R)$ theories of gravity, Rocco D'Agostino discussed a model-independent method to reconstruct the Lagrangian function $f(R)$ from cosmological observations, in both the metric and the Palatini formalisms in a talk entitled *Model-independent reconstructions of $f(R)$ gravity*. The method relies on building model-independent approximations of the luminosity distance by means of rational polynomials, in order to extend the convergence radius of the standard cosmographic series (Padé polynomials and ratios of Chebyshev polynomials are used)[7,8]. The function $f(R)$ is reconstructed from the Hubble function versus redshift $H(z)$ by first reconstructing $f(z)$ functions and then inverting the relation $R = R(z)$. The results of this method imply small deviations from the $\Lambda$CDM model and a time-evolving effective dark energy equation of state.

Roberto Giambò spoke about perfect fluids in $f(R)$ theories, presenting analytical results on the qualitative behavior of Friedmann-Lemaître-Robertson-Walker (FLRW) cosmologies in theories coupled nonminimally to matter in his talk: *Late Time Evolution of Perfect Fluids Universes in f(R) Theories of Gravity*. Assumptions on the scalar field potential arising from conformal compactification and on the fluid equation of state determine the late time behavior of the universe (big crunch if matter dominates over the scalar field, or perpetual expansion in the opposite situation)[9].

Again in the context of $f(R)$ gravity with a nonminimal coupling of $R$ to matter, Riccardo March reviewed models and Solar System constraints. In the talk *Nonminimally Coupled Curvature-Matter Gravity Models and Solar System constraints* that

he presented, an older perturbative approach due to Chiba *et al.*[10] was applied in[11] to nonminimally coupled $f(R) = R^{-n}$ gravity (with $n > 0$). It was claimed that, while pure $R^{-n}$ gravity violates Solar System constraints, the nonminimally coupled version of this theory does not. Another nonminimally coupled model admitting a Minkowski solution was found to possess a non-Newtonian Yukawa potential in the non-relativistic limit. A study of non-geodesic trajectories of test particles around a static spherical body was also reported.

In the broad context of metric-affine theories of gravity, concerning the contribution *Constraining metric-affine gravity with particle scattering*, Adriá Delhom I Latorre discussed how to probe non-metricity with particle scattering and how to constrain Ricci-based gravity from scattering data. Arguing that torsion and non-metricity could originate from new physics associated with defects in a hypothetical spacetime microstructure, he showed effects of non-metricity which are presumably observable in quantum fields in the form of 4-fermion contact interactions. Bhabha scattering then constrains the scale of non-metricity to be larger than 1 TeV (that is, orders of magnitude higher than previous experimental constraints)[12].

## 4. Symmetry violations

Deviations from the Standard Model of particle physics may take the form of symmetry violations. In a talk entitled *CP violation in space*, Giovanni Maria Piacentino discussed a new proposal to probe directly the gravitational acceleration of antimatter by measuring the branching fraction of CP-violating $K_L$ decays in space. He showed that, at the altitude of the International Space Station, gravitational effects could change the level of CP violation to the point that a $5-\sigma$ discrimination would be possible by collecting the $K_L$ produced by the cosmic proton flux within a few years.

Gravitational waves in the presence of string axion dark matter and the gravitational Chern-Simons coupling were instead the subject of Daiske Yoshida's contribution, *Exploring the string axiverse and parity violation in gravity with gravitational waves*. He reported on two recent papers[13,14] and discussed how parametric resonance of gravitational waves occurs due to coherent oscillation of the string axion and how circular polarization of gravitational waves is induced by the Chern-Simons coupling. The observational constraints set on the model by the failure to observe these two effects were also presented.

## 5. Quantum gravity-inspired scenarios

In a talk entitled *The gravity's rainbow cosmological constant*, Remo Garattini reported on his computation of the zero point energy due to quantum fluctuations around a fixed background using a reformulation of the Wheeler-DeWitt equation. Using a variational approach with Gaussian trial wave functionals, the first loop contribution of the graviton to the zero point energy was computed, controlling

ultraviolet divergences with a distorted gravitational field (the "gravity rainbow'). This finite zero point energy was identified with the induced cosmological constant.

Gabriele Gionti presented recent results of a Hamiltonian analysis of asymptotically safe quantum gravity in his talk entitled *Bouncing and Emergent Universes from Hamiltonian Analysis of Asymptotically Safe Quantum Gravity.* While renormalization group (RG) approaches to quantum gravity suggest that Newton's constant $G$ and the cosmological constant $\Lambda$ run with the characteristic energy scale, it is not clear how to embed this modification of Einstein theory in Dirac's theory of constrained systems. The Hamiltonian formalism for RG scale-dependent $G$ and $\Lambda$ were discussed with regard to Dirac's constraint analysis. It was reported that, under certain conditions, the algebra of Dirac constraints is closed. Brans-Dicke theory was also studied as a Dirac constrained system and compared with modified gravity via asymptotically safe quantum gravity. Assuming asymptotic safety, the results were applied to the early universe: in the minisuperspace with FLRW geometry, the RG-improved Friedmann equations exibit solutions describing bouncing and emergent universes. While, classically, emergent universes are only found in closed topology (curvature index $K = +1$), in the sub-Planckian regime they exist also for flat and open ($K = 0, -1$) topologies.

## 6. Miscellaneous

Sayantan Choudhury talked about *COSMOS-e-soft Higgsotic attractors.* He showed an algorithm to study the cosmological consequences from a huge class of quantum field theories (*i.e.*, superstring theory, supergravity, extra-dimensional theory, modified gravity, *etc.*), which are equivalently described by soft attractors in the effective field theory framework. He restricted the analysis to two scalar fields — dilaton and Higgsotic fields minimally coupled with Einstein gravity, which can be generalized to any arbitrary number of scalar field content with generalized non-canonical and non-minimal interactions. He used $R^2$ gravity to study the attractor and non-attractor phase and he presented also theoretical bounds on the amplitude, tilt and running of the primordial power spectrum and other quantities of interest. Additionally, three possible theoretical proposals have been presented to overcome the tachyonic instability at the time of late time acceleration. Last but not least, he provided also the bulk interpretation from the three- and four-point scalar correlation functions for completeness[15].

Andrea Addazi discussed aspects of black hole physics in extended theories of gravity. In his presentation, he focussed on classical evaporation and anti-evaporation instabilities, discussing their implications for black hole thermodynamics. He put particular emphasis on their connections with deformed energy conditions.

Aram Saharian spoke about *Current densities in braneworlds with compact dimensions.* There, the vacuum expectation values (VEVs) of the current densities for charged scalar and fermionic fields were investigated in braneworlds on AdS

spacetime with toroidally compact spatial dimensions and in the presence of a constant Abelian gauge field. Because of the non-trivial topology, the latter gives rise to an Aharonov-Bohm type effect for currents. The VEVs are thus decomposed into the purely AdS and brane-induced contributions. Both contributions are periodic functions of the magnetic flux enclosed by compact dimensions, with the period equal to the flux quantum. The asymptotic behavior of the current density along compact dimensions was investigated near the branes, near the AdS boundary, and near the horizon. In the talk, it was shown that, unlike the case of the Minkowski bulk, the total current density in supersymmetric models on an AdS bulk does not vanish.

Arban Uka in *New perspective in achieving the unification theory according to the ideas of Einstein and Wheeler* dealt with a philosophical conjecture between relativity and quantum physics.

## 7. Conclusions

The session AT7 represented the principal session in which different aspects of particle physics matched cosmology in a broad sense. The scope of the session was to stress the strong need of unifying quantum field theory with general relativity in a future context of a more universal theory. All the talks provided hints and represented first attempts toward this ambitious target.

Stellar-mass black holes come from the deaths of massive stars, and have been observed both in our own Galaxy and in other galaxies. Supermassive black holes have masses of up to 10,000,000,000 times the mass of the Sun and reside at the centers of galaxies. Intermediate-mass black holes (IMBHs), with masses in between these two regimes, are elusive and represent the missing link. When a compact object ventures too close the IMBH, it is captured because of the emission of gravitational waves, to be eventually swallowed whole when it crosses the event horizon. The process, an intermediate-mass ratio inspiral, represents a mapping of warped spacetime and can be observed with existing gravitational-wave ground-based detectors. Depending on the dynamical parameters, IMRIs can be detected jointly with space-borne ones, which will allow us to do multi-band width gravitational-wave astronomy.

*Keywords*: Gravitational waves.

## 1. Introduction

Contrary to the Newtonian description of gravity, in the theory of relativity compact objects can lose energy via the emission of gravitational radiation. A small compact object such as a stellar black hole, a neutron star, or a white dwarf, can therefore form a bound system with a massive black hole because of the emission of gravitational waves[1,2]. Since the binary loses energy, the semi-major axis shrinks which, combined with the precession and the change of inclination, represent a unique probe of spacetime around massive black holes in strong gravity[3]. The number of cycles that the small compact object will have to go until the plunge through the event horizon is roughly proportional to the mass ratio. Because this mass ratio is at least of five orders of magnitude, we call these systems extreme-mass ratio inspirals, EMRIs.

At such mass ratios, similar mass-ratio techniques to derive the waveforms are not useful, to say the least, because self-force is crucial[4]. But the problem is even more challenging than that, because the binary is not isolated. Surrounding it, the host environment can contain up to a few tens of millions of stars[2]. Since EMRI orbits are very eccentric, this poses another challenge at apocenter, where the bulk of the stellar system might have an impact at certain semi-major axes. This means that, in order to address the EMRI problem, we need to take into account not

"just" the relativistic two-body problem at these extreme mass ratios, but also the a-few-tens-of-millions body problem.

In spite of all of these problems, there has been impressive progress over the last two decades[2]. Even if we do not have a waveform which describes in precision this systems, there are good enough approaches that have proven to be accurate enough to ensure detection and, taking into account the restrictions of the different approaches, parameter extraction[5].

EMRIs are formed in galactic nuclei via two-body relaxation, which allows us to address this problem, within limitations, in an analytical way thanks to the analysis of the loss-cone[6–9]. This relies on the fact that the massive black hole is fixed at the centre of the system. Lighter-mass black holes, i.e. intermediate-mass black holes IMBHs, see[10,11] for reviews, with masses $\gtrsim 100\,M_\odot$ (but less massive than supermassive black holes) therefore pose a problem. We rely on numerical simulations to obtain a description of the process of formation and evolution of intermediate-mass ratio inspirals (IMRIs). This is unfortunate, because one numerical simulation of a cluster containing a realistic number of stars can last a few months of time to achieve a relevant amount of time[12]. The first numerical simulation of a globular cluster with an IMBH that formed an IMRI was performed by[13]. Their findings were corroborated by[14] and also the work of[15], which is almost a replica of their numerical setup. Also,[16] explore compact binaries forming with IMBHs, but in a lighter regime. These different numerical simulations show that IMRIs form at very small semi-major axes, $a \sim 10^{-5}$ pc, and very high eccentricities, $e \gtrapprox 0.999$, very likely (since the data writing does not capture the small timescale for this particular event) following the hyperbolic capture scenario described by[17], and see[18–22] for more recent works.

## 2. Cascade of harmonics

In Fig. (1) we show two typical examples of IMRIs forming at low-frequencies, within the LISA bandwidth, and merging in the range of ground-based detectors, such as the ET[23,24] or LIGO/Virgo. Because of the inspiral, it would be ideal to have a decihertz detector operating simultaneously to LISA and LIGO/Virgo such as the DECi-hertz Interferometer Gravitational Wave Observatory[25], the Superconducting Omni-directional Gravitational Radiation Observatory SOGRO, see[26,27] or the geocentric Tian Qin[28]. We can see that LISA can forewarn ground-based detectors up to five years in advance, and tenths of seconds of precision, so that ET (or LIGO/Virgo, depending on the parameters of the source) can optimise their sensitivity to optimise the detection.

## 3. Conclusions

IMRIs forming in globular clusters and have very high eccentricities and small semi-major axes, and are detectable both with space-borne observatories and ground-based detectors.

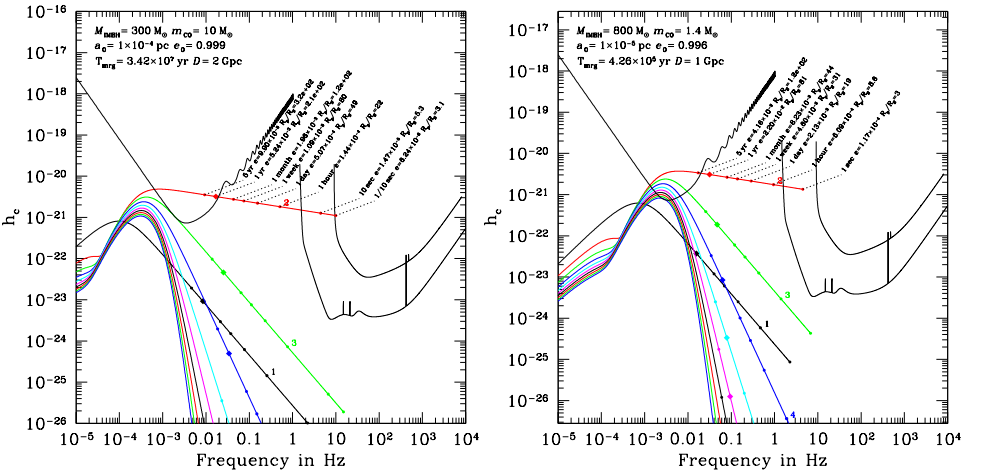

Fig. 1. Strain of the gravitational wave as a function of the frequency. The gravitational wave is approximated in the quadrupolar derivation of [29] in different harmonics, and we only show the first ten. The left curve corresponds to the LISA sensitivity curve and the lower-frequency, U-shaped curve to the Einstein Telescope, and the higher-frequency curve to Advanced LIGO. In each panel we give the initial parameters for the binary; namely the mass of the IMBH, $M_{\rm IMBH}$ in solar masses, the mass of the compact object, $m_{\rm CO}$, the initial semi-major axis, $a_0$ in pc, the initial eccentricity $e_0$, the distance to the source, $D$, as well as the timescale for merger, $T_{\rm mrg}$, in years. Along the second harmonic, which is the predominant one at higher frequencies, we show different values of the eccentricity and the periapsis in Schwarzschild radii, $R_{\rm S}$ at different moments in the evolution of the IMRI. The left panel corresponds to an IMBH of mass 300 $M_\odot$ and a stellar-mass black hole of 10 $M_\odot$ at a distance of 2 Gpc. The right panel depicts a binary of 800 $M_\odot$ and a neutron star of 1.4 $M_\odot$ at a distance of 1 Gpc.

The combined detection of a source of gravitational waves has been addressed in the literature previously [30–34], but with mass ratios not larger than 10. The joint detection of similar mass ratios for small compact objects, as motivated by the first detections of LIGO/Virgo, have been discussed by [35], and [36], who showed that a multi-bandwidth detection of this kind of binaries is only possible for circular binaries, so that the information about the formation channel (dynamical or via stellar evolution) cannot be obtained.

Conjunct IMRI detections from the space and the ground will allow us to place improved constraints on the physical parameters. A combined detection enables the possibility of splitting the different degeneracies as well. LISA can detect the inspiral with enough signal-to-noise ratio [37] and hence it can forewarn ground-based detectors years in advance with seconds and even tenths of seconds of precision. The ET and LIGO/Virgo can detect the merger with a very large SNR in the former case, of up to a few thousand, and LIGO/Virgo with more modest values, but still well above the threshold [37]. If LISA is operating at the same time as ET or LIGO/Virgo, one should think of them as a single detector. These results are discussed in more detail in the recent work of [37].

# Using "enhanced quantization" to bound the cosmological constant and quantum number $n$ for production of 100 relic mini black holes

Andrew Walcott Beckwith

*Physics Department, Chongqing University, Chongqing 401331, People's Republic of China*
*E-mail: Rwill9955b@gmail.com; abeckwith@uh.edu*
*english.cqu.edu.cn*

We compare two action integrals and identify the Lagrangian multiplier to set up a constraint equation on cosmological expansion. This is a direct result of the fourth equation of our manuscript which unconventionally compares the general-relativity action integral with the second derived action integral. This leads to Eq. (3)–(5), a bound on the cosmological constant. We replace the Hamber quantum-gravity reference-based action integral with a result from Klauder's "Enhanced Quantization," while showing its relevance to early-universe black-hole production and the volume of space producing 100 black holes of $10^2$ Planck mass in a radius of $10^3$ Planck length for entropy of about 1000.

*Keywords*: Inflaton, Action Integral, Cosmological Constant, Penrose Cyclic Cosmology.

## 1. Basic Idea, Can Two First Integrals Give Equivalent Information?

Instead of using the Hamber result[1] for a first integral, we use what John Klauder's first integral[2] to make a one–one equivalence with the first integral associated with general relativity.[3,4] We have a one–one relationship between two first action integrals.[5] The the two integrals have a one–one and onto relationship by details.[6,7]

## 2. Now for the General Relativity First Integral[5]

We use Padmanabhan's first integral[7,8] (Eq. (1)), with a Ricci scalar[9] and usually the curvature, $\aleph$, set as extremely small, with general relativity[2,10]

$$S_1 = \tfrac{1}{2\kappa}\int \sqrt{-g}\,\mathrm{d}^4x(\mathfrak{R}-2\Lambda) \quad -g = -\det g_{\mathrm{uv}} \quad \mathfrak{R} = 6\left[\tfrac{\ddot{a}}{a} + \left(\tfrac{\dot{a}}{a}\right)^2 + \tfrac{\aleph}{a^2}\right]. \qquad (1)$$

Also, the variation of $\delta g_{tt} \approx a_{\min}^2\phi$[11,12] will have an inflaton, $\phi$,[5,7,7,9,12] which is combined into other procedures for a solution to the cosmological constant problem. Here, $a_{\min}$ is a minimum value of the scale factor.[5,9]

## 3. The Idea from Klauder

Next, a restricted quantum action principle[2] (p. 78) $S_2$ with one–one equivalence,[1,3,5]

$$S_2 = \int_0^T \mathrm{d}t[p(t)\dot{q}(t) - H_N(p(t),q(t))] \approx S_1 = \frac{1}{2\kappa}\int \sqrt{-g}\,\mathrm{d}^4x(\mathfrak{R}-2\Lambda). \qquad (2)$$

We assume $\Lambda$ is a constant. Hence, we assume the following approximation,[4,6]

$$\frac{p_0^2}{2} = \frac{p_0^2(N)}{2} + N; \quad \text{for } 0 < N \leq \infty \text{ and } q = q_0 \pm p_0 t \tag{3}$$

$$V_N = \begin{cases} 0; & \text{for } 0 < x < 1 \\ N; & \text{otherwise} \end{cases} \tag{4}$$

$$H_N(p(t), q(t)) = \frac{p_0^2}{2} + \frac{(\hbar\pi)^2}{2} + N; \quad \text{for } 0 < N \leq \infty. \tag{5}$$

Our innovation is to equate $q = q_0 \pm p_0 t \sim \phi$ and assume small time-step values:

$$\Lambda \approx \frac{-\left[\frac{V_0}{3\gamma-1} + 2N + \frac{\gamma(3\gamma-1)}{8\pi G\tilde{\imath}^2}\right]}{\frac{1}{\kappa}\int\sqrt{-g}\,\mathrm{d}^3x} + \left\{6\left[\frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2\right]\right\}\Bigg|_{t=\tilde{\imath}}. \tag{6}$$

These terms within the bubble of space–time[7] use the same inflaton potential. The scale factor is presumed to obey the value of that in Camarade et al.[9]

## 4. Why This Is Linked to Gravity/Massive Gravitons

Klauder's program[2] is to embed via Eq. (6) as a quantum-mechanical well for a Pre-Planckian system for inflaton physics,[2] (Eq. (3)) as given in Klauder's treatment of the action integral[9] (p. 87) where Klauder talks of the weak correspondence principle in which an enhanced classical Hamiltonian is given one–one correspondence with quantum effects in a nonvanishing fashion. Thus, $m_g = \frac{\hbar\sqrt{\Lambda}}{c}$.[13]

## 5. Reviewing Penrose's Multiverse CCC Generalization and Suggestions as to a Uniform Bound to the Graviton

We extend Penrose's suggestion of cyclic universes, black-hole evaporation, and the embedding structure in which our universe is contained. This multiverse embeds black holes and may resolve what appears to be an impossible dichotomy. The following[14] has serious relevance to the final part of the conclusion. There are no fewer than $N$ universes undergoing Penrose "infinite expansion"[15] contained in a mega universe structure. Furthermore, each of the $N$ universes has black-hole evaporation, with Hawking radiation from decaying black holes. If each of the $N$ universes is defined by a partition function, called $\{\Xi_i\}_{i=N}^{i=1}$, then there exist an information ensemble of mixed minimum information correlated as about $10^7$–$10^8$ bits of information per partition function in the set $\{\Xi_i\}_{i=N}^{i=1}\big|_{\text{before}}$. So, minimum information is conserved between a set of partition functions per universe.[14]

$$\{\Xi_i\}_{i=N}^{i=1}\big|_{\text{before}} \equiv \{\Xi_i\}_{i=N}^{i=1}\big|_{\text{after}}. \tag{7}$$

However, there is nonuniqueness of information put into each partition function $\{\Xi_i\}_{i=N}^{i=1}$. Furthermore, Hawking radiation from the black holes is collated via a strange attractor collection in the mega universe structure to form a new big bang for

each of the $N$ universes represented by $\{\Xi_i\}_{i=N}^{i=1}$. Verification of this mega structure compression and expansion of information with a nonuniqueness of information placed in each of the $N$ universes favors ergodic mixing treatments of initial values for each universe expanding from a singularity beginning. The $n_f$, $S_{\text{entropy}} \sim n_f$.[16] Tying this energy in, as in Eq. (11), requires ig ignoring the formation of a nontrivial gravitational measure as a new big bang for each universe: $n(E_i)$. The density of states at a given energy $E_i$ for each partition function.[14]

$$\{\Xi_i\}_{i=N}^{i=1} \propto \left\{ \int_0^\infty \mathrm{d}E_i \cdot n(E_i) \cdot \mathrm{e}^{-E_i} \right\}_{i=1}^{i=N} . \tag{8}$$

Each $E_i$ identified with Eq. (8) iterates for $N$ universes.[14,15,17] Then, in the following two claims on the universe, as a mixed state, black holes playing a major part.

**Claim 1** Where subscipts bn and an refer to before and after nucleation,

$$\frac{1}{N} \cdot \sum_{j=1}^{N} \Xi_j\big|_{j\ \mathrm{bn}} \xrightarrow[\text{transfer}]{\text{vacuum nucleation}} \Xi_i\big|_{i\ \mathrm{an}} . \tag{9}$$

For $N$ universes, with each $\Xi_j\big|_{j\ \mathrm{bn}}$ for $j = 1$ to $N$ being the partition function of each universe just before the blend into the RHS of Eq. (12) for our present universe. Also, each of the independent universes given by $\Xi_j\big|_{j\ \mathrm{bn}}$ is constructed by the absorption of one to ten million black holes taking in energy.[14,15] Furthermore, the main point is in terms of general ergodic mixing.

**Claim 2**

$$\Xi_j\big|_{j\ \mathrm{bn}} \approx \sum_{k=1}^{\max} \widetilde{\Xi}_k\Big|_{\text{black holes in the } j\text{th universe}} . \tag{10}$$

In Claims 1 and 2, we show how a multidimensional black-hole physics enables continual space–time mixing[14,15] largely to avoid the anthropic principle and its preferred set of initial conditions. Claim 2 is CCC cosmology: First, have a big bang (initial expansion) for the universe, for say redshift $z = 10$. At ten billion years ago, SMBH formation starts. Matter–energy is vacuumed up by the SMBHs. Then,

$$\Lambda = c_1 \cdot T^{\beta}. \tag{11}$$

$c_1$ is constant. Penrose's proposal (Eq. (1)) evaluates a change in the metric $g_{ab}$ by a conformal mapping $\widehat{\Omega}$ to $\widehat{g}_{ab} = \widehat{\Omega}^2 g_{ab}$. Penrose suggested[14,15]

$$\widehat{\Omega} \xrightarrow[\mathrm{CCC}]{} \widehat{\Omega}^{-1}. \tag{12}$$

Infall into cosmic black holes has been the most useful mechanism for the recycling apparent in Eq. (12) with the caveat that $\hbar$ is kept constant from cycle to cycle as represented by $\hbar_{\text{old}} = \hbar_{\text{new}}$. We claim that the invariance of the Planck $\hbar$ combined with Eq. (10) gives a good indication of a uniform mass to a graviton, per cycle,

provided that $\hbar_{\text{old}} = \hbar_{\text{new}}$ holds. Note that all these above results should be compared with the initial Hamber-based results,[1] which led to an initial idea.[5] That is, we claim we have kept full fidelity with this program and improved on it.

We have what is known as a scale factor $a(t)$, which is nearly zero in the Pre-Planckian regime of space–time and equal to 1 in the present era. In addition, we will define, for the purpose of analysis of the integrals:

$$\int \mathrm{d}t\sqrt{g_{tt}}V_3(t) = V_4(t) \sim \tfrac{8\pi^2 r^4}{3} \quad V_3(t) = \tfrac{2\pi^2 a(t)^3}{3} \quad k_2 = 9(2\pi^2)^{\frac{2}{3}} \tag{13}$$

Here, the subscripts 3 and 4 in the volume refer to three- and four-dimensional spatial dimensions, and this will lead to us writing, a first integral,[1] if $G$ is the gravitational constant, a first integral defined by[1,5]

$$S_1 = \frac{1}{24\pi G}\cdot\left[\int \mathrm{d}t\sqrt{g_{tt}}\left(\frac{g_{tt}\dot{V}_3^2}{V_3(t)} + k_2 V_3^{\frac{1}{3}}(t) - \lambda V_3(t)\right)\right]. \tag{14}$$

Compare this to the Padmabhan first integral[7] of the form Eq. (1), with a Ricci scalar[3] and usually the curvature $\aleph$[3] set as extremely small.

Our presentation uses all this, and aligns it with the ideas of the Klauder's enhanced quantization[2] for what we think is a better extension of the same idea. We have improved upon this idea, and it is in full fidelity with the FFP 15 presentation.[5]

To obtain maximum results, we assume

$$\sqrt{g_{tt}}\left(\frac{g_{tt}\dot{V}_3^2}{V_3(t)} + k_2 V_3^{\frac{1}{3}}(t)\right) \sim \frac{1}{2\kappa}\int\sqrt{-g}\cdot\,\mathrm{d}^3x\cdot\left\{6\cdot\left[\frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2\right]\right\} \tag{15}$$

and

$$\sqrt{g_{tt}}\lambda V_3(t) \sim \frac{1}{2\kappa}\int\sqrt{-g}\cdot\,\mathrm{d}^3x\cdot(2\Lambda) \to \lambda \sim \frac{1}{\kappa}\sqrt{\frac{-g}{(\delta g_{tt} \approx a_{\min}^2\phi)}}\cdot\Lambda.^{5} \tag{16}$$

So, we argue that we have related "the Lagrangian multiplier and the cosmological constant."[5] We obtain the exact same physics for when we appeal to Eq. (7) as a bound to the enhanced quantization, hence we have extended our basic idea.[2,5]

## 6. Conclusion, Relevance to Black-Hole Production

Our assumption is that the Lagrangian multiplier is roughly equivalent to a mass of about $10^4$ times the mass of a Planck-sized black hole. That is, we have black holes initially produced which are say $10^2$ times the Planck mass. In Corda's recent work,[18] we have that $n$ is the quantum number where the Planck mass is normalized to 1. So, then, if there are $10^2$ black holes of mass $10^2$ times Planck mass $M = 10^2 mass_{\text{Planck}} = 100$. Here we simplify a horizon volume.

$$\Delta V_{n-1\to n}|_{\text{Total}} \approx 10^2 \times \Delta V_{n-1\to n} \approx 10^3 \times 16\pi\cdot\frac{n}{4\times 10^4}\cdot\left|\sqrt{1-\frac{n-1}{n}}\right|. \tag{17}$$

We assume $10^2$ mini black holes, each with a mass of $10^2$ times Planck mass. So, we find $n$ for quantum number.[18] Then we have an entropy count, on r.h.s. as

$$16\pi \cdot \frac{n}{4 \times 10^4} \cdot \left| \sqrt{1 - \frac{n-1}{n}} \right| \approx 10^6. \tag{18}$$

At 1000 Planck lengths, 100 mini black holes appear, each about 100 Planck masses, restricting $n$. Use Eq. (18) to choose a quantum value for quantization level used to penetrate beyond the shell creating the cosmological constant modeled in Eq. (6). The entire mass of initial black holes, $10^4$ Planck masses, would also scale to the right-hand side of Eq. (16). We use Corda's result[18] to delineate the quantum value of relic black holes and a quantum state commensurate with penetrating from Pre-Planckian to Planckian physics. Second, if there are, say, ten gravitons produced per relic black hole and 100 relic black holes, say, in a sphere of about 1000 times Planck distance, we can by Ng infinite quantum statistics,[16] as has been done by the author time and time again (entropy as a counting algorithm) of black holes creating entropy, use this above procedure to estimate an initially generated entropy of the order of $10^3$, in the immediate aftermath of black hole production, with $n$, as calculated by Eq. (18) as the production of initial entropy. We argue that all the above will, if we equate the nucleated black-hole mass of 100 relic black holes as proportional to the right-hand side of Eq. (16), lead to an integrated version of initial mass-energy. Note that the nonsingular start to the universe is justified.[4,9,19]

The first observational indication of the gravitomagnetic monopole is reported, based on the X-ray observations of an astrophysical collapsed object: GRO J1655-40. Earlier, the three independent primary X-ray observational methods gave significantly different spin values for GRO J1655-40. We show that the inclusion of an extra parameter, corresponding to the gravitomagnetic monopole, makes the spin and other parameter values inferred from the three methods consistent with each other. In addition, our result weakly indicates that GRO J1655-40 could also be a naked singularity.

*Keywords*: Gravitomagnetic monopole, QPOs, Singularity, X-rays: binaries.

## 1. Introduction

In 1931, British physicist P. A. M. Dirac showed that if the magnetic monopoles exist in the universe, then all electric charge in the universe must be quantized[1,2]. When the analogy of Einstein's general relativity is drawn with electromagnetism, 'gravitoelectric charge' exists and is referred to as 'mass' which is an important constituent of the physical world. The next evident question that arises is 'does gravitomagnetic charge or the so-called gravitomagnetic monopole exist in nature?'[3] Historically, Newman, Tamburino and Unti discovered a stationary and spherically symmetric vacuum solution (which is now known as the NUT solution) of the Einstein's equation, that contains the gravitomagnetic monopole or the so-called NUT parameter[4]. Though this gravitomagnetic monopole is physically interpreted as "a linear source of pure angular momentum", i.e., "a massless rotating rod"[5–8], and is the proposed gravitational analogue of Dirac's magnetic monopole, an observational evidence of this aspect of fundamental physics was elusive[3].

Perhaps Lynden-Bell and Nouri-Zonoz[9] were the first to motivate such an investigation. They argued that the best place to look for the gravitomagnetic monopole is in the spectra of supernovae, quasars, or active galactic nuclei. We demonstrate that the X-ray observations of a black hole X-ray binary (BHXB), i.e., an accreting stellar-mass collapsed object, can provide a way to detect a non-zero NUT parameter or the gravitomagnetic monopole. A rotating astrophysical collapsed object is generally described by the Kerr spacetime[10], and is characterized by only two parameters : mass and spin. Depending on the spin value of the rotating astrophysical collapsed object, it could be a black hole, or a naked singularity (also sometimes

called a "superspinar") which is visible in principle to external observers. Now, if the Kerr spacetime contains the gravitomagnetic monopole or vice-versa, it is regarded as the Kerr-Taub-NUT (KTN) spacetime[11]. This is geometrically a stationary, axisymmetric vacuum solution of Einstein equation, and reduces to the Kerr spacetime if the NUT parameter is zero. Thus, if one can identify a collapsed object with the KTN spacetime, this could establish the existence of the gravitomagnetic monopole. Here, we demonstrate[3] that the X-ray observations of a black hole X-ray binary (BHXB), i.e., an accreting stellar-mass collapsed object, can provide a way to infer and measure the gravitomagnetic monopole. Although, the collapsed object is generally thought to be a black hole, i.e., a singularity covered by an event horizon due to the Cosmic Censorship Conjecture, we do not exclude the possibility that it could also be a naked singularity in some cases[12]. However, before going into detail, we first briefly recapitulate the KTN spacetime and discuss some important observables which are useful to explore the possibility of gravitomagnetic monopole in nature.

## 2. Kerr-Taub-NUT Spacetime and Fundamental Frequencies

The metric of the KTN spacetime can be expressed as[11]

$$ds^2 = -\frac{\Delta}{p^2}(dt - Ad\phi)^2 + \frac{p^2}{\Delta}dr^2 + p^2 d\theta^2 + \frac{1}{p^2}\sin^2\theta(adt - Bd\phi)^2 \tag{1}$$

with

$$\begin{aligned} &\Delta = r^2 - 2Mr + a^2 - n^2, \quad p^2 = r^2 + (n + a\cos\theta)^2, \\ &A = a\sin^2\theta - 2n\cos\theta, \quad B = r^2 + a^2 + n^2, \end{aligned} \tag{2}$$

where $M$ is the mass, $a/M$ is the Kerr parameter and $n/M$ is the NUT parameter.

Now, using the metric components ($g_{\mu\nu}$) of KTN spacetime one can obtain the three fundamental frequencies. The orbital frequency can be written as[13]

$$\Omega_\phi^{\rm KTN} = 2\pi\nu_\phi^{\rm KTN} = \pm\frac{m^{\frac{1}{2}}}{r^{\frac{1}{2}}\ (r^2 + n^2) \pm a\ m^{\frac{1}{2}}}, \tag{3}$$

where $m = M\ (r^2 - n^2) + 2\ n^2 r$. Here, the upper sign is applicable for the prograde orbits and the lower sign is applicable for the retrograde orbits. Similarly, the radial and vertical epicyclic frequencies are written as[3]:

$$\begin{aligned} \nu_r^{\rm KTN} = \frac{\nu_\phi^{\rm KTN}}{m^{\frac{1}{2}}\ (r^2 + n^2)}.\Big[&M(r^6 - n^6 + 15n^4r^2 - 15n^2r^4) - 2M^2r(3r^4 - 2n^2r^2 + 3n^4) \\ &-16n^4r^3 \pm 8ar^{\frac{3}{2}}m^{\frac{3}{2}} + a^2\left\{M(n^4 + 6n^2r^2 - 3r^4) - 8n^2r^3\right\}\Big]^{\frac{1}{2}} \end{aligned} \tag{4}$$

and

$$\nu_\theta^{\rm KTN} = \frac{\nu_\phi^{\rm KTN}}{m^{\frac{1}{2}}\ (r^2+n^2)}.\ \big[M(r^6-n^6+15n^4r^2-15n^2r^4)+2n^2r(3r^4-2n^2r^2+3n^4)$$
$$+16M^2n^2r^3 \mp 4ar^{\frac{1}{2}}m^{\frac{1}{2}}(n^2+Mr)(n^2+r^2)$$
$$-a^2\left\{M(n^4+6n^2r^2-3r^4)-8n^2r^3\right\}\big]^{\frac{1}{2}} \qquad (5)$$

respectively. Setting the square of Eq. (4) equal to zero (i.e., $[\nu_r^{\rm KTN}]^2 = 0$), we obtain the innermost stable circular orbit (ISCO) condition as follows[13,14]:

$$M(r^6-n^6+15n^4r^2-15n^2r^4)-2M^2r(3r^4-2n^2r^2+3n^4)$$
$$-16n^4r^3 \pm 8ar^{\frac{3}{2}}m^{\frac{3}{2}}+a^2\left\{M(n^4+6n^2r^2-3r^4)-8n^2r^3\right\}=0. \qquad (6)$$

The gravitational redshift in the KTN spacetime is expressed as[3]

$$Z^{\rm KTN} = \frac{r^{\frac{1}{2}}(r^2+n^2)+a\ m^{\frac{1}{2}}}{\left[(r^2+n^2)\ \left\{r(r^2-3n^2)+M(n^2-3r^2)+2a(mr)^{\frac{1}{2}}\right\}\right]^{\frac{1}{2}}}. \qquad (7)$$

## 3. Exploring the possibility of non-zero gravitomagnetic monopole

$a/M$ measurement can be very useful to probe the strong gravity regime and to characterize the collapsed object. Some of the X-ray spectral and timing features which originate from the accreted matter within a few gravitational radii of a collapsed object in a BHXB, is generally used to measure $a/M$[15–17]. There are two main spectral methods for $a/M$ estimation: (1) using continuum X-ray spectrum[16], and (2) using broad relativistic iron K$\alpha$ spectral emission line[15]. There is also a timing method based on the relativistic precession model (RPM) of quasi-periodic oscillations (QPOs) of X-ray intensity[18].

In continuum X-ray spectrum method, thermal spectral component from the accretion disk is fit with a relativistic thin-disk model, and this gives a measure of the $r_{\rm in}$[19]. Then from a known $M$ and $r_{\rm ISCO}/M$ values, $a/M$ is inferred assuming Kerr spacetime. In the second method, a broad relativistic iron K$\alpha$ spectral emission line in X-rays is observed from many BHXBs, which is believed to originate from the reflection of hard X-rays from the inner part of the geometrically thin accretion disk. The red wing of the line that determines the observed constraint on $a/M$[20], gives a measure of the gravitational redshift at the disk inner edge radius $r_{\rm in}$, and for $r_{\rm in} = r_{\rm ISCO}$ ($r_{\rm ISCO}$ is the innermost stable circular orbit (ISCO) radius), the $a/M$ value is inferred for a prograde accretion disk assuming the Kerr spacetime.

In the QPO-based timing method, three observed QPO frequencies are used to estimate $a/M$: (a) the upper high-frequency (HF) QPO, (b) the lower HFQPO, and (c) the type-C low-frequency (LF) QPO[18]. This method is based on the relativistic precession model (RPM)[21,22], in which the Type-C QPO frequency is identified with the LT precession frequency ($\nu_{\rm LT}$)[23–25], and the upper and lower HFQPO frequencies are identified with the orbital frequency ($\nu_\phi$) and the periastron precession

frequency ($\nu_{\rm per}$) respectively[18]. In Kerr spacetime, each of these three frequencies is a function of three parameters: $M$, $a/M$ and $r_{\rm qpo}$ ($r_{\rm qpo}$ is the location of origin of these QPOs). Therefore, one can obtain the numerical values of these three parameters[18] for a particular Kerr compact object using the RPM method.

The RPM method could be fully applied for GRO J1655–40, as the three above-mentioned QPOs could be simultaneously observed only from this BHXB[18]. The mass of GRO J1655–40 is either $(6.3 \pm 0.5)M_{\odot}$[26] or $(5.4 \pm 0.3)M_{\odot}$[27]. It is not known until now, which mass value is reliable[19]. The observed frequencies of the above mentioned three simultaneous QPOs imply $\nu_{\phi} = 440$ Hz, $\nu_{\rm per} = 300$ Hz and $\nu_{\rm LT} = 17$ Hz for GRO J1655–40. Using these frequencies, Motta et. al.[18] determined $a/M \approx 0.286 \pm 0.003$, $M \approx (5.31 \pm 0.07)M_{\odot}$ and $r_{\rm qpo} \approx (5.68 \pm 0.04)\ M$. Moreover, GRO J1655–40 is currently the only BHXB, for which all the three above mentioned $a/M$ estimation methods are available. Thus, this source provides a unique opportunity to test the reliability of these methods by comparing the three estimated $a/M$ values. The timing method gives $a/M \approx 0.286 \pm 0.003$[18], the line spectrum method gives $a/M \approx 0.90 - 0.99$[20], and the continuum spectrum method gives $a/M \approx 0.65 - 0.75$ for GRO J1655–40. Therefore, the $a/M$ value inferred from these three methods are grossly inconsistent with each other.

Are these three methods missing an essential ingredient, is it possible to make these methods reliable? We explore an possibility that the inclusion of NUT charge may make the results from three methods consistent, and it suggests that gravitomagnetic monopole exists in nature[3]. We have already calculated the important observables with non-zero NUT parameter values, i.e., by considering the KTN spacetime, instead of the previously used Kerr spacetime. Now, we can use those results directly to show the possibility of existence of non-zero gravitomagnetic monopole in GRO J1655–40.

As we have already discussed, we can apply the RPM method to GRO J1655–40 using KTN spacetime, instead of Kerr spacetime which was used in[18]:

$$\nu_{\phi}^{\rm KTN} = 440 \text{ Hz};\ \nu_{\rm per}^{\rm KTN} = 300 \text{ Hz};\quad \nu_{\rm LT}^{\rm KTN} = 17 \text{ Hz}. \tag{8}$$

Using Eqs. (3–5) we can solve Eqs.(8) for $a/M$, $M$ and the radius $r_{\rm qpo}$ of QPO origin for a given $n/M$ value[3]. For $n = 0$, one can easily recover the above-mentioned parameter values as described in[18]. As the three equations are also satisfied for other non-zero values of $n$, a new range of $n$ could be found[3], and this can give the same QPO values for GRO J1655–40 with a specific combinations of $M$, $a/M$ and $r_{qpo}$. One should note here that the range of $0 < a/M \leq 1$ represents a Kerr black hole, whereas $a/M > 1$ represents Kerr naked singularity[12,28]. Similarly, the KTN naked singularity is represented with the following range $a/M > \sqrt{1 + (n/M)^2}$[29] and KTN BH is represented with $0 < a/M \leq \sqrt{1 + (n/M)^2}$.

Using the line spectrum method[20], the $a/M$ range for GRO J1655–40 was estimated as $\approx 0.90 - 0.99$, assuming it as a Kerr black hole. Now, one can calculate the gravitational redshift range ($\approx 2.70 - 6.08$) from the reported $a/M$ range ($\approx 0.90 - 0.99$), and using this range ($\approx 2.70 - 6.08$) as the primary

observational constraint, and assuming GRO J1655–40 as the KTN spacetime, i.e., $Z^{\rm KTN}(\text{at } r_{\rm ISCO}) = 2.70 - 6.08$ (L.H.S. is given by Eqs. 6 and 7), one can solve for $M$, $a/M$, $n/M$, $r_{\rm ISCO}/M$ and $r_{\rm qpo}$ from Eq. (8). This solution gives the following constraints for GRO J1655–40, which are consistent with both the RPM method and the line spectrum method: $M \approx 6.76 - 6.83 M_{\odot}$, $a/M \approx 2.12 - 2.27$, $n/M \approx 1.86 - 1.97$ and $r_{\rm qpo}/M \approx 4.99 - 5.04$[3]. The $M$ range is consistent with an independently measured mass ($[6.3 \pm 0.5] M_{\odot}$;[26]) for GRO J1655–40, which provides a confirmation of the reliability of our method and results.

Using the continuum spectrum method, one can find the $a/M$ range as $\approx 0.65 - 0.75$[30] for GRO J1655–40. This was inferred from the $r_{\rm ISCO}$ range as $\approx 29.8 - 34.2$ km, using $M = 6.3 M_{\odot}$. Now, considering $r_{\rm ISCO} = 29.8 - 34.2$ km as the primary constraint and assuming the KTN spacetime (using Eq. 6), we solve Eq. (8) for $M$, $a/M$, $n/M$, $r_{\rm ISCO}/M$ and $r_{\rm qpo}/M$. Consequently, the following parameter constraints could be obtained: $M \approx 6.79 - 6.86 M_{\odot}$, $a/M \approx 2.04 - 2.21$, $n/M \approx 1.79 - 1.93$ and $r_{\rm qpo}/M \approx 4.96 - 5.02$[3]. It can be seen that these parameter ranges overlap with the parameter ranges obtained from the combined RPM and line spectrum methods.

## 4. Conclusion and Discussion

We have shown that $a/M \approx 2.12 - 2.21$ and $n/M \approx 1.86 - 1.93$ are consistent with all the three methods[3]. These ranges imply that the collapsed object in GRO J1655–40 could also be a naked singularity (see Fig. 1 of[3]). One can also realize from the above mentioned $n/M$ range ($\approx 1.86 - 1.93$) that the inferred non-zero $n/M$ values cannot be caused by the systematics, as is significantly away from $n/M = 0$. The earlier three independent primary X-ray observational methods provided significantly different spin values for GRO J1655-40, which were $0.286 \pm 0.003$, $0.65 - 0.75$ and $0.90 - 0.99$. Employing an interesting technique, we have demonstrated that the inclusion of one extra parameter (i.e., gravitomagnetic monopole) not only makes the spin and other parameter values inferred from the three methods consistent with each other, but also makes the inferred black hole mass consistent with an independently measured value[3]. This confirmation provides a new way to measure the NUT parameter, even when only two $a/M$ measurement methods are available for a BHXB. Here, one should note that the value of $n/M$ can be different for different objects like the value of $a/M$ and a high $n/M$ value inferred for one object does not mean that every object will have a high $n/M$ value. The value of $n/M$ can even be very close to zero for some objects[3]. However, the inferred significantly non-zero $n/M$ value for even one object, i.e., GRO J1655-40 could strongly suggest the existence of gravitomagnetic monopole in nature[3]. Finally, our inference of the first significant observational indication of the gravitomagnetic monopole, which, even though is not a direct detection, can have an exciting impact on fundamental physics and astrophysics. Moreover, as the accreting collapsed object GRO J1655-40 could be better described with the more general KTN spacetime, instead of the Kerr spacetime, this makes the KTN spacetime astrophysically relevant.

# Kerr–Newman black hole in the formalism of isolated horizons

Aleš Flandera* and Martin Scholtz

We study the Kerr–Newman black hole in the formalism of isolated horizons using a general solution found by Krishnan in 2012.[1] It establishes the existence of a null tetrad which is tangent to the horizon and parallelly propagated off the horizon along a non-twisting null geodesic congruence. However, the explicit construction of such a tetrad for the Kerr–Newman metric was not given. We have formulated appropriate initial data and found the exact form (up to integrals) of the solution everywhere in the Kerr–Newman space-time.[2] In the near future we aim to apply this formulation to the study of distorted black holes by perturbing the initial data found in this work.

*Keywords*: Kerr–Newman black hole; isolated horizons; tetrad formalism.

## 1. Introduction

In 2012, Krishnan investigated the near horizon geometry in the vicinity of an isolated horizon in the Newman–Penrose formalism.[1] He found a solution of the Einstein field equations in the form of a power series of the Newman–Penrose tetrad. It was possible since the properties of weakly isolated horizons allow one to solve the constraint part equations in the Newman–Penrose formalism. The solution tells us a lot about how the Newman–Penrose tetrad shall look like. On the other hand, the approach does not provide an insight into the choice of the initial data for any particular space-time and, hence, it stayed unknown, including the Kerr–Newman space-time.

This particular space-time (in the formalism of isolated horizons) was interesting for us for the previous treatment of the Meissner effect in Ref. 3. They proved that the magnetic field is expelled from a general extremal axisymmetric stationary black hole. To be able to do so, one, however, needs to know the initial data. They found a first order approximation for the particular case. This solution represented a deformed Kerr solution, however, it was not clear, how it was deformed. The aim of our work was to find an approach which would lead to a general solution to this problem.

## 2. Weakly isolated horizons

A **non-expanding horizon** is a null hypersurface $\mathcal{H}$ with topology $\mathbb{R} \times \mathcal{S}^2$, where the Einstein equations hold and for any null normal of the horizon $l^a$ its expansion

is zero and if the normal is future pointing, also the vector $T_{ab}l^b$ is future pointing. The tensor $T_{ab}$ is the energy-momentum tensor.

The introduced expansion is the well-known optical scalar for null geodesic congruences[4] and its zeroness implies also vanishing shear and twist. Among other relations we can derive from the properties of non-expanding horizons there is one to be discussed here:

$$\mu = \bar{\mu}\,. \tag{1}$$

This tells us that $\mu$ is real and it shall be a key feature for us. For the discussion of all relevant relations, see Ref. 5.

A **weakly isolated horizon** is a pair $(\mathcal{H},\, [l^a])$ where $\mathcal{H}$ is a non-expanding horizon and $[l^a]$ is an equivalence class of normals satisfying

$$[\pounds_l, \mathcal{D}_a]l^b \doteq 0 \tag{2}$$

for any $l^a$ in this class. Here $\pounds$ is the Lie derivative and $\mathcal{D}_a$ is an induced covariant derivative on the horizon introduced by $X^a\,\mathcal{D}_aY^b \doteq X^a\,\nabla_aY^b$ for any tangent vectors $X^a$, $Y^a$. Eq. (2) ensures that the $l^a$-part of the induced connection is time independent.

## 3. Krishnan construction

In Ref. 1, it was described how a Newman–Penrose tetrad is constructed to reflect (and describe) the properties of isolated horizons and the initial value problem was formulated, though without stating the initial data. Here let us just summarize the key principles.

An arbitrary sphere $\mathcal{S}_0$ is chosen on the horizon and the vectors $m^a$ and $\bar{m}^a$ are chosen as the basis of its tangent space. They are Lie propagated along the null normal $l^a$ on the horizon. It is possible thanks to the following: the normal is null and therefore also tangent to the horizon, the normal is surface forming for it has vanishing twist,[6] the Lie transport preserves the scalar products in the case of a non-expanding horizon. In this manner, the triad is introduced on the entire horizon and thanks to the scalar products of the Newman–Penrose tetrad ($l^an_a = 1$, $m^a\bar{m}_a = -1$, others zero) the last vector $n^a$ is already fixed on the horizon. We are left with the propagation of the vectors off the horizon which is achieved by parallel transport of the triad ($l^a$, $m^a$, $\bar{m}^a$) alongside a geodesic in the direction of vector $n^a$ which is constructed first. The coordinates are propagated alike. The situation is schematically illustrated in Fig. 1.

The Bondi-like coordinates are introduced in the following way: $x^I$ are spherical coordinates on the sphere $\mathcal{S}^2$, $v$ is a time coordinate in the direction of $l^a$ and $r$ is a radial coordinate in the transversal direction of $n^a$.[a]

[a] The Newman–Penrose tetrad is a non-holonomic one and therefore there are no coordinates which could be connected to it. However, since some of the coordinates are connected to only some of

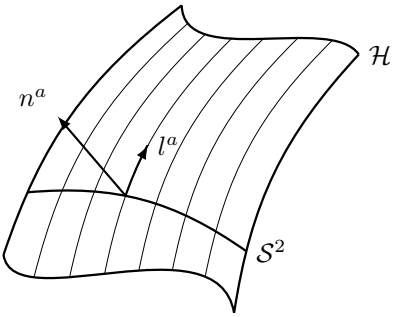

Fig. 1. Local topology of the space-time.

We have already discussed the vanishing optical scalars for the geodesic congruence in the direction of $l^a$. Let us now recall that $\mu$ spin coefficient has vanishing imaginary part, Eq. (1). Since the imaginary part of spin coefficient $\mu$ is the twist of a geodesic congruence in the direction of $n^a$, let us call such a tetrad *non-twisting* (in the direction of $n^a$). If there is an imaginary part of $\mu$, the tetrad is to be called *twisting*.

This tetrad is expanded in the radial parameter $r$

$$X = X^{(0)} + rX^{(1)} + \tfrac{1}{2}r^2X^{(2)} + \cdots \tag{3}$$

and the constraints are solved.[1] To do so, one employs the Ricci and Bianchi identities which, in the Newman–Penrose formalism, play the role of the field equations. In this manner Krishnan formulated the initial value problem which is displayed in Fig. 2. There are two characteristics: the horizon $\mathcal{H}$ and a transversal hypersurface $\mathcal{N}_0$ intersecting each other in the sphere $\mathcal{S}_0$ (both $l^a$ and $n^a$ are surface forming). On the sphere $\mathcal{S}_0$ are introduced the quantities: spin coefficients $\alpha$, $\pi$, $\mu$, $\lambda$, Maxwell scalar $\phi_1$ and the surface gravity $\kappa_{(l)}$. After solving all the constraints on $\mathcal{S}_0$ and obtaining so the Weyl scalars $\Psi_2$ and $\Psi_3$, the full geometry of the horizon can be reconstructed from the data on $\mathcal{S}_0$. Finally, in order to propagate the solution off the horizon, scalars $\phi_2$ and $\Psi_4$ must be prescribed on the entire $\mathcal{N}_0$.

## 4. Perturbative solution

Now we are ready to look for the appropriate tetrad connecting the Kerr–Newman space-time to the formalism of isolated horizons. We started with the Kinnersley tetrad[7] which is a Newman–Penrose tetrad, however, it is twisting. On the other hand, there must exist a sequence of Lorentz transformations of the tetrad which eliminates the imaginary part of the spin coefficient $\mu$.

the vectors, there is a way how to make a correspondence between the vectors of the tetrad and the coordinates. E.g. a gradient of vector $n^a$ is given by all the coordinates, but the $r$ coordinate is only present in this gradient.

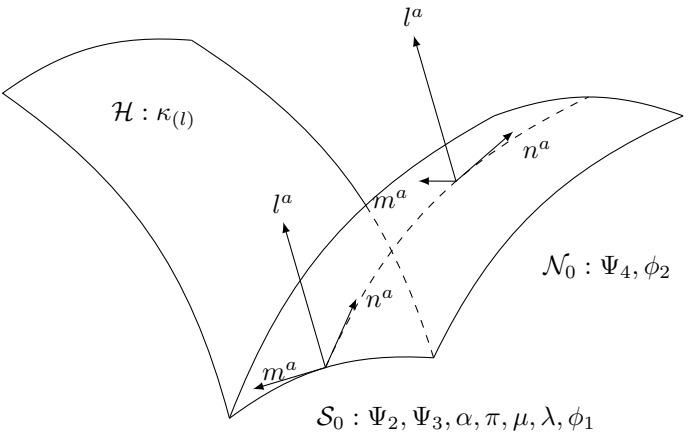

Fig. 2. The neighbourhood of the horizon and initial value surfaces. The scalars enlisted after the colons have to be introduced on the corresponding (hyper)surface.

In Ref. 5, we used a coordinate transformation, boost and rotation about $l^a$ (all valid on the horizon) and we ended up with a tetrad on the horizon:

$$\begin{aligned} l_{\mathrm{R}} &\doteq \partial_v \,, \\ n_{\mathrm{R}} &\doteq -\frac{a^2 \sin^2\theta}{2\left(r_+^2 + a^2\cos^2\theta\right)}\,\partial_v - \frac{a^2 + r_+^2}{r_+ + a^2\cos\theta}\,\partial_r - \frac{a}{a^2 + r_+^2}\,\partial_\phi \,, \\ m_{\mathrm{R}} &\doteq \frac{1}{\sqrt{2}\,(r_+ + \mathrm{i}a\cos\theta)}\,\partial_\theta + \frac{\mathrm{i}\,(r_+ - \mathrm{i}a\cos\theta)}{\sqrt{2}\left(a^2 + r_+^2\right)\sin\theta}\,\partial_\phi \,. \end{aligned} \tag{4}$$

The tetrad has all required properties on the horizon and to get it also off the horizon we used an expansion in the radial parameter $r$:

$$l^a = l^a_{(0)} + (r - r_+) l^a_{(1)} + \mathcal{O}(r - r_+)^2 \,, \qquad l^a_{(1)} = l^a_{(1)}(\theta, \phi) \,, \tag{5}$$

where the time-independence was inferred from the existence of the time-like Killing vector in Kerr–Newman space-time.

The subsequent orders of the tetrad were computed, using the parallel transport conditions, in Wolfram Mathematica. By this we get all quantities exactly on the horizon and up to an arbitrary order elsewhere.

## 5. Exact solution

To get the exact solution, it is needed to use all four types of Lorentz transformations: spin, boost, rotation about $l^a$ and rotation about $n^a$. Moreover, unlike for the expansion, they have to transform the tetrad properly in the entire space-time. We were unable to find the parameters directly, since the final step requires the solution of a difficult differential equation.

Instead, it is possible to write the vector $n^a$ in the form of a gradient:

$$n_\mu \mathrm{d}x^\mu \equiv E\,\mathrm{d}v - \frac{a^2}{P+\sqrt{R}}\,\mathrm{d}r + \sqrt{\Theta}\,\mathrm{d}\theta + L\,\mathrm{d}\varphi = \mathrm{d}\tilde{v} \tag{6}$$

where $P = aL + E(a^2 + r^2)$, $R = P^2 - \mathcal{K}\tilde{\Delta}$, $\Theta = \mathcal{K} - (L + a\,E)^2 + \left(a^2\,E^2 - L^2 \sin^{-2}\theta\right)\cos^2\theta$ and $\tilde{\Delta} = a^2 + r^2 - 2\,M\,r + Q^2$. Inspection of the integrability conditions for Eq. (6) implies the values $L = 0$ and $E = 1$,[8] then we also arrive at $K = a^2$.

With this simplification in hand, we can apply the Lorentz transformations. For the discussion see,[2] here we only briefly recapitulate them. We start with a boost followed by a rotation about $l^a$ to set the vector $n^a$ to the direction given by Eq. (6). The transformations are:

$$l^a \mapsto A^2 l^a\,, \qquad n^a \mapsto A^{-2} n^a\,, \qquad m^a \mapsto m^a\,, \tag{7}$$

$$l^a \mapsto l^a\,, \qquad n^a \mapsto n^a + c m^a + \bar{c}\bar{m}^a + |c|^2 l^a\,, \qquad m^a \mapsto m^a + \bar{c} l^a \tag{8}$$

and their parameters are (let us introduce also function $\rho = r + \mathrm{i}a\cos\theta$):

$$A^2 = \frac{2P}{P+\sqrt{R}}\,, \qquad c = -\frac{\mathrm{e}^{-\mathrm{i}\vartheta}}{\sqrt{2}\bar{\rho}}\,. \tag{9}$$

We proceed by the spin:

$$m^a \mapsto \mathrm{e}^{-\mathrm{i}\vartheta} m^a\,, \qquad \bar{m}^a \mapsto \mathrm{e}^{\mathrm{i}\vartheta}\bar{m}^a\,. \tag{10}$$

The remaining transformation is the rotation about $n^a$ and in order to find the corresponding parameter we have to solve the equation $n^a \nabla_a d = \tau$, where $\tau$ is a spin coefficient. This is however very difficult in the Kerr coordinates. In order to solve the problem, we perform a transformation to Bondi-like coordinates introduced by

$$\mathsf{v} = v - \int_{r_+}^{r} \frac{a^2\,\mathrm{d}r}{P+\sqrt{R}} + a\sin\theta\,, \qquad \sin\theta = \tanh\mathsf{X}\,, \qquad \tilde{\phi} = \varphi + J(r)\,, \tag{11}$$

where

$$\begin{aligned} \mathsf{X} &= \alpha(r) + \operatorname{arth}\sin\vartheta\,, \qquad \alpha(r) = \int_{r_+}^{r} \frac{a\,\mathrm{d}u}{\sqrt{u^4 + a^2\,u^2 + 2\,a^2\,M\,u - a^2\,Q^2}}\,, \\ J(r) &= -\int_{r_+}^{r} \frac{a}{P(u) + \sqrt{R(u)}}\left(1 + \frac{u^2}{\sqrt{R(u)}}\right)\mathrm{d}u\,. \end{aligned} \tag{12}$$

Then the equation for parameter $d$ is $-\partial_r d = \tau$ and can be integrated to get:

$$d(r,\vartheta) = -\int_{r_+}^{r} \frac{|\rho(u,\vartheta)|^2}{\sqrt{R(u)}}\,\tau(u,\vartheta)\,\mathrm{d}u\,. \tag{13}$$

Unfortunately, this cannot be evaluated explicitly and, hence, the final tetrad shall also be an implicit expression. To complete the construction of the Bondi-like coordinates, we define

$$\mathsf{r} = \int_{r_+}^{r} \frac{|\rho(u,\vartheta)|^2}{\sqrt{R(u)}}\,\mathrm{d}u\,, \qquad \phi = \tilde{\phi} - \frac{a\mathsf{v}}{a^2 + r_+^2}\,. \tag{14}$$

We arrive at the final tetrad, which is of the Krishnan type and has the form $(I = 2, 3)$:

$$l = \partial_v + U\,\partial_{\mathsf{r}} + X^I\,\partial_I\,, \qquad n = -\partial_{\mathsf{r}}\,, \qquad m = \Omega\,\partial_{\mathsf{r}} + \xi^I\,\partial_I\,. \tag{15}$$

The functions $U$, $X^I$, $\Omega$ and $\xi^I$ shall not be shown here for their length, see Ref. 2.

## 6. Conclusion

We constructed a parallelly propagated, Bondi-like tetrad in the Kerr–Newman space-time and, hence, we were able to formulate the initial data not only on the horizon, as in the previous works, but also on the transversal null hypersurface. Although the tetrad is not calculated explicitly, we present the results in the form suitable for both symbolic manipulations (e.g. in computer algebra systems) and numeric calculations, since all functions are expressed in terms of the integrals of one variable. These results were published in the paper.[2] In the near future we will apply this formalism to the study of deformed black holes. This is a promising approach since by varying data on the hypersurface $\mathcal{N}_0$ (see Fig. 2) one can generate a wide class of exact solutions describing black holes.

# Testing the Kerr spacetime with X-ray reflection spectroscopy

Masoumeh Ghasemi-Nodehi

*National Astronomical Observatories, Chinese Academy of Sciences, Beijing 100101, China*
*E-mail: ghasemi@nao.cas.cn*

Astrophysical black holes are thought to be Kerr solution of general relativity but their Kerr geometry have not yet verified. Iron line is prominent feature in X-ray reflection spectra. Shape of iron line in X-ray reflection spectra of both stellar-mass and super massive black hole candidates are supposed to be strongly affected by spacetime geometry. This method is a powerful technique to prob strong gravity regime and deviations from Kerr spacetime. In this talk, I present iron line of some non-Kerr spacetimes. I also present data simulations of X-ray missions. The purpose is to understand whether X-ray reflection spectroscopy can distinguish these non-Kerr spacetimes from Kerr solution of general relativity.

*Keywords*: Tests of General Relativity, X-ray Reflection Spectroscopy.

## 1. Introduction

Final product of gravitational collapse is Kerr spacetime according to Einstein's theory of general relativity. General relativity is strongly constrained by weak field regime experiments. There have been efforts to test strong gravity regime by probing the metric around astrophysical candidates in the recent years[1]. The studies are based on properties of electromagnetic radiation emission of accretion disk. Kerr black holes are only characterized by mass and spin based on multipole moment expansions. Higher multipole moment expansions in a Kerr spacetime are only function of mass and spin. The compact object cannot be the Kerr black hole of general relativity in the case of measurement of independent higher multipole moments such as quadrupole moment by observational data.

Neutron stars have high density and strong gravity. They are fascinating laboratory to study possible deviation from prediction of general relativity, and in general, to study strong gravity regime. Multipole moment expansion can provide accurate approximation of spacetime surrounding a neutron star. Study of higher order multipole moments can reveal properties of neutron stars.

Approximate solution of exterior spacetime of neutron star is presented in reference[2]. The solution is based on Ernst formulation of general relativity up to five multipole moments, mass, angular momentum, mass quadrupole, spin octupole, and hexadecapole. The relation between these hairs and neutron star surrounding spacetime is also introduced in the reference. The hairs only depends on mass, spin, and quadrupole moment.

In present paper, I considered this metric based on Ernst formalism up to five multipole moments to study observational test of the neutron star exterior spacetime and distinguish it from Kerr spacetime. I employ iron line method. The iron line is prominent feature in X-ray reflection spectra. The emission is fluorescent narrow

lines from geometrically thin and optically thick accretion disk which produced by absorption of a hard X-ray photon of corona. This emission would be broadened and skewed in the inner region of the accretion disk due to relativistic effect of compact object there. In this paper, first, iron lines are simulated. Then, observational data are simulated and analyzed. The result is as follows. It is hard to constrain parameters of neutron star exterior spacetime using iron line method since both fast rotating and slow rotating case cannot be distinguished from Kerr solution of general relativity. The paper is structured as follows. In section 2, I present the spacetime metric. Section 3 is devoted to iron line method and data simulation and analysis is presented in section 3. Finally, section 4.1 is a short summary and conclusion. Throughout the paper, I employ units in which $G_N = c = 1$ and metric signature is $(-,+,+,+)$.

## 2. Theoretical Framework

A stationary and axially symmetric spacetime based on Ernst potential formalism to describe spacetime surrounding a neutron star is reported in [2]. The solution contains the first five relativistic multiple moments, the mass, $M$, angular momentum, $J$, the mass quadrupole, $M_2$, spin octupole, $S_3$, and the mass hexadecapole, $M_4$. The line element reads

$$ds^2 = -f\left(dt - \omega d\varphi\right)^2 + f^{-1}\left[e^{2\gamma}\left(d\rho^2 + dz^2\right) + \rho^2 d\varphi^2\right], \tag{1}$$

where metric functions $f$, $\omega$, and $\gamma$ are given as

$$\begin{aligned}
f(\rho,z) &= 1 - \frac{2M}{\sqrt{\rho^2+z^2}} + \frac{2M^2}{\rho^2+z^2} + \frac{\left(M_2 - M^3\right)\rho^2 - 2\left(M^3 + M_2\right)z^2}{\left(\rho^2+z^2\right)^{5/2}} \\
&\quad + \frac{2z^2\left(-J^2 + M^4 + 2M_2 M\right) - 2MM_2\rho^2}{\left(\rho^2+z^2\right)^3} \\
&\quad + \frac{A(\rho,z)}{28\left(\rho^2+z^2\right)^{9/2}} + \frac{B(\rho,z)}{14\left(\rho^2+z^2\right)^5}, \\
\omega(\rho,z) &= -\frac{2J\rho^2}{\left(\rho^2+z^2\right)^{3/2}} - \frac{2JM\rho^2}{\left(\rho^2+z^2\right)^2} + \frac{F(\rho,z)}{\left(\rho^2+z^2\right)^{7/2}} \\
&\quad + \frac{H(\rho,z)}{2\left(\rho^2+z^2\right)^4} + \frac{G(\rho,z)}{4\left(\rho^2+z^2\right)^{11/2}}, \\
\gamma(\rho,z) &= \frac{\rho^2\left(J^2\left(\rho^2-8z^2\right) + M\left(M^3+3M_2\right)\left(\rho^2-4z^2\right)\right)}{4\left(\rho^2+z^2\right)^4} - \frac{M^2\rho^2}{2\left(\rho^2+z^2\right)^2},
\end{aligned}$$

where

$$
\begin{aligned}
A(\rho,z) &= \left[8\rho^2z^2\left(24J^2M+17M^2M_2+21M_4\right)+\rho^4\left(-10J^2M+7M^5+32M_2M^2\right)\right.\\
&\quad \left.-21M_4+8z^4\left(20J^2M-7M^5-22M_2M^2-7M_4\right)\right],\\
B(\rho,z) &= \left[\rho^4\left(10J^2M^2+10M_2M^3+21M_4M+7M_2^2\right)+4z^4\left(-40J^2M^2-14JS_3\right.\right.\\
&\quad \left.+7M^6+30M_2M^3+14M_4M+7M_2^2\right)-4\rho^2z^2\left(27J^2M^2-21JS_3\right.\\

G(\rho,z) &= \left[\rho^2\left(J^3\left(-\left(\rho^4+8z^4-12\rho^2z^2\right)\right)+JM\left(\left(M^3+2M_2\right)\rho^4\right.\right.\\
&\quad -8\left(3M^3+2M_2\right)z^4+4\left(M^3+10M_2\right)\rho^2z^2\\
&\quad \left.\left.+M^2S_3\left(3\rho^4-40z^4+12\rho^2z^2\right)\right)\right]\\
F(\rho,z) &= \left[\rho^4\left(S_3-JM^2\right)-4\rho^2z^2\left(JM^2+S_3\right)\right].
\end{aligned}
$$

The first multipole moments can be expressed as follows to use for neutron star case

$$
\begin{aligned}
M_2 &= -\alpha j^2M^3\,,\\
S_3 &= -\beta j^3M^4\,,\\
M_4 &= \gamma j^4M^5\,,
\end{aligned}
\tag{2}
$$

where $M$ is mass and $j = J/M^2$ is spin parameter. The case $\alpha = \beta = \gamma = 1$ presents the Kerr case but these parameters can be large for neutron star case. The relation between $\alpha, \beta$, and $\gamma$ is[3,4]

$$
\begin{aligned}
y_1 &= -0.36 + 1.48\,x^{0.65}\\
y_2 &= -4.749 + 0.27613\,x^{1.5146} + 5.5168\,x^{0.22229}\,,
\end{aligned}
\tag{3}
$$

where $x = \sqrt{\alpha}\,, y_1 = \sqrt[3]{\beta}$, and $y_2 = \sqrt[4]{\gamma}$. Thus, one can determine the neutron star exterior spacetime by mass, spin, and parameter $\alpha$, ranges from $\sim 1.5$ for non-rotating case to 8 for cases with maximum value of spin parameter such as 0.5.

## 3. X-ray Reflection Spectroscopy

Iron line is prominent feature in X-ray reflection spectra of astrophysical black hole candidates. Iron atom absorbs hard X-ray photon of optically thin comptonized corona and emits fluorescence lines. This line is at 6.4 keV for weakly ionized or neutral atom and shifts up to 6.97 keV in the case of ionized H-like iron. This line would be broadened and skewed as the result of presence of strong gravity region and relativistic effects such as Doppler shift, gravitational redshift and light bending in the inner region of the accretion disk. This broad and skewed line provide us powerful tool to test strong gravity regime. This observational feature is determined by background metric, viewing angle, and emissivity profile of the disk. In my simulation, the inner edge of the disk is considered at the ISCO radius and

the outer edge is large enough that its impact is small. The emissivity is power-law, $1/r^q$, where $q$ is emissivity index. The assumption is $q = 3$ which corresponds to Newtonian limit at large radii. The code is described in [5,6].

The iron lines for metric 1 with two sets of spin parameter 0.5 and 0.2, and viewing angle 55° are presented in figures 1 and 2. The lines present slight difference with respect to Kerr one for case with spin 0.5 and the impact on the line profile with spin 0.2 is weak and maybe harder to constrain.

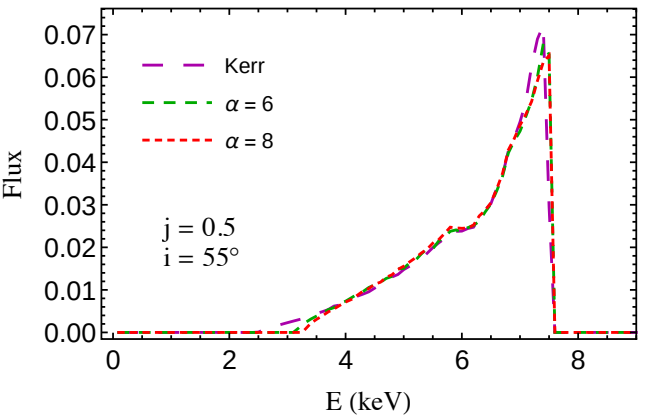

Fig. 1. Spin parameter value is 0.5 and viewing angle is 55°. The parameter values for $\alpha$ are 6 and 8. See text for more details.

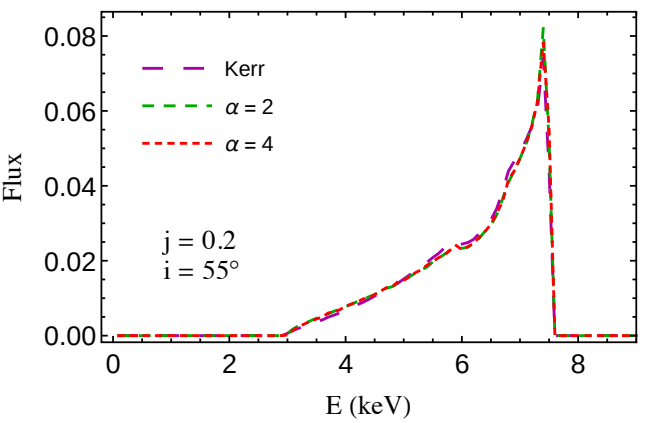

Fig. 2. This figure present the iron lines with spin parameter value 0.2 and viewing angle 55°. The parameter values for $\alpha$ are 2 and 4. See text for more details.

## 4. Simulating Data and Analysis

In this section, I simulate observed data of a neutron star and analyze them with a Kerr model. This tells us whether the Kerr model fit the data or not. I simulate data with a model consists of power-law and a single iron line of previous section. The considered flux is about $10^{-11}$ erg/cm$^2$/s in the range $2-10$ keV for neutron star case. The equivalent width is about 200 eV and photon index of power-law is 2. The simulation is done with *fakeit* command of XSPEC using RMF, ARF, and background file of LAD instrument with large area detector on board of enhanced X-ray Timing and Polarimetry (eXTP) China-Europe mission which is planned to launch before 2025. The LAD instrument has large effective area to provide more counts with less poisson noise. The data fitting is done with a power-law model and a RELINE model (a Kerr iron line). Figure 3 shows data to model ratio of best fit model for neutron star data simulation with spin parameter 0.5 and $\alpha = 8$ in the left panel. Right panel shows the case with spin value 0.2 and $\alpha = 2$. As we see there are slight differences for the case with spin 0.5 and there are not strong effect for spin value 0.2 which means it is hard to be constrained.

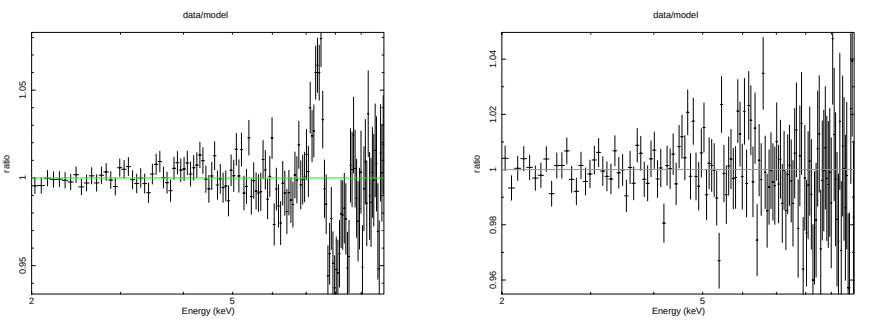

Fig. 3. Left panel: Data-to-model model ratio for simulation with iron line $j = 0.5$, $i = 55^\circ$ and $\alpha = 8$. The reduced $\chi^2$ is 2.1 and there are unresolved features. Right panel: The spin parameter for this figure is 0.5, $i = 55^\circ$ and $\alpha = 2$ for the iron line. The figure shows the data-to-model ratio. The reduced $\chi^2$ is 1.1 and there are no remarkable unresolved features, which makes this case harder constrain.

### 4.1. *Summary and Conclusion*

A solution of Einstein's field equations using Ernst potential formalism up to five multipole moments is introduced in the reference[2]. This method can accurately describe the exterior spacetime of neutron star. The iron line emitted from medium around neutron star is simulated in the present paper. Two different values of spin parameter 0.5 and 0.2 with different value of $\alpha$ are considered. The impact of iron lines with spin value 0.5 is not very strong and there is no impact on iron lines spin

value 0.2. The 100ks observation with LAD-eXTP for neutron star with different sets of parameter value are also presented. If the fit is not good, the neutron star exterior spacetime parameters and the deviations from the Kerr case can be constrained. The fit for higher value of spin parameter 0.5 and $\alpha = 8$ does not seem good. But the impact on iron lines are small and also there are uncertainties. Thus, it might be hard to constrain neutron star solution. The fit for spin value 0.2 and $\alpha = 2$ is good which indicates it is not possible to constrain deviations from Kerr solution.

Super-Massive Black Holes reside in galactic nuclei, where they exhibit episodic bright flares due to accretion events. Taking into account relativistic effects, namely, the boosting and lensing of X-ray flares, we further examine the possibility to constraint the mass of the SMBH from the predicted profiles of the observed light curves. To this end, we have studied four bright flares from Sagittarius A*, which exhibit an asymmetric shape consistent with a combination of two intrinsically separate peaks that occur with a specific time delay with respect to each other. We have thus proposed (Karssen et al. 2017, Mon. Not. R. Astron. Soc. 472, 4422) that an interplay of relativistic effects could be responsible for the shape of the observed light curves and we tested the reliability of the method.

*Keywords*: Gravitation; Black Holes; Accretion; Galactic center.

## 1. Introduction

Astrophysical black holes influence their cosmic environs by gravitational and electromagnetic effects. They are described by a small number of free parameters, namely, the mass and angular momentum.[1] All evidence as well as theoretical arguments point to the fact that the effects of electric charge must be very small (at least in the steady-state limit), whereas the magnetic monopole and additional even more exotic parameters are thought to be negligible or they vanish completely to zero.[2–4] Several independent methods have been developed to measure the black hole mass as a primary parameter defining the black hole action on luminous matter in their neigborhood.[5–7] A new method of mass determination from optical polarization of broad emission lines has been proposed to constrain SMBH mass in active galactic nuclei.[8,9] In X-rays, also the possibility of measuring the black hole mass from the energy shift of narrow spectral lines has been discussed widely.[10–13] We describe a recently developed method that is based on the assumption that a fast orbital motion of radiating X-ray flares can be detected in time variability of accreting black holes.[14,15]

## 2. Bright flares from a source orbiting near a black hole

The time-scale of matter orbiting along $r$ = const circular trajectory around Kerr black hole of mass $M$ can be written

$$T_{\rm orb}(r;a) \simeq 310(r^{\frac{3}{2}} + a)M_7 \text{ sec.} \quad (1)$$

Hereafter we use dimensionless geometric units, where length is expressed in terms of gravitational radius, $R_g \equiv GM/c^2 \simeq 1.5 \times 10^{12} M_7$ cm and the spin parameter $-1 \leq a \leq 1$ (positive values for the prograde rotation with the black hole). The dimension-less angular momentum $a$ adopts values in the range $-1 \leq a \leq 1$. Positive values correspond to co-rotating motion, while negative values describe counter-rotation (many papers assume that the accretion disc co-rotates, although such an assumption may not be necessarily true). Circular orbits of free particles are possible above the innermost stable circular orbit (ISCO a.k.a. marginally stable orbit).[16] Gravitation governs the orbital motion near the horizon, and so the apparent variability associated with the motion can be scaled with the black hole mass.

The gravitational field is described by the metric of Kerr black hole[1]

$$ds^2 = -\frac{\Delta}{\Sigma}\Big(dt - a\sin^2\theta\, d\phi\Big)^2 + \frac{\Sigma}{\Delta}\, dr^2 + \Sigma\, d\theta^2 + \frac{\sin^2\theta}{\Sigma}\Big[a\, dt - \big(r^2 + a^2\big)\, d\phi\Big]^2 \quad (2)$$

in Boyer-Lindquist (spheroidal) coordinates $t$, $r$, $\theta$, $\phi$. The metric functions $\Delta(r)$ and $\Sigma(r,\theta)$ are known in an explicit form. The event horizon occurs at the roots of equation $\Delta(r) = 0$; the outer solution is found given by $r = R_+ = 1 + (1-a^2)^{1/2}$, which exists for $|a| < 1$. Once the black hole rotates ($a \neq 0$), particles and photons are pushed to co-rotate with the black hole due to frame-dragging effect. The co-rotation is obligatory within the ergosphere. Let us note that the Kerr spin parameter is limited to an equilibrium value by photon recapture from the disc ($a \simeq 0.998$) and by magnetic torques.[17,18]

The existence of ISCO is a remarkable feature of motion in strong gravity.[16] For a co-rotating equatorial disc,

$$R_{\rm ISCO} = 3 + z_2 - \big[\,(3-z_1)(3+z_1+2z_2)\,\big]^{\frac{1}{2}}, \quad (3)$$

where $z_1 = 1 + \alpha_+\alpha_-[\alpha_+ + \alpha_-]$, $\alpha_\pm = (1 \pm a)^{\frac{1}{3}}$, and $z_2 = (3a^2 + Z_1^2)^{\frac{1}{2}}$. The ISCO radius as function of spin spans the range of dimensionless radius from $R_{\rm ISCO} = 1$ (for $a = 1$, i.e. a maximally co-rotating Kerr black hole) to $R_{\rm ISCO} = 6$ (for $a = 0$, a static case of Schwarzschild black hole) to $R_{\rm ISCO} = 9$ ($a = -1$, case of maximum counter-rotation). The velocity of prograde Keplerian circular motion is

$$v^{(\phi)} = \Delta^{-1/2}\left(r^2 - 2ar^{1/2} + a^2\right)\left(r^{3/2} + a\right)^{-1} \quad (4)$$

with respect to locally non-rotating observers (LNRF). The corresponding angular velocity is $\Omega(r;a) = (r^{3/2} + a)^{-1}$. Finally, to derive the interval measured by

a distant observer, one needs to consider the Lorentz factor associated with the orbital motion,

$$\Gamma = \frac{\left(r^{3/2} + a\right) \Delta^{1/2}}{r^{1/4} \sqrt{r^{3/2} - 3r^{1/2} + 2a}\, \sqrt{r^3 + a^2 r + 2a^2}}\,. \tag{5}$$

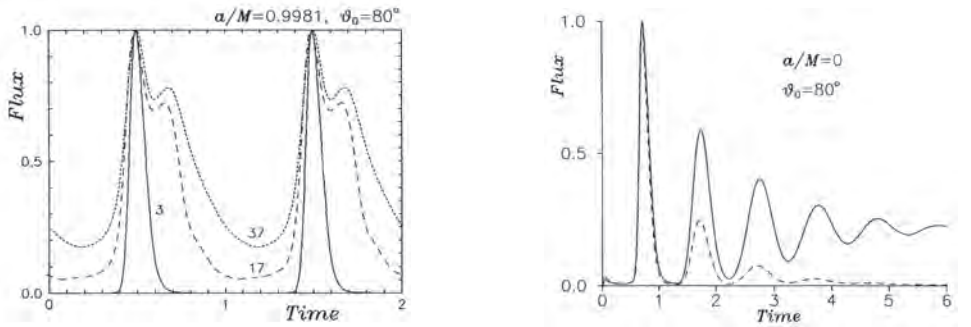

Fig. 1. Exemplary light curves of the signal from a spot orbiting on Keplerian circular trajectory near Kerr black hole. Effects of General Relativity have been taken into account, which allows us to constrain the parameters of the system. Left panel: radiation flux variation over a two revolutions. Parameters of the system are specified with the plot (radius of the orbits is given with each curve in units of the black hole gravitational radius, $R_g = GM/c^2$). Right panel: Two cases of tidally decaying spots due to differential rotation; (a) constant total emission from the spot (solid line) vs. (b) exponentially decaying intrinsic emission with time (dashed line), motivated by modelling the origin of the spot. Location of the spot is centered at $r = 6R_+$.[21]

Geodesic motion is determined by three constants of motion: the total energy $\mathcal{E}$, the azimuthal component of angular momentum $L_{\rm z}$, and Carter's constant $Q$. Null geodesics are relevant to describe propagation of photons, and for these the number of free constants can be reduced: $\xi = L_z/\mathcal{E}$, $\eta = Q/\mathcal{E}^2$. For photons propagating from the accretion disk towards a distant observer, the initial point is set at a given radius in the equatorial plane of the black hole, whereas the final point is at radial infinity, along the view angle of the observer. Relativistic effects become more prominent an high inclination angles.[12,19]

We employ geometrical optics and derive predicted light-curves from a source of light orbiting at a particular radius with the equatorial accretion disk. The equation for photon rays (null geodesics) relates an emission point $\mathcal{P}_0 = (r, \theta, \phi)_{\rm em}$ near the black hole with the terminal point $(\alpha, \beta)$ in observer's detector plane at spatial infinity.[20,21] The rays can be integrated in terms of elliptic integrals,

$$\int_{R_{\rm em}}^{R} \mathcal{R}(r')^{-1/2}\, dr' = \int_{\theta_{\rm em}}^{\theta} \Theta(\theta')^{-1/2}\, d\theta = \int_{\phi_{\rm em}}^{\phi} \mathcal{F}(\phi')^{-1}\, d\phi', \tag{6}$$

where

$$\mathcal{R}(r) = r^4 + (a^2 - \xi^2 - \eta)r^2 + 2[\eta + (\xi - a)^2]r - a^2\eta, \tag{7}$$
$$\Theta(\theta) = \eta + a^2\cos^2\theta - \xi^2\cot^2\theta, \tag{8}$$
$$\mathcal{F}(\phi) = [2ar + (\Sigma - 2r)\xi\csc^2\theta]\Delta^{-1}, \tag{9}$$
$$\Delta(r) = r^2 - 2r + a^2, \quad \Sigma = r^2 + a^2\cos^2\theta, \tag{10}$$
$$A(r,\theta) = (r^2 + a^2)^2 - \Delta(r)a^2\sin^2\theta. \tag{11}$$

The two constants of motion of the photon motion satisfy

$$\xi = A^{1/2}\Sigma^{-1/2}E^{-1}\sin\theta\sin\alpha\sin\beta_{|\mathcal{P}_0}\,, \tag{12}$$
$$\eta = \Delta^{-1}(r^2 + a^2 - a\xi)^2 - \Sigma E^{-2}\cos^2\alpha - \xi^2 + 2a\xi - a^2{}_{|\mathcal{P}_0} \tag{13}$$

with $EA^{1/2} = \Sigma^{1/2}\Delta^{1/2} + 2ar\Sigma^{-1/2}\sin\theta\,\sin\alpha\,\sin\beta$. Finally, time coordinate can be integrated in the form

$$t = \int_{t_0}^{t} \frac{A(r,\theta) - 2ar\xi}{\Sigma(r,\theta)\,\Delta(r)}\,d\tau. \tag{14}$$

To show exemplary solutions of the above-given equations and to illustrate the main effects of General Relativity, we plot several model light curves of an orbiting spot in Fig. 1. The main parameters are the radial position of the center of the spot, view angle of a distant observer, and the Kerr parameter of the black hole.[21–23] One can distinguish two local maxima that dominate the light curve variation over the revolution of the spot: (i) the Doppler boosting peak near the phase $\approx 0.7$ (on the approaching side of the trajectory with respect to the observer, with a certain time delay due to light-travel time), and (ii) the lensing peak near the phase 0.5 (due to light bending at the point of upper conjunction of the trajectory). Only one of the peaks may appear in some cases; the occurrence and the relative height of the two peaks depend on the model parameters. For spots on a close orbit around the black hole, the light rays are bent to the extent that the Doppler-peak follows immediately after the lensing peak, whereas for larger orbits the two peaks can be a quarter of an orbit apart from each other. We propose that the changing profile can be used to constrain the parameters of the system; in particular, this can allow us to determine the parameters of the central black hole.[14]

Solving the above-given equations usually requires to perform several steps numerically. Alternatively, let us mention that a number of semi-analytical approximations have been formulated that allow us to examine selected aspects (e.g. extremal values of the redshift function from an orbiting spot).[24–26] These can provide simple and practical estimates that are useful in analyzing the redshifted narrow lines, however, the approximation approaches assume additional limitations that reduce the accuracy.

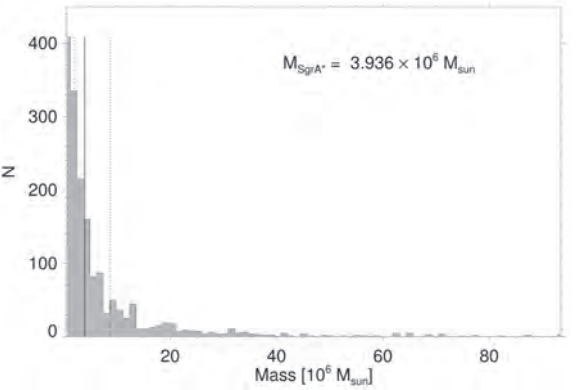

Fig. 2. Histogram of the predicted mass of Sgr A* supermassive black hole derived from a combination of the four flares taken into account. The most likely mass predicted by the method is the median value indicated by the solid vertical line; figure from Karssen et al. 2017.[14]

## 3. The Method and Results

Karssen et al. (2017) studied the light curves of the four bright flares of Sagittarius A* (Sgr A*) in the center of the Milky Way. They allowed the mass of the black to vary as a free parameter and employed the model profiles to fit the most likely value. The flare time-scale in periods is matched with the actual duration of the observed flare in physical units, which provides a way to constrain the black hole mass. The quality and the volume of data for Sgr A* SMBH is the best, however, the same approach can be employed also with other bright objects. In particular, the method has been tested with the Seyfert I galaxy RE J1034+396.[14]

The simulated light curves are normalized to the maximum flux of the light curve, which is set to be identical to the observed light curve. To conduct a time efficient fit of the models to the data, we introduce a time shift, a flux density scaling factor and a flux density offset. For each light curve the ratio is considered between the number of data points of the light curve which belong to the flaring period (defined by the requirement to on the flux to exceed 30 per cent of the maximum value) and the number of data points of the quiescent state. The main features of the flares are contained in the upper two-thirds of the flares. Every simulated light curve ratio is then compared to an observed one; quiescent state data points are removed from or added to the simulated data until the ratio is comparable.

By the fitting process the theoretical light curves are lined up with the observed ones and the conversion factor is determined between geometrized time units of a particular model and the physical time-scale of the observation. This relation depends on the mass of the black hole. By gauging the intrinsic clock of the black hole in its gravitational units to the clocks of the observations in seconds, the mass of the black hole can be estimated. Each fit of a particular simulated light curve to a particular observed flare then results in an estimate for $M$. The simulated data is

multiplied by a factor because in general the best-fit shape of the light curves does not depend on the initial normalization we inferred earlier. In Fig. 2 we show the resulting mass predicted from a combination of the four brightest Sgr A* flares by; the y-axis of the diagram represents the number of model results that have predicted the particular mass value. A peak in this diagram occurs where the most models predicting the corresponding value in the particular mass bin find the minimum of best-fit statistics. Let us note that the resulting distributions are not normal distributions, hence we use the medians as a measure for the most probable mass, as indicated by the vertical solid line in the graph.

## 4. Conclusions

The null geodesics were obtained by solving numerically the equations governing the photon propagation in Kerr spacetime. In this initial work we have not included additional complexities due to the intrinsic variation (decay) of the flares; such a generalization is postponed for a future study, however, the necessary methodology has been already developed; cf. the right panel in Fig. 1, where an exponentially fading signal of a tidally sheared spot has been studied.

We have outlined a method based on a comparison between the simulations with the bright X-ray flares from Sgr A*, which gives an estimate on the mass of the black hole. Let us emphasize that the result does not depend on the uncertainties about the object distance, which otherwise complicates approaches to the mass estimation by different methods. On the other hand, the hereby described method has other underlying assumptions and it can be applied only if the light curves of the flare events are dominated by the effects of relativistic motion of the source orbiting the black hole. This may be adequate for a limited sub-sample of targets; we have argued that the bright flares belong within the suitable category. For further details, see Karssen et al. (2017).[14]

The quintessence is one of the several candidates which represents the dark energy responsible for the acceleration of the universe. The quintessence is described by a canonical scalar field minimally coupled to gravity. We study the timelike geodesic congruences in the background of a rotating black hole spacetime surrounded by quintessence in equatorial plane. The effect of equation of state (EOS) parameter for quintessence and the normalization factor on geodesics is investigated in detail in view of the structure of possible orbits, including the innermost stable circular orbits (ISCOs). The structure of photon orbits is also studied for the different values of parameters involved in. The results obtained are also then compared with those of the Kerr black hole spacetime and Schwarzschild black hole spacetime in GR with or without quintessence.

*Keywords*: Geodesics, Black Holes, Dark Energy, Quintessence, ISCO.

## 1. Introduction

The Black Holes (BHs) are one of the numerous consequences of General Relativity (GR)[1]. A number of BH spacetimes emerge as the solution of Einstein field equations in GR and other alternative theories of gravity. The study of geodesic motion in the background of a given spacetime is one of the most an elegant ways to describe the underlying geometry of that particular spacetime[2]. Further, different observations from supernovae (Type Ia), cosmic microwave background radiation (CMBR), Baryon acoustic oscillations (BAO) and the Hubble measurements strongly advocates for an accelerated expansion of our universe which is believed to be due to the presence of some mysterious form of energy known as dark energy having a large negative pressure[2–4]. There are several candidates to represent the dark energy in our universe and *quintessence* is one among them. It would therefore be quite interesting and important to study the geodesic motion in the background of a rotating BH spacetime surrounded by quintessence to see the effect of dark energy, if any, on the universe locally.

## 2. The Effective Potential

The metric of a Rotating BH surrounded with quintessences is given below[2,5,6],

$$ds^2 = \frac{\left(\Delta - a^2 sin^2\theta\right) dt^2}{\Sigma} - \frac{\Sigma dr^2}{\Delta} + 2asin^2\theta \left[1 - \frac{\Delta - a^2 sin^2\theta}{\Sigma}\right] dtd\phi - \Sigma d\theta^2 - sin^2\theta \left[\Sigma + a^2 sin^2\theta \left(2 - \frac{\Delta - a^2 sin^2\theta}{\Sigma}\right)\right] d\phi^2, \quad (1)$$

with, $\Delta = r^2 + a^2 - 2Mr - \frac{\alpha}{\Sigma^{\frac{3\omega-1}{2}}}$ and $\Sigma = r^2 + a^2 cos^2\theta$ where $\alpha$ is normalization factor and $\omega$ is quintessential EOS parameter. For equatorial plane (i.e. $\theta = \frac{\pi}{2}$), the Lagrangian corresponding to the spacetime given by (1) can be written as[1],

$$2\mathcal{L} = (1 - f_r)\,\dot{t}^2 - \left(\frac{r^2}{r^2(1 - f_r) + a^2}\right)\dot{r}^2 + (2af_r)\,\dot{t}\dot{\phi} - \left(r^2 + a^2(1 + f_r)\right)\dot{\phi}^2, \quad (2)$$

where, $f_r = \frac{2M}{r} + \frac{\alpha}{r^{3\omega+1}}$. The generalized momentum may thus be written as,

$$\dot{t} = \frac{E\left(r^2 + a^2(1 + f_r)\right) - af_rL}{r^2(1 - f_r) + a^2}, \quad (3)$$

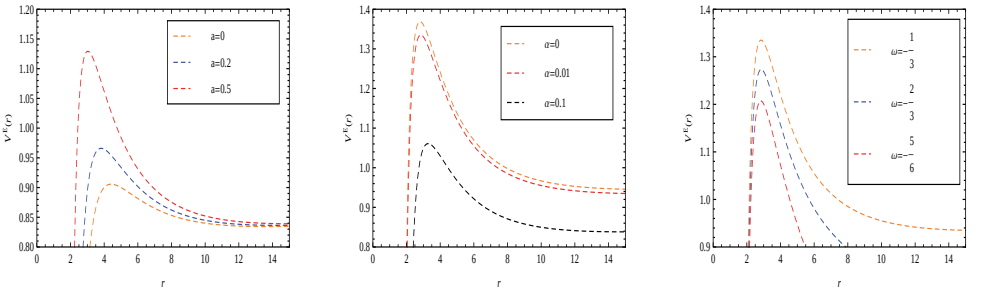
$$\dot{\phi} = \frac{af_rE + (1 - f_r)L}{r^2(1 - f_r) + a^2}, \quad (4)$$

$$\dot{r}^2 = E^2 + \frac{2M(L - aE)^2}{r^3} - \frac{\left(L^2 - a^2E^2\right)}{r^2} - \frac{r^2 + a^2 - 2Mr}{r^2} + f_r\frac{(L - aE)^2}{r^2} + f_r. \quad (5)$$

Here $E$ is the total energy per unit rest mass of test particle at infinity while $L$ is the angular momentum per unit rest mass of test particle. The effective potential $(V)$ with $\dot{r}^2 = E^2 - V^2$ then reads as[7–9],

$$V = \frac{\beta + \sqrt{\beta^2 - \delta\gamma}}{\delta}, \quad (6)$$

where, $\beta = \frac{La}{r^2}f_r$, $\delta = \frac{r^2 + a^2(1 + f_r)}{r^2}$ and $\gamma = \frac{L^2}{r^2}(f_r - 1) - 1 - \frac{a^2}{r^2} + f_r$.



(a) (b) (c)

Fig. 1. Effective Potential with M = 1, $L = \sqrt{20}$ for (a) $\alpha = 0.1$ $\omega = -1/3$ (b) a = 0.4 and $\omega = -1/3$ (c) $\alpha = 0.1$ and a = 0.4.

## 3. The ISCO Parameters

With $r = \frac{1}{u}, L - aE = x$ and the condition for Innermost Stable Circular Orbit (ISCO) $V = 0, V' = 0$ respectively further leads to [1,5,7,10–13] ,

$$E^2 + 2Mu^3x^2 - (x^2 + 2Eax)u^2 - (a^2u^2 - 2Mu + 1) + x^2u^2f_u + f_u = 0, \quad (7)$$

and

$$3Mx^2u^3 - (a^2u^2 - Mu) - (x^2 + 2Eax)u^2 + x^2u^2f_u + \left(x^2u^2 + 1\right)\left(\frac{3\omega + 1}{2}\right)f_u = 0, \quad (8)$$

here, $f_u = \alpha u^{3w+1}$. Solving equations (7) and (8) simultaneously,

$$x = -\frac{au \pm \sqrt{Mu + \left(\frac{3\omega + 1}{2}\right)f_u}}{uY}, \quad (9)$$

$$E = \frac{1 - 2Mu \mp au\sqrt{Mu + \left(\frac{3\omega + 1}{2}\right)f_u} - f_u}{Y}, \quad (10)$$

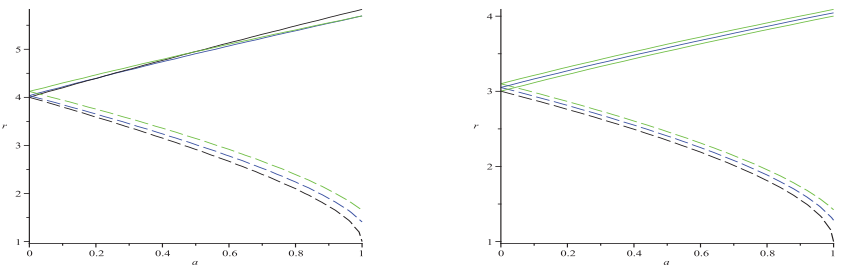
$$L = \frac{\mp\left(a^2u^2 + 1\right)\sqrt{Mu + \frac{(3\omega + 1)}{2}f_u} - 2Mau^2 - auf_u}{uY}, \quad (11)$$

with,

$$Y^2 = 1 - 3Mu - \left(\frac{3\omega + 3}{2}\right)f_u \mp 2au\sqrt{Mu + \left(\frac{3\omega + 1}{2}\right)f_u}, \quad (12)$$

where $\mp$ signature correspond to direct (i.e. co-rotating with $L > 0$) and retrograde (i.e. counter-rotating with $L < 0$) orbits respectively. The photon orbit is found to only exist if the denominator of equation (10) is real i.e.

$$1 - 3Mu - \left(\frac{3\omega + 3}{2}\right) f_u = \pm 2au\sqrt{Mu + \left(\frac{3\omega + 1}{2}\right) f_u}. \tag{13}$$



(a) (b)

Fig. 2. Variation of (a) Radii of marginally bound orbits (b) Radii of photon orbits. Here, black, blue and green colors correspond to $\alpha = 0$, 0.05, 0.1 at $\omega = -1/3$ as a function of specific angular momentum. Here, dash and solid lines represent direct and retrograde orbits respectively.

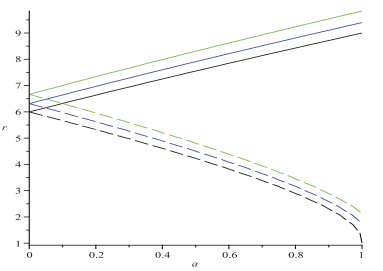


Fig. 3. Marginally stable orbit M = 1 for $\omega = -1/3$ here black, blue and green colors correspond to the cases $\alpha = 0$, $\alpha = 0.01$ and $\alpha$ =0.1 respectively. Here, dash and solid lines represent direct and retrograde orbit respectively.

Similarly for a marginally bound (MB) orbit, one can examine the variation of $r$ with $a$ and the condition for MB orbits just read as $E = \mu$. However, bound orbits are not necessarily stable and for the stability, we have the condition $V'' = 0$ [10,14,15]. For $\omega = -1/3$, the condition for marginally stable (MS) orbit is reduced as below,

$$3a^2 + 6Mr - r^2 \pm 8a\sqrt{Mr} + \alpha r^2 \leq 0. \tag{14}$$

The effective potential, ISCO parameters and radius of circular orbits (photon orbit, marginally bound orbit and ISCO orbit) are also visually presented (see figures for different sets of parameters involved in.

## 4. Conclusions

We have investigated the geodesic motion and structure of orbits in particular ISCO, MB and Photon orbits in the background of a rotating BH in presence of quintessence which is spherically symmetric solution of Einstein field equations with the quintessence as a source of energy-momentum. Some of the key results obtained are summarized below.

(i) The extrema of effective potential lies at lower value as compared to Kerr BH in GR when normalization factor ($\alpha$) increases and EOS parameter ($\omega$) for quintessence decreases which therefore indicates that unstable orbits can even be found at lower energy values.
(ii) The radius of direct photon orbit, MB orbit and MS orbit increases as normalization factor ($\alpha$) increases for the case of a non rotating BH.
(iii) The radius of photon orbit, MB orbit, and MS orbit are larger as compared to the Kerr BH when normalization factor increases, EOS parameter $\omega = -1/3$ and for finite value of spin parameter 'a' which in fact lies between 0 and M.
(iv) The direct photon orbit, direct MB orbit and direct MS orbit coincide at $a = M$ which is the same as for Kerr BH in GR which is basically due to the subtle nature of Boyer-Lindquist coordinates at $r = M$ for $a = M$.
(v) The radius of retrograde orbit for photons and retrograde MB orbits increases as normalization factor increases, for a fixed value of EOS parameter while spin parameter is small.
(vi) The radius of retrograde MS orbit increases with the increase in normalization factor at a particular value of EOS parameter i.e. $\omega = -1/3$.

In view of the current observations related to dark energy, the value of EOS parameter $\omega$ tends to $-1$ and similar investigations for the value $\omega = -1$ along with $\omega = -2/3$ are currently underway.

*Keywords*: Collisional Penrose process; energy extraction; spinning test particle.

## 1. Introduction

It is known that the center of mass energy can take arbitrarily large value if a collision occurs near the event horizon of an extreme rotating black hole[1]. However, it does not mean that an ejected particle will have very high energy at infinity because of red-shift. Hence, how large energy we will observe at infinity has been evaluated for various situations[2]. Most of those results were obtained for a point test particle. But a matter around a black hole normally has rotation. Since the equation of motion of a spinning particle is totally different from the geodesic equation, and the effect of spin is nontrivial, it is important to study the efficiency of the extracted energy ($\eta =$ (extracted energy)/(input energy)) in the collision of spinning particles. We focus on the collisional Penrose process of spinning particles near the horizon of an extreme Kerr black hole and evaluate the maximal value of the energy efficiency for various processes.

## 2. The orbit of a spinning particle

In the Kerr spacetime, there are two Killing vectors, and then we have two conserved quantities; the particle energy $E$ and the particle total angular momentum $J$. For simplicity, we assume that a spinning particle is orbiting on the equatorial plane ($\theta = \pi/2$) and the direction of a particle spin is parallel to the rotation of a black hole. The spin parameter $s$ is positive when a particle is parallelly spinning to the rotation of the black hole, while $s$ is negative when it is counter-rotating.

By this setting, we obtain the specific momentum $u^{(a)} = p^{(a)}/\mu$, where $p^{(a)}$ is the momentum and $\mu$ is the particle mass, as

$$u^{(0)} = \frac{\left[(r^3 + a(a+s)r + aMs)E - (ar + Ms)J\right]}{\mu r^2\sqrt{\Delta}\left(1 - \frac{Ms^2}{r^3}\right)}, \tag{1}$$

$$u^{(3)} = \frac{[J - (a+s)E]}{\mu r\left(1 - \frac{Ms^2}{r^3}\right)}, \tag{2}$$

where $M$ and $a$ are the black hole mass and its specific angular momentum, respectively. The suffix $(a)$ denotes the tetrad components. From the definition of the particle mass, we obtain the radial component $u^{(1)}$ as

$$u^{(1)} = \sigma\sqrt{(u^{(0)})^2 - (u^{(3)})^2 - 1}, \tag{3}$$

where $\sigma = \pm 1$ denotes the direction of the radial motion of the particle, i.e., a particle is moving outward for $\sigma = +1$ while it does inward for $\sigma = -1$.

Before the discussion of the collisional Penrose process, we should note a few important points as follows:
(1) Since the four-velocity of a spinning particle $v^{(a)} = dx^{(a)}/d\tau$ is not always parallel to the four-momentum $u^{(a)}$, we have to impose the timelike condition $v^{(a)}v_{(a)} < 0$ in our analysis.
(2) In order for a particle to reach the horizon, the condition $J_- \leq J \leq J_{cr}$ must be satisfied. Here, $J_{cr}(> 0)$ and $J_-(< 0)$ are the maximum and minimum values of the particle angular momentum, respectively. This condition is obtained from $(u^{(1)})^2 > 0$ for any radius of $r \geq r_H = M$.
(3) To obtain arbitrarily large center-of-mass energy, the collision must take a place near the horizon and one of collisional particles must have the critical angular momentum $J_{cr} = 2EM$, and the other particle must have sub-critical angular momentum $(J_- <)J < J_{cr}$.

## 3. Collisional Penrose process

We assume that two particles (the particle 1 [critical, $J_1 = 2E_1M$] and the particle 2 [sub-critical, $J_2 < J_{cr}$]) plunge from infinity, and collide at the point $r_c = r_H/(1-\epsilon)$ $(0 < \epsilon \ll 1)$, where $r_H = M$ is the horizon radius. After collision, the particle 3 (= the particle 1) is coming back to infinity, while the particle 4 (= the particle 2) will fall into a black hole.

At the collision, we have the following onservation laws:

$$E_1 + E_2 = E_3 + E_4, \quad J_1 + J_2 = J_3 + J_4, \tag{4}$$

$$s_1 + s_2 = s_3 + s_4, \quad p_1^{(1)} + p_2^{(1)} = p_3^{(1)} + p_4^{(1)}. \tag{5}$$

From these conservation laws, we find that particle 3 must have near-critical angular momentum $(J_3 = 2E_3M + O(\epsilon))$. We consider only the head-on collision with $\sigma_1 = \sigma_3 = +1$ $\sigma_2 = \sigma_4 = -1$, $s_2 = s_4$, and $s_1 = s_3$, because it gives the maximum efficiency.

We expand the above conservation equations in terms of $\epsilon$ and solve the energies $E_2$ and $E_3$ by use of the expansion coefficients. We then evaluate the energy efficiency $\eta = E_3/(E_1 + E_2)$. The detailed analysis is given in Ref. 4.

In Table 1, we show the maximal efficiencies and the input and output energies for the following three cases : [1] Collision of two massive particles, [2] "Compton" scattering (the particle 1: massless, the particle 2: massive), and [3] "Inverse Compton" scattering (the particle 1: massive, the particle 2: massless).

In the case of the collision of two massive particles, the maximal efficiency $\eta$ is about 15.01, while it is about 26.85 for the case of the "Compton" scattering in the limit of $E_1 \to \infty$. The maximal efficiency becomes the largest for the "Compton" scattering, which in fact is the same as the case for without spin. Compared with the spinless case, these maximal efficiencies become twice larger than the spinless case. We then conclude that a spin plays an important role in the context of energy extraction. Note that the efficiency does not change significantly in the case of the "inverse Compton" scattering because the absorbed massless particle is spinless and the escaped massive particle with large energy cannot have a large spin.

Table 1. The maximal efficiencies and energies for three cases of collisions of particles plunging from infinity. We include the result for the nonspinning case (Ref. 3) for comparison. The maximal efficiencies and maximal energies are enhanced when the spin effect is taken into account.

| collisional process | spin $(s_1, s_2)$ | input energy $(E_1, E_2)$ | output energy $(E_3)$ | maximal efficiency |
|---|---|---|---|---|
| Collision of two massive particles | non-spinning | $(\mu, \mu)$ | $12.66\mu$ | 6.328 |
| | $(0.01379\mu M, -0.2709\mu M)$ | | $30.02\mu$ | 15.01 |
| "Compton" scattering | non-spinning | $(+\infty, \mu)$ | $+\infty$ | 13.93 |
| | $(0, -0.2709\mu M)$ | | $+\infty$ | 26.85 |
| "Inverse Compton" scattering | non-spinning | $(\mu, 0)$ | $12.66\mu$ | 12.66 |
| | $(0.02679\mu M, 0)$ | | $15.64\mu$ | 15.64 |

The present setting may be very unlikely in more realistic astrophysical situations. Since there are many particles in an accretion disc around a black hole, it may be more natural for a particle plunging from infinity will collide particles in the innermost stable circular orbit (ISCO). The result in this case will be published elsewhere[5]. The ansatz of an extreme black hole is also not natural. The study for a non-extreme black hole is in progress.

# Bound orbit domains in the phase space of the Kerr geometry

Prerna Rana[1,†] and A. Mangalam[1,‡]

[1] *Indian Institute of Astrophysics, Sarjapur Road, 2nd Block Koramangala, Bangalore, 560034, India*

*E-mail: prernarana@iiap.res.in*[†], *mangalam@iiap.res.in*[‡]

We derive the conditions for a non-equatorial eccentric bound orbit to exist around a Kerr black hole in two-parameter spaces: the energy, angular momentum of the test particle, spin of the black hole, and Carter's constant space ($E$, $L$, $a$, $Q$), and eccentricity, inverse-latus rectum space ($e$, $\mu$, $a$, $Q$). These conditions distribute various kinds of bound orbits in different regions of the ($E$, $L$) and ($e$, $\mu$) planes, depending on which pair of roots of the effective potential forms a bound orbit. We provide a prescription to select these parameters for bound orbits, which are useful inputs to study bound trajectory evolution in various astrophysical applications like simulations of gravitational wave emission from extreme-mass ratio inspirals, relativistic precession around black holes, and the study of gyroscope precession as a test of general relativity.

*Keywords*: Classical black holes; Relativity and Gravitation; Bound orbit trajectories.

## 1. Introduction

Bound trajectories in the Kerr geometry have been studied extensively, and some of the important results are discussed in a pioneering work by S. Chandrasekhar (Ref. 1). The general trajectory in the Kerr spacetime was first expressed in terms of quadratures in Ref. 2, while Ref. 3 discusses the essential conditions for bound spherical geodesics, and also horizon-skimming orbits. The quadrature form of the fundamental orbital frequencies for a general eccentric trajectory was first presented in Ref. 4. Later, to decouple the $r$ and $\theta$ motions, a parameter called Mino time, $\lambda$, was introduced in Ref. 5, which was then implemented to calculate a closed-form trajectory solution and orbital frequencies in Ref. 6. Recently, an alternate analytic solution was derived for the general bound and separatrix trajectories in a compact form using the transformation $1/r = \mu\,(1 + e\cos\chi)$ in Refs. (7, 8). The inputs to these integrals for calculating the trajectories are the constants of motion $E$, $L$, $Q$, and spin of the black hole, $a$. These parameters can also be translated to ($e$, $\mu$, $a$, $Q$) space, as derived in Refs. (7, 8). It is essential to find the canonical bound orbit conditions in these two parameter spaces to calculate the trajectory evolution.

We express the bound orbit conditions on ($E$, $L$, $a$, $Q$) parameters for the non-equatorial eccentric bound orbits around a Kerr black hole, and then find the analog of these conditions in the ($e$, $\mu$, $a$, $Q$) space. The regions of different bound orbits were graphically separated in the ($E$, $L$) plane in Ref. 9, according to the pair of roots of the effective potential spanning the radius of the bound orbit. It is essential to find the canonical bound orbit conditions in these two parameter spaces.

## 2. Conditions for bound trajectories around Kerr black hole

Now, we consider the radial motion of the bound trajectory which is described by the equation (Refs. 2, 4, 7, 8)

$$\frac{\left(E^2-1\right)}{2}=\frac{\rho^4}{2r^4}\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2-\frac{1}{r}+\frac{L^2-a^2\left(E^2-1\right)+Q}{2r^2}-\frac{\left(L-aE\right)^2+Q}{r^3}+\frac{a^2Q}{2r^4}, \quad (1)$$

to derive the conditions in $(E, L, a, Q)$ and $(e, \mu, a, Q)$ spaces for various bound orbit regions previously discussed in Ref. 9, where $\rho^2 = r^2 + a^2\cos^2\theta$, $\tau$ is the proper time, and $a = J/M^2$ which have their usual meanings; we use geometrical units throughout.

### 2.1. *Dynamical parameter space $(E, L, a, Q)$*

Next, we solve the quartic equation, Eq. (1), to find the four roots (that include the turning points of the bound orbit) of $\mathrm{d}r/\mathrm{d}\tau = 0$, which can be expressed as

$$r^4+\frac{2}{\left(E^2-1\right)}r^3+\frac{\left(a^2E^2-L^2-Q-a^2\right)}{\left(E^2-1\right)}r^2+\frac{2\left(x^2+Q\right)}{\left(E^2-1\right)}r-\frac{a^2Q}{\left(E^2-1\right)}=0, \quad (2)$$

where $x = L - aE$. Applying Ferrari's method (Ref. 10) to the above equation gives

$$r_1=\frac{1}{2\left(1-E^2\right)}+\frac{\sqrt{2z}}{2}+\frac{1}{2}\sqrt{D_1}, \quad (3a)$$

$$r_2=\frac{1}{2\left(1-E^2\right)}+\frac{\sqrt{2z}}{2}-\frac{1}{2}\sqrt{D_1}, \quad (3b)$$

$$r_3=\frac{1}{2\left(1-E^2\right)}-\frac{\sqrt{2z}}{2}+\frac{1}{2}\sqrt{D_2}, \quad (3c)$$

$$r_4=\frac{1}{2\left(1-E^2\right)}-\frac{\sqrt{2z}}{2}-\frac{1}{2}\sqrt{D_2}, \quad (3d)$$

where $r_1 > r_2 > r_3 > r_4$, and

$$D_1=-2G-2z-\frac{\sqrt{2}H}{\sqrt{z}}, \quad D_2=-2G-2z+\frac{\sqrt{2}H}{\sqrt{z}}, \quad (3e)$$

$$z=U+V-\frac{G}{3}, \quad U=\left(I+\sqrt{I^2+J^3}\right)^{1/3}, \quad V=\left(I-\sqrt{I^2+J^3}\right)^{1/3}, \quad (3f)$$

$$I=\frac{\left(2G^3+27H^2-72GT\right)}{432}, \quad J=-\frac{\left(G^2+12T\right)}{36}, \quad (3g)$$

$$G=\frac{\left[L^2-a^2\left(E^2-1\right)+Q\right]}{\left(1-E^2\right)}-\frac{3}{2\left(1-E^2\right)^2}, \quad (3h)$$

$$H=\frac{\left[L^2-a^2\left(E^2-1\right)+Q\right]}{\left(1-E^2\right)^2}-\frac{2\left(x^2+Q\right)}{\left(1-E^2\right)}-\frac{1}{\left(1-E^2\right)^3}, \quad (3i)$$

$$T=\frac{\left[L^2-a^2\left(E^2-1\right)+Q\right]}{4\left(1-E^2\right)^3}-\frac{3}{16\left(1-E^2\right)^4}-\frac{\left(x^2+Q\right)}{\left(1-E^2\right)^2}+\frac{a^2Q}{\left(1-E^2\right)}. \quad (3j)$$

The bound orbit regions were graphically classified in the $(E, L)$ plane in Ref. 9 on the basis of which pair of roots of quartic equation, Eq. (2), contains the bound orbit. We algebraically classify these regions using the expressions of roots, Eqs. (3a-3d), in the $(E, L, a, Q)$ parameter space as follows (Ref. 11):

(1) **Region $\Delta$**: Bound orbits exist between $(r_1, r_2)$, and between $(r_3, r_4)$: $D_1 > 0$, $D_2 > 0$, and $E < 1$.
(2) **Region $\varsigma$**: Bound orbit either exists between $r_1$ and $r_2$ if $(r_3, r_4)$ forms a complex pair i.e. $D_2 < 0$ or exists between $r_3$ and $r_4$ if $(r_1, r_2)$ forms a complex pair i.e. $D_1 < 0$: $(D_1 \cdot D_2) < 0$. This region exists for both $E < 1$ and $E > 1$.
(3) **Region $\Lambda$**: Bound orbit exists between $r_2$ and $r_3$ with $r_4 < r_3$ and $r_1 > r_2$: $D_1 > 0$, $D_2 > 0$, and $E > 1$.

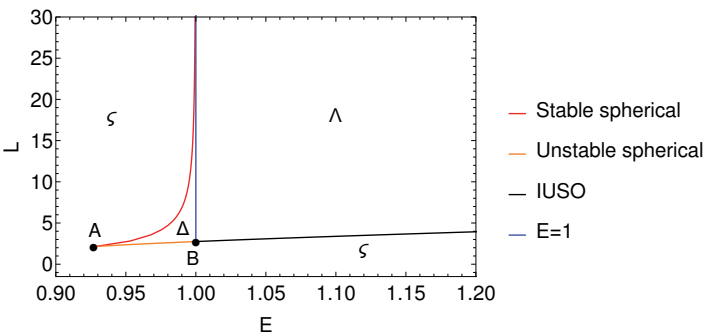

Fig. 1. The bound orbit regions $\Delta$, $\varsigma$, and $\Lambda$ are shown in the $(E, L)$ plane for $a = 0.5$, $Q = 5$, where the region $\Delta$ is bounded by stable and unstable (also corresponds to the separatrices) spherical orbits, and $E = 1$; the $\Lambda$ region is bounded by the inner unstable spherical orbits (IUSO). Points A and B represent the innermost stable spherical orbit (ISSO) and marginally stable spherical orbit (MBSO) respectively.

The classification of these regions in the $(E, L)$ plane is shown in Fig. 1. The bounding curves of these regions represent spherical orbits. The eccentricity and inverse latus-rectum of the bound orbit are defined as (Ref. 11)

$$e_{ij} = \frac{r_i - r_j}{r_i + r_j}, \quad \mu_{ij} = \frac{r_i + r_j}{2 r_i r_j}, \tag{4}$$

where we see that $\{e_{ij}, \mu_{ij}\}$ can be expressed in terms of $(E, L, a, Q)$ through roots, Eqs. (3). The details of derivations presented here will be provided in Ref. 11.

### 2.2. *Conic parameter space $(e, \mu, a, Q)$*

According to the definitions given for regions $\Delta$, $\varsigma$, and $\Lambda$ in §2.1, the convention adopted for $\{e, \mu\}$ is as follows: Region $\Delta$ given by $\{e_{12}, \mu_{12}\}$; Region $\Lambda$ given by $\{e_{23}, \mu_{23}\}$; Region $\varsigma$ given by $\{e_{12}, \mu_{12}\}$ or $\{e_{34}, \mu_{34}\}$, depending on which pair is

real. Now, we derive the defining conditions for $\Delta$, $\varsigma$, and $\Lambda$ regions in the ($e$, $\mu$, $a$, $Q$) space:

(i) **Region $\Delta$**: The defining conditions for this region was derived using the necessary constraints on the parameters of the Elliptic integrals involved in the trajectory solutions (Refs. 7, 8), which are

$$\left[\mu^3 a^2 Q\left(1+e\right)^2+\mu^2\left(\mu a^2 Q-x^2-Q\right)\left(3-e\right)\left(1+e\right)+1\right]>0, \tag{5a}$$

$$\left[\mu\left(1+e\right)\left(1+\sqrt{1-a^2}\right)\right]<1, \tag{5b}$$

$$E(e,\mu,a,Q)<1. \tag{5c}$$

(ii) **Region $\varsigma$**: The region $\varsigma$ is defined by two complex roots of $r$ or $u=1/r$ with a bound orbit existing between the two remaining real roots. We can write Eq. (2) for region $\varsigma$ in the form (Ref. 11)

$$\left[u-\mu\left(1-e\right)\right]\cdot\left[u-\mu\left(1+e\right)\right]\cdot\left(u^2+Au+B\right)=0, \tag{6a}$$

where bound orbit exists between $\mu\left(1+e\right)$ and $\mu\left(1-e\right)$ which is a real pair of the roots, and

$$A=-2\left[\frac{x^2+Q}{a^2Q}-\mu\right],\quad B=\frac{1-E^2}{\mu^2a^2Q\left(1-e^2\right)}. \tag{6b}$$

Hence, the remaining factor $\left(u^2+Au+B\right)$ of Eq. (6a) should have complex roots for the $\varsigma$ region, which reduces to the condition (Ref. 11)

$$\left\{\left(Q+x^2\right)^2\mu+a^4e^2Q^2\mu^3-a^2Q\left[1+\left(1+e^2\right)\left(Q+x^2\right)\mu^2\right]\right\}<0, \tag{7}$$

where we have substituted for the factor $(1-E^2)$ in terms of ($e$, $\mu$, $x$) using relations previously derived in Refs. (7, 8).

(iii) **Region $\Lambda$**: The region $\Lambda$ is defined by the condition that a bound orbit exists between $r_2$ and $r_3$ (or $u_2$ and $u_3$) with $r_1>r_2$ (or $u_1<u_2$) and $r_3>r_4$ (or $u_3<u_4$). We can express Eq. (2) for this region as

$$\left[u-\mu\left(1-e\right)\right]\cdot\left[u-\mu\left(1+e\right)\right]\cdot\left(u^2+Au+B\right)=0. \tag{8}$$

The remaining roots $u_1$ and $u_4$ can be derived from the factor $\left(u^2+Au+B\right)$, which can be substituted into the conditions $u_1<u_2$ and $u_3<u_4$ to obtain

$$\left[\mu^3 a^2 Q\left(1-e\right)^2+\mu^2\left(\mu a^2 Q-x^2-Q\right)\left(3+e\right)\left(1-e\right)+1\right]<0, \tag{9a}$$

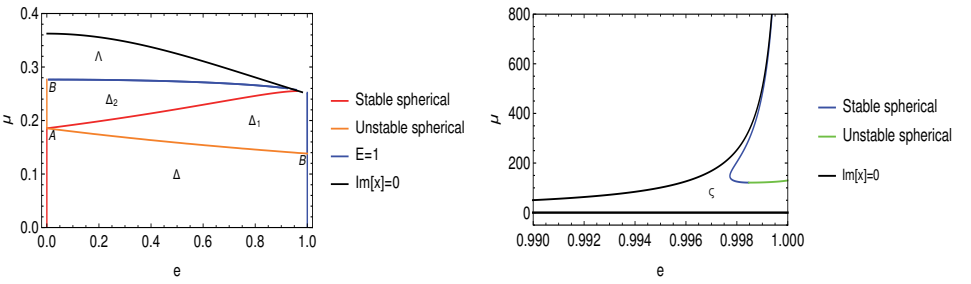
and

$$\left[\mu^3 a^2 Q\left(1+e\right)^2+\mu^2\left(\mu a^2 Q-x^2-Q\right)\left(3-e\right)\left(1+e\right)+1\right]<0, \tag{9b}$$

respectively. Next, as we see from Fig. 1, that the region $\Lambda$ corresponds to the orbits with $E>1$; this implies

$$\left[\mu^2\left(1-e^2\right)\left(\mu a^2 Q-Q-x^2\right)+1\right]<0. \tag{9c}$$

In effect, Eqs. (9a, 9b, 9c) together define $\Lambda$ region the ($e$, $\mu$) plane, and Fig. 2 shows all these regions in the ($e$, $\mu$) plane. The details of derivations of the above conditions will be provided in Ref. 11.



(a) (b)

Fig. 2. The bound orbit regions (a) $\Delta$ and $\Lambda$, and (b) $\varsigma$ in the $(e,\ \mu)$ plane for $(a = 0.2,\ Q = 2)$ are shown along with their defining bounding curves and end points. The regions $\Delta_1$ and $\Delta_2$ are replicas of region $\Delta$ when $(e_{13},\ \mu_{13})$ and $(e_{23},\ \mu_{23})$ are chosen respectively.

## 3. A prescription for selecting bound orbits

We present the scaling formulae specifying the parameters $(E,\ L)$ and $(e,\ \mu)$ in terms of the variables $(x_1,\ y_1)$ and $(x_2,\ y_2)$, where $x_i,\ y_i \in [0, 1]$, $i = 1, 2$, can be chosen to produce valid combinations of the parameters $(E,\ L)$ and $(e,\ \mu)$ for bound orbits. The formula for selecting $E$ for bound orbits written in terms of the variable $x_1$, $a$, and $Q$ for region $\Delta$ in Fig. 1 is (Ref. 11)

$$E\left(x_1, a, Q\right) = E_Z\left(a, Q\right) + x_1\left[E_Y\left(a, Q\right) - E_Z\left(a, Q\right)\right], \tag{10}$$

where $E_Z\left(a, Q\right)$ and $E_Y\left(a, Q\right)$ are the spherical orbit energies at ISSO and MBSO respectively, and where $Z(a, Q)$ and $Y(a, Q)$ are radii of ISSO and MBSO respectively (Eqs. (19), (20) in Refs. 7, 8).

Now, for a fixed $x_1$ and $a$, $y_1 \in [0, 1]$ defines the range of $L\left(r, a, Q\right)$ for bound orbits. The formula for selecting allowed $L$ ($\Delta$ in Fig. 1) can be written as (Ref. 11)

$$\frac{1}{L\left(x_1, y_1, a, Q\right)} = \frac{1}{L_-\left(x_1, a, Q\right)} - y_1\left[\frac{1}{L_-\left(x_1, a, Q\right)} - \frac{1}{L_+\left(x_1, a, Q\right)}\right], \tag{11a}$$

where $L_+\left(x_1, a, Q\right)$ and $L_-\left(x_1, a, Q\right)$ are end points of the $\Delta$ region in Fig. 1 given by (Ref. 11)

$$L_+\left(x_1, a, Q\right) = x(r_v\left(x_1, a, Q\right), a, Q) + a \cdot E(r_v\left(x_1, a, Q\right), a, Q), \tag{11b}$$

$$L_-\left(x_1, a, Q\right) = x(r_u\left(x_1, a, Q\right), a, Q) + a \cdot E(r_u\left(x_1, a, Q\right), a, Q), \tag{11c}$$

where $x\left(r_s, a, Q\right)$ and $E\left(r_s, a, Q\right)$ can be calculated using the spherical orbit formulae (derived in Refs. 7, 8) and where $r_v\left(x_1, a, Q\right)$ and $r_u\left(x_1, a, Q\right)$ are the two roots of $r_s$ in the equation

$$E\left(r_s, a, Q\right) = E_Z\left(a, Q\right) + x_1\left[E_Y\left(a, Q\right) - E_Z\left(a, Q\right)\right]. \tag{12}$$

The radii $r_v\left(x_1, a, Q\right)$ and $r_u\left(x_1, a, Q\right)$ obey $r_v\left(x_1, a, Q\right) > Z(a, Q)$ and $Y\left(a, Q\right) < r_u\left(x_1, a, Q\right) < Z\left(a, Q\right)$.

For the $(e, \mu)$ space, the corresponding formulae for the $\Delta$ region in Fig. 2 are given by

$$e\,(x_2) = \; x_2, \tag{13a}$$

$$\mu\,(y_2, r_x, a, Q) = \; y_2 \cdot \mu_s\,(r_x, a, Q)\,, \tag{13b}$$

where the allowed range of $\mu$ is $0 < \mu < \mu_s\,(r_x, a, Q)$ for a given $x_2$, and $\mu_s\,(r_x, a, Q)$ is the value of $\mu$ at the separatrix [Eq. (25b) in Refs. (7, 8)], and $r_x$ is a root of $r_s$ in the equation $x_2 = e_s\,(r_s, a, Q)$ and $e_s\,(r_s, a, Q)$ is the eccentricity value at the separatrix [Eq. (25a) in Refs. (7, 8)]. The radius $r_x$ lies between $Y\,(a, Q)$ and $Z\,(a, Q)$ for a given $a$ and $Q$. Hence, for a fixed $a$ and $Q$, $x_2$ and $y_2 \in [0, 1]$ which thereby defines the range of $(e, \mu)$.

## 4. Summary and discussion

We presented the algebraic conditions for non-equatorial bound trajectories in the $(E,\ L,\ a,\ Q)$ and $(e,\ \mu,\ a,\ Q)$ spaces and showed how these conditions classify the bound orbits into various regions, $\Delta$, $\varsigma$, and $\Lambda$, in the $(E,\ L)$ plane, which was previously discussed graphically in Ref. 9; see Fig. 1. In this article, we have also shown these bound orbit regions in the $(e,\ \mu)$ plane, Fig. 2, geometrically specified by their bound curves and vertices. For astrophysically relevant orbits, only the region $\Delta$ is applicable. We also provided a useful prescription to select the parameters $(E,\ L)$ and $(e,\ \mu)$ in the $\Delta$ region, which are canonical inputs to the trajectory solutions for studying their evolution in various applications like gravitational wave emission from extreme-mass ratio inspirals, relativistic precession around black holes, and the study of gyroscope precession as a test of general relativity.

# Schwarzschild phase without a black hole

Sandipan Sengupta*

*Department of Physics and Centre for Theoretical Studies,*

**E-mail: sandipan@phy.iitkgp.ac.in*

We present a smooth extension of the Schwarzschild exterior geometry, where the singular interior is superceded by a vacuum phase with vanishing metric determinant. Unlike the Kruskal-Szekeres continuation, this solution to the first order field equations in vacuum has no singularity in the curvature two-form fields, no horizon and no global time. The underlying non-analytic structure provides a distinct geometric realization of 'mass' in classical gravity. We also find that the negative mass Schwarzschild solution does not admit a similar extension within the first order theory. This is consistent with the general expectation that degenerate metric solutions associated with the Hilbert-Palatini Lagrangian formulation should satisfy the energy conditions.

*Keywords*: Curvature singularity, Schwarzschild, Degenerate metric, Naked singularity.

## 1. Introduction

In view of the imposing experimental success of Einstein's theory of general relativity, one could be tempted to accept the invertible metric phase ($\det g_{\mu\nu} \neq 0$) as a self-contained and complete framework in describing the classical dynamics of spacetimes. However, in general, (the first order formulation of) gravity theory is known to exhibit an additional phase based on non-invertible metrics[1–3]. From a general perspective, the Einsteinian theory is nothing more or less than the special phase of first order theory where the metric is invertible everywhere. It then seems natural to ask as to how certain robust features of Einsteinian solutions, such as singularities, get manifested in a more generic solution where both the phases could coexist.

In the spherically symmetric vacuum Einstein theory, the Schwarzschild spacetime happens to be the unique solution. For a positive (negative) mass, its singular interior represents a black hole with a horizon (a naked singularity without a horizon). However, in the presence of both the phases of first order gravity, there is no reason for Birkhoff's uniqueness theorem to be applicable, as it works only under the assumption of the invertibility of metric. Here we provide an explicit realization of such a scenario[4,5]. The solutions discussed are smooth extensions of the Schwarzschild exterior through a noninvertible metric phase, which supercedes the interior of the standard Schwarzschild solution of Einstein equations. These spacetimes are solutions to the first order equations of motion everywhere. The associated field-strength components are manifestly finite everywhere, unlike in the standard Schwarzschild case. Even though it is not possible to construct four dimensional curvature scalars in regions where the metric is degenerate, it is still possible to define effective lower-dimensional curvature scalars associated with the nondegenerate subspace of the four geometry in such regions. All such scalars are found to be finite, implying that the emergent three-geometry is regular.

Let us now elucidate our construction for the positive mass Schwarzschild geometry, followed by a brief discussion of the negative mass case.

## 2. A smooth extension of the Schwarzschild exterior

Our aim is to construct a smooth continuation of the Schwarzschild exterior, such that it satisfies the vacuum field equations of first order gravity[a]. These equations of motion are obtained through a variation of the Hilbert-Palatini Lagrangian density with respect to the tetrad and connection fields:

$$e^{[K}_{[\mu}D_{\nu}(\omega)e^{L]}_{\alpha]} = 0,\ e^{[J}_{[\nu}R_{\alpha\beta]}{}^{KL]}(\omega) = 0\ . \tag{1}$$

Although degenerate solutions to these equations may be associated with nontrivial torsion in general, we shall consider torsionless configurations which would be sufficient for our purpose here.

### 2.1. *Basic fields*

We define the two phases of the full spacetime through the following metric ($t \in (-\infty, \infty),\ u \in (-\infty, \infty),\ \theta \in [0, \pi],\ \phi \in [0, 2\pi]$):

$$\begin{aligned} ds^2 &= -\left[1 - \frac{2M}{f(u)}\right]dt^2 + \frac{f'^2(u)}{\left[1 - \frac{2M}{f(u)}\right]}du^2 + f^2(u)\left[d\theta^2 + \sin^2\theta d\phi^2\right]\ \ (u > u_0), \\ &= 0 + \sigma F^2(u)du^2 + H^2(u)\left[d\theta^2 + \sin^2\theta d\phi^2\right]\ \ (u \leq u_0). \end{aligned} \tag{2}$$

The smooth functions $f, F$ satisfy the following set of boundary conditions:

$$\begin{aligned} &f(u) \to 2M,\ f'(u) \to 0,\ F(u) \to 0 \text{ as } u \to u_0; \\ &f(u) \to \infty,\ f'(u) \to 1 \text{ as } u \to \infty. \end{aligned} \tag{3}$$

While the first line above ensures the continuity of the metric, the last line implies that the spacetime is flat as $u \to \infty$. The internal metric is given by $\eta_{IJ} = diag[-1, 1, 1, 1]$. The metric at $u > u_0$ may be brought to the Schwarzschild form through a reparametrization $u \to r = f(u)$. However, the degenerate metric at $u \leq u_0$ has no semblance to the Schwarzschild interior. Also, $u_0$ in this construction is not a new free parameter, but rather is dependent on the 'mass' parameter M. Although it is not necessary to adopt any specific $f(u)$, we choose it to be the following in order to be explicit:

$$f(u) = 2M\left[1 + \left|\frac{u}{u_0} - 1\right| e^{-\frac{u_0^2}{(u-u_0)^2}}\right].$$

This satisfies all the boundary conditions in (3) provided $u_0 = 2M$.

[a]The form of the metric defining the full spacetime here is the same as introduced in Ref. 5. However, the solutions there are based on fields that are continuous but not smooth and have nonvanishing torsion, unlike the case here.

The nonvanishing components of the associated (torsionless) spin-connection and the resulting field-strength are given below:

$$\omega_t{}^{01} = \frac{M}{f^2(u)},\ \omega_\phi{}^{23} = -\cos\theta,\ \omega_\phi{}^{31} = \left(1-\frac{2M}{f(u)}\right)^{\frac{1}{2}}\sin\theta = -\omega_\theta{}^{12}\sin\theta;$$
$$R_{tu}^{01} = \frac{2Mf'(u)}{f^3(u)},\ R_{t\phi}^{03} = -\frac{M}{f^2(u)}\left(1-\frac{2M}{f(u)}\right)^{\frac{1}{2}}\sin\theta = R_{t\theta}^{02}\sin\theta,$$
$$R_{\theta\phi}^{23} = \frac{2M}{f(u)}\sin\theta,\ R_{\phi u}^{31} = -\frac{Mf'(u)}{f^2(u)}\left(1-\frac{2M}{f(u)}\right)^{-\frac{1}{2}}\sin\theta = R_{u\theta}^{12}\sin\theta. \qquad (4)$$

At the region $u \le u_0$ with a degenerate phase, we choose a zero-torsion configuration, defined by the following connection fields along with the associated field-strength:

$$\hat{\omega}_\phi{}^{23} = -\cos\theta,\ \hat{\omega}_\phi{}^{31} = \frac{H'(u)}{\sqrt{\sigma}F(u)}\sin\theta = -\hat{\omega}_\theta{}^{12}\sin\theta;$$
$$\hat{R}_{\theta\phi}^{23} = \left[1-\sigma\left(\frac{H'(u)}{F(u)}\right)^2\right]\sin\theta,\ \hat{R}_{\phi u}^{31} = -\left[\frac{H'(u)}{\sqrt{\sigma}F(u)}\right]'\sin\theta = \hat{R}_{u\theta}^{12}\sin\theta, \qquad (5)$$

where we have displayed only the nonvanishing components. Note that even though some of the field components are imaginary for $\sigma = -1$, the physical fields, given by their $SO(3,1)$ gauge-invariant counterparts $\hat{R}_{\mu\nu\alpha\beta} = \hat{R}_{\mu\nu}{}^{IJ}\hat{e}_{\mu I}\hat{e}_{\nu J}$, are all real.

### 2.2. *Solving the field equations*

Since this configuration with degenerate tetrads have vanishing torsion by construction, the first of the set of equations of motion (1) is already satisfied. The remaining equation involving the curvature two-form is also satisfied provided the fields obey the constraint:

$$\left(\frac{H'^2(u)}{F^2(u)} - \sigma\right)F(u) + 2H(u)\left(\frac{H'(u)}{F(u)}\right)' = 0. \qquad (6)$$

A solution to the continuity conditions at $u = u_0$ and the constraint (6) is given by:

$$F(u) = -\frac{f'(u)}{\sqrt{\sigma}\left(1-\frac{2M}{f(u)}\right)^{\frac{1}{2}}},\ H(u) = f(u). \qquad (7)$$

Note that all the gauge covariant fields (tetrad and field-strength) are smooth across the phase boundary. The apparent discontinuity in the connection field ($\omega_t{}^{01} \neq \hat{\omega}_t{}^{01}$ at $u = u_0$) could be gauged away by a boost of the form:

$$\Lambda^I{}_J = \begin{pmatrix} \cosh\left[\frac{t}{4M}\right] & \sinh\left[\frac{t}{4M}\right] & 0 & 0 \\ \sinh\left[\frac{t}{4M}\right] & \cosh\left[\frac{t}{4M}\right] & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

### 2.3. *Distinct features*

We now summarize the main features of these new solutions of first order field equations:

a) The spacetime metric, along with all the gauge-covariant fields in this solution, are smooth everywhere.

b) This (nonanalytic) extension has no horizon; The two values $\sigma = \mp 1$ correspond to a Lorentzian and Euclidean three geometry which supercedes the standard Schwarzschild interior.

c) The curvature two-form fields are finite everywhere, in contrast to the case of a Schwarzschild interior.

d) The solution has a free parameter 'M', exactly as in the usual Schwarzschild case. However, there is no matter sourcing this mass, rather, its origin is purely geometric.

e) There is no horizon; Rather, the two-sphere at $u = u_0$ characterizes a minimal area surface $A_{min} = 16\pi M^2$ and is impenetrable, at least classically.

f) The method of defining the degenerate phase through $\hat{g}_{tt} = 0$ is unique, since it is not possible to obtain a nontrivial extension of the Schwarzschild exterior through any other kind of degeneracy (e.g. $\hat{g}_{uu} = 0$).

Finally, note that even though the four-curvature scalar polynomials cannot be defined everywhere due to the noninvertibility of tetrads, the spacetime at $u \leq u_0$ may be treated as an emergent three-geometry defined solely by the induced metric:

$$ds^2 = \sigma F^2(u) du^2 + H^2(u) \left[ d\theta^2 + \sin^2\theta d\phi^2 \right].$$

The three-scalar curvature polynomials built upon the torsionless connection for this three-geometry also turn out to be finite everywhere.

## 3. Naked singularity

Next, let us analyze the case of negative mass Schwarzschild geometry, the corresponding metric being obtained through a sign reversal $M \to -M$. This represents a naked singularity solution of vacuum Einstein equations.

Since there is no horizon in the original geometry ($g_{tt} \neq 0$), let us consider an extension in first order gravity through $g_{uu} = 0$ at $u \leq u_0$ is as follows:

$$\begin{aligned} ds^2 &= -\left[1 + \frac{2M}{f(u)}\right] dt^2 + \frac{f'^2(u)}{\left[1 + \frac{2M}{f(u)}\right]} du^2 + f^2(u) \left[ d\theta^2 + \sin^2\theta d\phi^2 \right] \ (u > u_0), \\ &= -\left[1 + \frac{2M}{f_0}\right] dt^2 + 0 + f_0^2 \left[ d\theta^2 + \sin^2\theta d\phi^2 \right] \ (u \leq u_0), \end{aligned} \tag{8}$$

where $u = u_0$ corresponds to the phase boundary hypersurface and $f_0 = f(u_0)$. Since the phase boundary must correspond to some finite but nonzero Schwarzschild radius ($r$), $f_0 > 0$. However, the noninvertible phase above just corresponds to the trivial restriction of the original negative mass solution at $u = u_0$ rather than a new

spacetime region. The same conclusion holds for a possible degeneracy through $g_{tt} = 0$ (based on a redefined 'time').

Thus, the singular curvature-two form fields associated with 'negative mass' solution cannot be regularized using a degenerate extension, in contrast to the 'positive mass' case discussed in the previous section.

## 4. Conclusions

The smooth extension of the exterior Schwarzschild geometry, as discussed here, involves a modification of the standard picture of a singular black hole interior in a purely classical setting[5,6]. These solutions could provide a fresh perspective into the information loss problem. Being rooted within a fairly conservative framework based on first order gravity, such an approach could complement (and perhaps supercede) some of the more exotic proposals (e.g. Firewall or Fuzzball programme) that have been put forth to resolve this celebrated paradox.

The cases of positive and negative mass curvature singularities of the Einsteinian theory are perceived very differently within this framework. While the singular interior of positive mass Schwarzschild geometry may be traded for a zero-determinant phase with regular field-strength components, the negative mass naked singularity admits no such smooth extension in first order gravity. This outcome, however, is consistent with the general expectation[7] that degenerate metric ($\det g_{\mu\nu} = 0$) solutions obtained within the Hilbert-Palatini Lagrangian formulation[1–3] should satisfy the energy conditions. The scenario here may be contrasted with the case of degenerate triad ($\det E^a_i = 0$) solutions obtained earlier within the complex SU(2) (Sen-Ashtekar) Hamiltonian framework, which are known to contain negative energy geometries[8].

Finally, let us note that in the vacuum solution constructed here, there is no matter sourcing the 'mass' M. Rather, its origin could be attributed to the time-nonorientability at the phase boundaries[5,6,9,10]. This is an interesting realization of mass through pure geometry. Further, this scenario is distinct from the remarkable ideas explored first by Einstein-Rosen[11] and later by Wheeler-Misner[12], through their respective attempts to generate 'mass' and 'charge' from a nontrivial geometry or topology. To emphasize, our analysis here does not involve wormholes (which are not solutions to the vacuum field equations in general) or quantum configurations such as geons. It would be natural to ask if there is a more interesting manifestation of such geometric 'mass' sourced by noninvertible phases in vacuum.

To conclude, given the number of intriguing features of these 'two-phased' solutions, one wonders if quantum gravity could be a more suitable arena for further explorations based on these.

The scattering of the Dirac fermions by the black-holes with spherical symmetry is studied by applying the method of partial wave analysis. The analytical expressions for the phase shifts and analytical formulas for the differential scattering cross section are written down for the fermion scattering from Schwarzschild, Reissner-Nordsrtöm and Bardeen black holes. A brief comment about the principal features of these cases is outlined.

*Keywords*: Black holes, fermions, scattering.

## 1. Introduction

In this paper we want to present a comparative study of the scattering of Dirac fermions by black-holes with spherical symmetry. For that we choose the Schwarzschild, the Reissner-Nordsrtöm and Bardeen black holes, which were each analysed separately in our previous works[1–4]. Other works that studied numerically the scattering of fermions by these three types of black holes can be found for example in Refs. 5–19.

The main steps for solving the Dirac equation in the geometries that describe black-holes with spherical symmetry are detailed. We obtain the scattering modes resulted solving the Dirac equation in the asymptotic zone of the black hole, which help us to obtain the phase shifts and the analytical expression of the differential scattering cross section. The differential scattering cross section will be analysed in terms of the relevant parameters such as the mass of the black hole and the charge of the black hole and scattering angle. From the analytical expression for the cross section the zero mass limit can be obtained.

We begin in the second section with the basic notions about the Dirac equation in geometries that describe black holes with spherical symmetry. The third section is dedicated to the phase shifts obtained using the partial wave analysis and in the fourth section we make a graphical analysis of the cross section in terms of scattering angle.

## 2. Dirac Equation and Black Holes

In this work we are discussing fermion scattering by black holes with spherical symmetry that have the following generic metric

$$ds^2 = h(r)dt^2 - \frac{dr^2}{h(r)} - r^2\left(d\theta^2 + \sin^2\theta d\phi^2\right) \tag{1}$$

In the case of Schwarzschild, electrically charged Reissner-Nordsrtöm and (regular) Bardeen black holes the function $h(r)$ reads:

$$h(r)_S = 1 - \frac{2M}{r}, \qquad h(r)_{RN} = 1 - \frac{2M}{r} + \frac{Q^2}{r^2}, \qquad h(r)_B = 1 - \frac{2Mr^2}{\sqrt{(r^2+Q_m^2)^3}} \quad (2)$$

where $M$ is the mass of each black hole; $Q$ is the total electric charge and $Q_m$ is the nonlinear magnetic monopole charge[20].

It can be shown (for details see our previous papers[1,2,4,23]) that the Dirac equation, $i\gamma^a D_a\psi - m\psi = 0$, in the black holes geometries given by eq. (1) can be reduced to only a radial equation, namely

$$\begin{pmatrix} m\sqrt{h(r)} + V(r) & -h(r)\frac{d}{dr} + \frac{\kappa}{r}\sqrt{h(r)} \\ h(r)\frac{d}{dr} + \frac{\kappa}{r}\sqrt{h(r)} & -m\sqrt{h(r)} + V(r) \end{pmatrix} \begin{pmatrix} f^+_{E,\kappa}(r) \\ f^-_{E,\kappa}(r) \end{pmatrix} = E \begin{pmatrix} f^+_{E,\kappa}(r) \\ f^-_{E,\kappa}(r) \end{pmatrix} \quad (3)$$

where $f^{\pm}(r)$ are two radial wave function and $V(r) = eQ/r$. The angular part of the Dirac equation is contained into the standard 4-component angular spinors $\Phi^{\pm}_{m,\kappa}(\theta,\phi)$[21]. Thus the particle-like solutions with energy $E$ can be expressed as

$$\psi_{E,j,m,\kappa}(t,r,\theta,\phi) = \frac{e^{-iEt}}{r\,h(r)^{1/4}} \left\{ f^+_{E,\kappa}(r)\Phi^+_{m,\kappa}(\theta,\phi) + f^-_{E,\kappa}(r)\Phi^-_{m,\kappa}(\theta,\phi) \right\} \quad (4)$$

The separation of angular variables as in eq. (4) was possible by using the Cartesian gauge (see eqs. (1)–(4) in Ref. 2). In this gauge the Dirac equation is manifestly covariant under rotations.

The radial equation (3) can not be solved analytically for any of the three black holes (2) and up to now a combination of analytical and numerical methods was used to solve it and to compute numerical phase shifts as was done for ex. in Ref. 6 for Schwarzschild BH or in Ref. 19 for Bardeen BH.

### 2.1. *Scattering modes*

In the following we will briefly show how to obtain analytical phase shifts by finding (approximative) analytical scattering modes resulted from solving the Dirac equation in the asymptotic zone of the black hole as done in Refs. 1–4. One starts by changing the variable $r$ to a Novikov-like one, namely

$$x = \sqrt{\frac{z}{r_+} - 1}, \quad (5)$$

with $r_+$ the radius of the outer black hole horizon. For Schwarzschild BH $z = r$ and $r_+ = r_0 = 2M$; for Reissner-Nordsrtöm BH $z = r$ and $r_+ = M + \sqrt{M^2 - Q^2}$; while for Bardeen BH $z = \sqrt{r^2 + Q_M^2}$ and $r_+$ has a more complicated analytical expression not given here.

By rewriting eq. (3) in terms of the new variable $x$ and making a Taylor expansion with respect to $1/x$ one can show, after discarding the $O(1/x^2)$ terms and

higher, that in the asymptotic zone of the black hole the new equation becomes

$$\begin{pmatrix} \frac{1}{2}\frac{d}{dx}+\frac{\kappa}{x} & -x(\mu+\varepsilon)-\frac{1}{x}(\zeta+\beta) \\ x(\varepsilon-\mu)-\frac{1}{x}(\zeta-\beta) & \frac{1}{2}\frac{d}{dx}-\frac{\kappa}{x} \end{pmatrix} \begin{pmatrix} f^{+}_{E,\kappa}(x) \\ f^{-}_{E,\kappa}(x) \end{pmatrix} = 0 \tag{6}$$

where $\mu = r_+ m$, $\varepsilon = r_+ E$ and

- for Schwarzschild black hole one has:

$$\zeta = \frac{\mu}{2}, \quad \beta = \varepsilon, \quad r_+ = 2M \tag{7}$$

- for Reissner-Nordström black hole:

$$\zeta = \frac{1}{2}\,\mu\left(1-\frac{r_-}{r_+}\right), \quad \beta = \varepsilon - eQ, \quad r_\pm = M \pm \sqrt{M^2-Q^2} \tag{8}$$

- for regular Bardeen black hole:

$$\zeta = \mu\left(1-\frac{M}{r_+}\right), \quad \beta = \varepsilon, \tag{9}$$

The scattering mode solutions (with $\varepsilon > \mu$) of eq. (6) can be found in terms of Whittaker functions[1,2,4,23]

$$\begin{pmatrix} f^{+}(x) \\ f^{-}(x) \end{pmatrix} = \begin{pmatrix} -i\sqrt{\mu+\varepsilon} & i\sqrt{\mu+\varepsilon} \\ \sqrt{\varepsilon-\mu} & \sqrt{\epsilon-\mu} \end{pmatrix} \begin{pmatrix} C_1^{+}\,\frac{1}{x}M_{\rho_+,s}(2i\nu x^2) + C_2^{+}\,\frac{1}{x}W_{\rho_+,s}(2i\nu x^2) \\ C_1^{-}\,\frac{1}{x}M_{\rho_-,s}(2i\nu x^2) + C_2^{-}\,\frac{1}{x}W_{\rho_-,s}(2i\nu x^2) \end{pmatrix} \tag{10}$$

were $\nu = \sqrt{\varepsilon^2-\mu^2}$. The four integration constants $C_1^{\pm}$, $C_2^{\pm}$ are not independent, satisfying the following relations[1,23]:

$$\frac{C_1^{-}}{C_1^{+}} = \frac{s-iq}{\kappa-i\lambda}, \quad \frac{C_2^{-}}{C_2^{+}} = -\frac{1}{\kappa-i\lambda} \tag{11}$$

and were the following parameters are used:

$$s = \sqrt{\kappa^2+\zeta^2-\beta^2}, \quad \rho_\pm = \mp\frac{1}{2} - iq, \quad q = \frac{\beta\varepsilon-\zeta\mu}{\nu}, \quad \lambda = \frac{\beta\mu-\zeta\varepsilon}{\nu} \tag{12}$$

### 2.2. *Analytical Phase Shifts*

Applying the partial wave method on the scattering modes (10) as done in Refs. 1,2,4 we obtained for the first time in the literature analytical expressions for the phase shifts associated to the scattering of Dirac fermions by black holes, namely:

$$S_\kappa = e^{2i\delta_\kappa} = \left(\frac{\kappa-i\lambda}{s-iq}\right)\frac{\Gamma(1+s-iq)}{\Gamma(1+s+iq)}e^{i\pi(l-s)}\,. \tag{13}$$

Using these phase shifts one can now calculate analytical expressions for the differential scattering cross section

$$\frac{d\sigma}{d\Omega} = |f(\theta)|^2 + |g(\theta)|^2 \tag{14}$$

were the scalar amplitudes $f(\theta)$ and $g(\theta)$ are defined in terms of Legendre polynomials[22] and the phase shifts $e^{2i\delta_l}$

$$f(\theta) = \sum_{l=0}^{\infty} \frac{1}{2ip} \left[(l+1)(e^{2i\delta_{-l-1}} - 1) + l(e^{2i\delta_l} - 1)\right] P_l^0(\cos\theta)$$
$$g(\theta) = \sum_{l=1}^{\infty} \frac{1}{2ip} \left[e^{2i\delta_{-l-1}} - e^{2i\delta_l}\right] P_l^1(\cos\theta) \tag{15}$$

The above infinite series have a singularity present at $\theta = 0$ that can not be removed. This makes the scattering section to be divergent in the forward direction. However, by using a method first proposed in Ref. 24 one can define new reduced series for $f(\theta)$ and $g(\theta)$ (see eqs. (72)–(75) in Ref. 1 for more details) that converge more quickly.

## 3. Main Results and Brief Comments

In this section we perform a graphical analysis of the cross section in terms of the scattering angle. The relevant parameters in our analysis are the black hole mass $M$, the fermion mass $m$, fermion speed $v$, the charge of the black hole $Q$ and the scattering angle $\theta$.

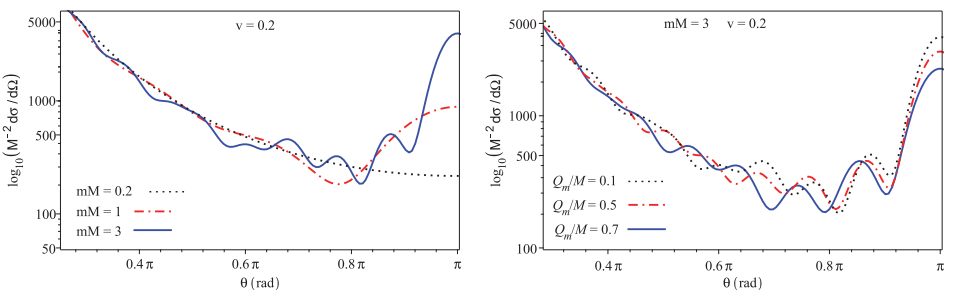

Fig. 1. Differential scattering cross section for fermion scattering by a Schwarzschild black hole (left panel), respectively for a Bardeen black hole (right panel).

In Fig. 1, we make a comparative study of the differential scattering cross section for fermion scattering by a Schwarzschild black hole and a Bardeen black hole. Our graphical results prove that the cross section has a oscillatory behaviour which become more pronounced as we increase the product of masses $mM$ in the case of scattering on Schwarzschild black hole. When the scattering angle approaches the value $\theta = 0$ the cross section increase proving that the forward scattering is dominant. In the case of Bardeen black hole the differential cross section depend on the ratio between the charge of the magnetic monopole and the black hole mass and we observe a variation of the differential cross section when we modify the ratio $Q_m/M$. In both cases the differential cross section have a maximum for $\theta = \pi$, which prove

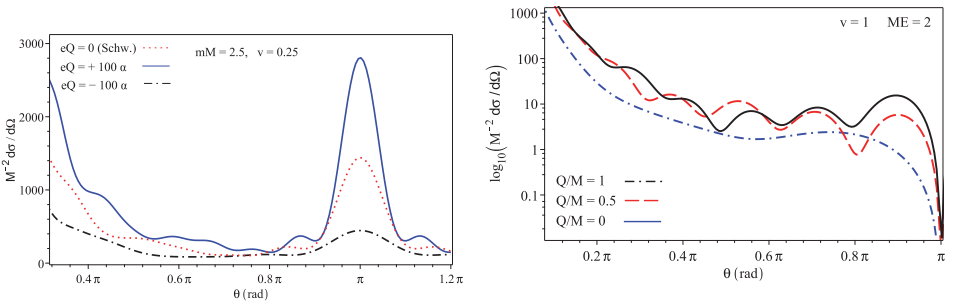

Fig. 2. Differential scattering cross section for fermion scattering by a Reisnner-Nordstrom black hole (left panel). Scattering of massless fermions (right panel).

that the backward scattering is also relevant. In the case of Schwarzschild black hole the backward scattering become important as the parameter $mM$ increase.

The results presented in Fig. 2, shows the dependence of the differential scattering cross section for fermions scattered by a Reisnner-Nordsrtöm black hole on the scattering angle. Here we analyse the case of massive fermions as well as the case when the mass of the fermion is zero. In the case of scattering of massive fermions we observe the differential scattering cross section variation in terms of the charge of the black hole and the charge of the fermion in comparison with the scattering on Schwarzschild black hole (left panel). When the charge of the black hole and the fermion charge have the same sign, the backward scattering become important because of the electrostatic repulsion between charges. For scattering of fermions with zero mass we observe the variation of the differential scattering cross section in terms of the ratio $Q/M$ and that in the backward direction the differential scattering cross section is vanishing.

## 4. Conclusions

The principal conclusion is that the scattering processes analyzed here can be studied by using exclusively analytical methods with suitable asymptotic conditions. In this manner we complete the previous studies which combine analytical and numerical methods obtaining new results and a synthetic overview over the considered processes, pointing out that these are described by similar formulas.

# Weak conservation law from hidden symmetry of spinning black holes

Vojtěch Witzany*

*Astronomical Institute of the Czech Academy of Sciences,*
*Boční II 1401, 141 00 Praha 4, Czechia*

*Center of Applied Space Technology and Microgravity (ZARM), University Bremen*
*Am Fallturm 2, 28359 Bremen, Germany*

**E-mail: vojtech.witzany@asu.cas.cz*

The Kerr space-time possesses a "hidden symmetry", which exhibits itself in an unexpected conserved quantity along geodesics known as the Carter constant. Here I report on a recent paper [1], where I answer the question whether this hidden symmetry can be used to formulate a conservation law for a general matter field. First, I show that there cannot exist a conserved sum of Carter constants for a matter system with momentum exchange between its components. Then, I derive a "weak" conservation law associated with the hidden symmetry and demonstrate its properties. Finally, I show how this weak conservation law and related identities can be used to detect violations of the evolution equations in numerical simulations of astrophysical processes near spinning black holes.

*Keywords*: Black holes; conservation laws; symmetries; numerical simulations.

## 1. Introduction

Accreting black holes are now widely believed to reside in many astrophysical systems including X-ray binaries and active galactic nuclei. Even though simple analytical models provide reasonable agreement with the observational appearance of such black holes, the detailed observational signature of their accretion disks are obtained from expensive numerical simulations that involve the non-linear and often turbulent interaction of magnetic fields, non-thermal radiation, and possibly non-thermal plasmas. This all takes place on the stage of the Kerr space-time, the gravitational field of a spinning black hole.

It is very much possible that errors occur in such computer simulations. This may come about either as an inherent error of the numerical method, or as an understandable mistake in the writing of such complex simulation programs. Hence, it is very useful to devise independent checks of the validity of the evolutions obtained with such numerical codes. This can be done either by checking the codes against known exact solutions [2–4], or by checking against conservation laws. For example, one may look for conservation laws that apply to general evolutions of particular matter models but also for conservation laws that apply only in situations with a given symmetry of the matter configuration, such as was done for the case of ideal magnetohydrodynamics [5]. However, both of these approaches will typically test the code only in very specific modes, and there are only two conservation laws that hold for completely general evolutions. These laws are the conservation of energy and azimuthal angular-momentum fluxes, which emerge, in fact, from the stationarity and axisymmetry of the Kerr background.

Nevertheless, the Kerr space-time has an additional geometric property that is often called a "hidden symmetry". The hidden symmetry follows from the existence of a Killing-Yano (KY) tensor, and it leads to conservation laws of an "angular momentum squared", also known as the Carter constant[6], for free test particles as well as linear wave equations (free test quantum particles) in Kerr space-time. It is natural to ask whether these conservation laws form a pattern which can be generalized to *any* test matter field evolving in the Kerr space-time. In other words, is there a conserved Carter-constant flux for general matter systems, even such as those needed to describe accretion disks near black holes? It turns out that the answer is *no* and that this can be easily proven. Nevertheless, there *does* exist a conserved *KY vorticity flux* which has the character of a differential constraint or a "weak conservation law". I briefly summarize these results in this contribution to the Proceedings, while further information can be found in Ref. 1.

## 2. Carter constant and colliding particles

I use the $G = c = 1$ geometrized units and the $-+++$ signature of the metric. Coordinate gradients are denoted by a comma preceding an index, and covariant gradients with a semi-colon preceding an index.

The Kerr metric is independent of time $t$ and azimuthal angle $\varphi$, which makes $\xi^\mu_{(t)} = \delta^\mu_t$ and $\xi^\mu_{(\varphi)} = \delta^\mu_\varphi$ Killing vectors with antisymmetric covariant gradients, $\xi_{\mu;\nu} = -\xi_{\nu;\mu}$. Consequently, geodesics with four-velocity $u^\mu$ have constants of motion $\xi^\mu u_\mu$,

$$\frac{\mathrm{d}}{\mathrm{d}\tau}(\xi^\mu u_\mu) = \xi^\mu u_{\mu;\nu} u^\nu + \xi_{\mu;\nu} u^\mu u^\nu = 0\,. \tag{1}$$

A natural generalization of a Killing vector is a KY tensor, which fulfills $Y_{\mu\nu} = -Y_{\nu\mu}$, $Y_{\mu\nu;\kappa} = -Y_{\mu\kappa;\nu}$. Now a projection of four-velocity into a KY tensor is a vector that is parallel-transported along the geodesic,

$$\frac{\mathrm{D}}{\mathrm{d}\tau}(Y_{\mu\nu}u^\nu) = Y_{\mu\nu;\kappa}u^\nu u^\kappa + Y_{\mu\nu}u^\nu{}_{;\kappa}u^\kappa\,. \tag{2}$$

The square of a vector is conserved, so $C \equiv K_{\nu\lambda}u^\nu u^\lambda$, $K_{\nu\lambda} \equiv Y_{\mu\nu}Y^\mu{}_\lambda$ is an integral of motion of the geodesic.

Now consider a collisionless cloud of free test particles. This will have a stress-energy tensor and conserved current of Carter constants

$$T^{\mu\nu}(x^\lambda) = \sum_i m_{(i)} u^\mu_{(i)} u^\nu_{(i)} \int_{-\infty}^{\infty} \delta^4(x^\lambda - x^\lambda_{(i)}(\tau))\mathrm{d}\tau\,, \tag{3}$$

$$\mathcal{C}^\mu(x^\lambda) = \sum_i C_{(i)} m_{(i)} u^\mu_{(i)} \int_{-\infty}^{\infty} \delta^4(x^\lambda - x^\lambda_{(i)}(\tau))\mathrm{d}\tau\,, \tag{4}$$

where $(i)$ labels quantities associated with the $i$-th particle in the cloud. In other words, $\mathcal{C}^\mu_{\ ;\mu} = 0$ and the integral of $\mathcal{C}^t$ over the spatial extent of an isolated cloud will be conserved and equal to the sum of (mass-weighed) Carter constants at time $t$.

However, if we consider elastic collisions between particles, we notice that even though these do not violate the conservation of the sum of constants of motion *linear* in momenta, they will destroy the conservation of the sum of the constants of motion *quadratic* in momenta. Formally the elastic collision is characterized by

$$\sum_i p'^{\mu}_{(i)} - \sum_i p^{\mu}_{(i)} = 0\,, \tag{5}$$

where the primed and unprimed quantities always signify quantities right after and before the collision respectively.

As a consequence, one can contract the momentum conservation (5) with the KY tensor to see that the sums of angular momentum vectors associated with KY tensors are always conserved

$$\sum_i (Y_{\mu\kappa} p'^{\mu}_{(i)}) - \sum_i (Y_{\mu\kappa} p^{\mu}_{(i)}) = 0\,. \tag{6}$$

Similarly, if we contract (5) with a Killing vector $\xi_\mu$, we see that that the sum of $\xi_\mu p^{\mu}_{(i)}$ is conserved in collisions. However, as was noticed also by[7], if we try to see what happens to the sum of the quadratic Carter constants $C_{(i)} \equiv K_{\mu\nu} p^{\mu}_{(i)} p^{\nu}_{(i)}\,, K_{\mu\nu} \equiv Y_{\mu\kappa} Y^{\kappa}_{\ \nu}$, in momentum exchanges, we obtain

$$\sum_i C'_{(i)} - \sum_i C_{(i)} = \sum_i \sum_{j\neq i} K_{\mu\nu} p^{\mu}_{(i)} p^{\nu}_{(j)} - \sum_i \sum_{j\neq i} K_{\mu\nu} p'^{\mu}_{(i)} p'^{\nu}_{(j)}\,. \tag{7}$$

It can then be shown that this leads to $\mathcal{C}^{\mu}_{\ ;\mu} \neq 0$ whenever collisions occur within the particle cloud. The conservation of the angular momentum vectors (6) leads to the identity $(T^{\mu\nu} Y_{\nu}^{\ \kappa})_{;\mu} = 0$, but this is not a conservation law for a current. However, it is possible to create one by taking a divergence with respect to the redundant index and thus one obtains a conserved current $j^{\mu}_{\mathrm{KY}} = T^{\mu\nu;\kappa} Y_{\nu\kappa}$. I will call it the flux of KY vorticity, since it is proportional to anti-symmetric gradients of stress-energy.

As an interesting side note, the recent work[8,9] discusses that even though the collisions spoil the long-term evolution of the sum of Carter constant of a general matter flow, it is always possible to find a certain effective Carter constant that is conserved for sufficiently compact bodies for a short enough time. However, this fact seems to be useful only for the evolution of compact astrophysical objects such as neutron stars and black holes in extreme mass ratio inspirals.

## 3. Demonstration on dust in Kerr

Consider the Kerr space-time in Boyer-Lindquist coordinates $t, \varphi, r, \vartheta$, $\Delta \equiv r^2 - 2Mr + a^2$, $\Sigma = r^2 + a^2 \cos^2\vartheta$, and $M, a$ are the black hole mass and spin respectively.

We set up a field of dust $T^{\mu\nu} = \rho u^\mu u^\nu$ which is infalling into the Kerr black hole with a mass density $\rho$ and the four-velocity

$$u_\varphi = u_\vartheta = 0\,, \tag{8}$$

$$u_t = -1\,, \tag{9}$$

$$u_r = -\frac{\sqrt{2Mr(r^2+a^2)}}{\Delta} + \varepsilon\,, \tag{10}$$

where when the dimensionless constant $\varepsilon = 0$ then the velocity field fulfils the geodesic equation $a^\mu = 0$ but violates it for $\varepsilon \neq 0$ by introducing two non-zero components of acceleration

$$a_\vartheta = -\varepsilon\frac{2a^2\sin\vartheta\cos\vartheta\sqrt{2Mr(r^2+a^2)}}{\Sigma^2} + \mathcal{O}(\varepsilon^2)\,, \tag{11}$$

$$a_r = -\varepsilon\left(\frac{\sqrt{2Mr(r^2+a^2)}}{\Sigma}\right)_{,r} + \mathcal{O}(\varepsilon^2)\,. \tag{12}$$

Since the velocity field is purely radial, the continuity equation $(\rho u^\mu)_{;\mu} = 0$ has the simple solution

$$\rho = -\frac{\dot{M}(\vartheta)}{2\pi\Delta u_r}\,, \tag{13}$$

where $\dot{M}(\vartheta)$ is an arbitrary positive function of $\vartheta$ which represents the dust accretion rate through a $\vartheta = \text{const.}$ layer. In the examples here we choose $\dot{M} = const.$.

Now the $\varepsilon$ term will *not* induce deviations from the conservation of mass, energy, or angular momentum. Hence, it cannot be detected by existing tests. However, it *will* induce deviations from the KY conservation laws and relations given above. Specifically, I considered the integral formulation of the KY vorticity conservation $(j^\mu_{\rm KY})_{;\mu} = 0$, the KY-projected equations of motion $(T^{\mu\nu}Y_\nu{}^\kappa)_{;\mu} = 0$, and the equations of motion $T^{\mu\nu}{}_{;\nu} = 0$.

Now consider receiving the data about the flow on a finite numerical grid in the interval $r \in (3M, 6M)$. When evaluated numerically, the non-zero value of the right-hand sides of the equations above indicate an error in the evolution (in our case the dust infall). However, there will always be numerical noise in the right-hand sides. In particular, the evaluation of $j^\mu_{\rm KY}$ requires taking numerical derivatives of the data, which proved to be a strong source of noise. I have thus defined a "detection" value $\varepsilon_{\rm d}$ of $\varepsilon$ as such that the values of the right-hand sides are ten times that of the noise for the unperturbed "correct" flow. It is then instructive to see how sensitive is the conservation law as a function of the numerical grid spacing.

The results of the comparison are given in Fig. 1. It turns out that even though the KY vorticity is a "proper" conservation law, the numerical noise associated with the numerical derivatives makes it difficult to use for data with large grid spacings. Nevertheless, the "KY-projected equations of motion" represent an interesting alternative to just integrating the equations of motion themselves.

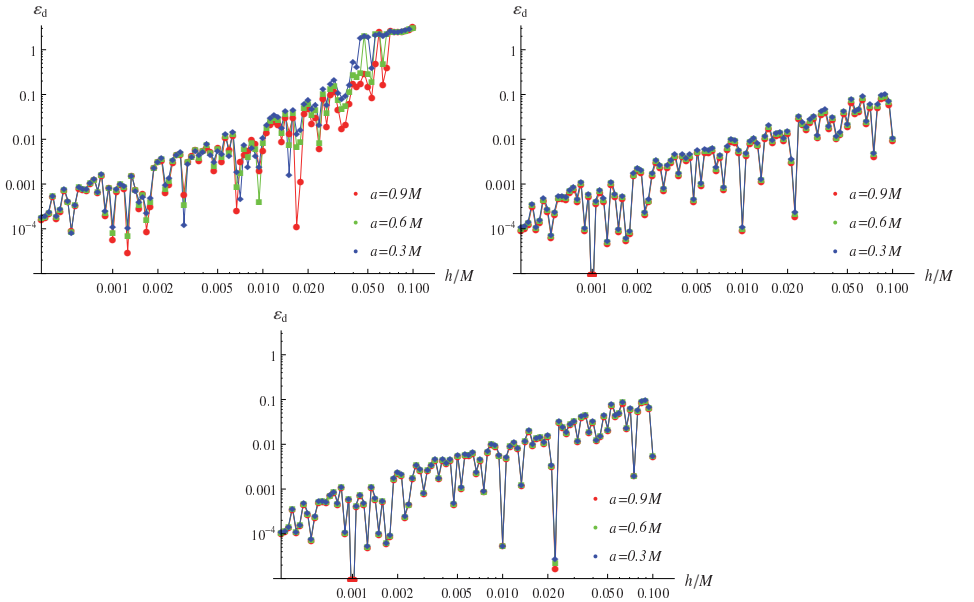

Fig. 1. The detection value of the perturbation $\varepsilon_d$ as a function of grid spacing $h$ for various choices of the black hole spin. The top left figure corresponds to the KY vorticity conservation, top right to KY-projected equations of motion, and the bottom to the plain equations of motion.

We consider the effects of rotations on the calculation of some thermodynamical quantities like the free energy, internal energy and entropy. In ordinary gravity, when we evaluate the density of states of a scalar field close to a black hole horizon, we obtain a divergent result which can be kept under control with the help of some standard regularization and renormalization processes. We show that when we use the Gravity's Rainbow approach such regularization/renormalization processes can be avoided. A comparison between the calculation done in an inertial frame and in a comoving frame is presented.

## 1. Introduction

Gravity's Rainbow (GRw) is a modification of the space-time close to the Planck scale. It has been introduced for the first time by Magueijo and Smolin [1]. Basically one defines two unknown functions $g_1\left(E/E_P\right)$ and $g_2\left(E/E_P\right)$ having the following property

$$\lim_{E/E_P\to 0} g_1\left(E/E_P\right)=1 \qquad \text{and} \qquad \lim_{E/E_P\to 0} g_2\left(E/E_P\right)=1. \tag{1}$$

This property guarantees the recovery of ordinary General Relativity when sub-planckian physics is involved. In this formalism, the Einstein's field equations are replaced by a one parameter family of equations

$$G_{\mu\nu}\left(E\right)=8\pi G\left(E\right)T_{\mu\nu}\left(E\right)+g_{\mu\nu}\Lambda\left(E\right), \tag{2}$$

where $G\left(E\right)$ is an energy dependent Newton's constant and $\Lambda\left(E\right)$ is an energy dependent cosmological constant, respectively. They are defined so that $G\left(0\right)$ is the physical Newton's constant and $\Lambda\left(0\right)$ is the usual cosmological constant. In this context, the Schwarzschild solution of (2) becomes

$$ds^2\left(E\right)=-\left(1-\frac{2MG\left(0\right)}{r}\right)\frac{dt^2}{g_1^2\left(E/E_P\right)}+\frac{dr^2}{\left(1-\frac{2MG(0)}{r}\right)g_2^2\left(E/E_P\right)}+\frac{r^2}{g_2^2\left(E/E_P\right)}d\Omega^2. \tag{3}$$

An immediate generalization of the metric (3) is represented by the following line element

$$ds^2\left(E\right)=-\left(1-\frac{b\left(r\right)}{r}\right)\frac{\exp\left(-2\Phi\left(r\right)\right)}{g_1^2\left(E/E_P\right)}dt^2+\frac{dr^2}{\left(1-\frac{b(r)}{r}\right)g_2^2\left(E/E_P\right)}+\frac{r^2}{g_2^2\left(E/E_P\right)}d\Omega^2. \tag{4}$$

The function $b\left(r\right)$ will be referred to as the "shape function" and it may be thought of as specifying the shape of the spatial slices. The location of the horizon is

determined by the equation $b(r_H) = r_H$. On the other hand, $\Phi(r)$ will be referred to as the "redshift function" and describes how far the total gravitational redshift deviates from that implied by the shape function. The line element (4) describes any spherically symmetric space-time with a horizon: by definition, this is a black hole distorted by GRw. Note that a metric of the form

$$ds^2(E) = -\frac{\exp(-2\Phi(r))}{g_1^2(E/E_P)}dt^2 + \frac{dr^2}{\left(1-\frac{b(r)}{r}\right)g_2^2(E/E_P)} + \frac{r^2}{g_2^2(E/E_P)}d\Omega^2, \qquad (5)$$

describes a traversable wormhole modified by GRw if $\exp(-2\Phi(r))$ never vanishes[18]. The line element (5) has been used in a series of papers where to avoid any regularization/renormalization scheme which appear in conventional Quantum Field Theory calculations like one loop corrections to classical quantities[2]. On the other hand, the line element (5) has been considered for the computation of black hole entropy[3]. In this last case, the idea is to avoid to introduce a cut-off of Planckian size known as "*brick wall*"[4]. The "*brick wall*" appears when one uses a statistical mechanical approach to explain the famous Bekenstein-Hawking formula[5,6]

$$S_{BH} = \frac{1}{4}A/l_P^2, \qquad (6)$$

relating the entropy of a black hole and its area. Indeed, when one tries to adopt such an approach, one realizes that the density of energy levels of single-particle excitations is divergent near the horizon. Of course, several attempts have been done to avoid the introduction of the *brick wall*. For instance, without modifying gravity at any scale, it has been suggested that the *brick wall* could be absorbed in a renormalization of Newton's constant[7–9], while other authors approached the problem of the divergent brick wall using Pauli-Villars regularization[10–12]. Other than GRw other proposals have been made in the context of modified gravity. For instance, non-commutative geometry introduces a natural thickness of the horizon replacing the 't Hooft's brick wall[17] and *Generalized Uncertainty Principle* (GUP) modifies the Liouville measure[13–16]. Nevertheless we can wonder what happens when one introduces rotations. For instance, one could consider the free energy obtained for a real massless scalar field, rotating with an angular velocity $\Omega_0$ around the $z$ axis in Minkowski space

$$F = \frac{1}{\beta}\sum_m \int_0^\infty dg(E,m)\ln\left(1-e^{-\beta(E-m\Omega_0)}\right). \qquad (7)$$

For this case, it is better to work in cylindrical coordinates

$$ds^2 = -dt^2 + dr^2 + r^2 d\phi^2 + dz^2 \qquad (8)$$

and with the help of a WKB approximation it is possible to show that a divergence appear close to the speed-of-light (SOL) surface, defined as the surface where $r = \Omega_0^{-1}$[19]. This divergence can be taken under control with the help of GRw by

modifying the line element (8) in the following way [20]

$$ds^2 = -\frac{dt^2}{g_1^2\left(E/E_P\right)} + \frac{dr^2}{g_2^2\left(E/E_P\right)} + \frac{r^2 d\phi^2}{g_2^2\left(E/E_P\right)} + \frac{dz^2}{g_2^2\left(E/E_P\right)}, \tag{9}$$

where for simplicity we have replaced $ds^2\left(E\right)$ with $ds^2$. The same above thermodynamical system can be analyzed on a comoving frame rotating with the same angular velocity $\Omega_0$. By plugging $\phi' = \phi - \Omega_0 t$, from the line element (3) we obtain

$$ds^2 = -\frac{\left(1-\Omega_0^2 r^2\right)}{g_1^2\left(E/E_P\right)}dt^2 + \frac{2\Omega_0 r^2 d\phi' dt}{g_1\left(E/E_P\right)g_2\left(E/E_P\right)} + \frac{dr^2}{g_2^2\left(E/E_P\right)} + \frac{r^2 d\phi'^2}{g_2^2\left(E/E_P\right)} + \frac{dz^2}{g_2^2\left(E/E_P\right)}. \tag{10}$$

It is immediate to see that in this system of coordinates appears a fictitious horizon located at $r = \Omega_0^{-1}$, namely the SOL surface of the rotating heat bath introduced in (7). Note that a mixing between $g_1\left(E/E_P\right)$ and $g_2\left(E/E_P\right)$ appears. A similar mixing appears also in a Vaidya spacetime for

$$ds^2 = -\left(1 - \frac{2M\left(v\right)G}{r}\right)\frac{dv^2}{g_1^2\left(E/E_P\right)} + 2\frac{dvdr}{g_1\left(E/E_P\right)g_2\left(E/E_P\right)} + \frac{r^2 d\Omega^2}{g_2^2\left(E/E_P\right)}, \tag{11}$$

where $v$ is the advanced (ingoing) null coordinate and finally also for the Kerr metric which, in the context of GRw, becomes [22]

$$ds^2 = \frac{g_{tt}dt^2}{g_1^2\left(E/E_P\right)} + \frac{2g_{t\phi}dtd\phi}{g_1\left(E/E_P\right)g_2\left(E/E_P\right)} + \frac{g_{\phi\phi}d\phi^2}{g_2^2\left(E/E_P\right)} + \frac{g_{rr}dr^2}{g_2^2\left(E/E_P\right)} + \frac{g_{\theta\theta}d\theta^2}{g_2^2\left(E/E_P\right)}, \tag{12}$$

where

$$\begin{aligned} g_{tt} &= -\frac{\Delta - a^2\sin^2\theta}{\Sigma}, \qquad g_{t\phi} = -\frac{a\sin^2\theta\left(r^2+a^2-\Delta\right)}{\Sigma}, \\ g_{\phi\phi} &= \frac{\left(r^2+a^2\right)^2 - \Delta a^2\sin^2\theta}{\Sigma}\sin^2\theta, \qquad g_{rr} = \frac{\Sigma}{\Delta}, \qquad g_{\theta\theta} = \Sigma, \end{aligned} \tag{13}$$

and

$$\Delta = r^2 - 2MGr + a^2, \qquad \Sigma = r^2 + a^2\cos^2\theta. \tag{14}$$

Here $M$ and $a$ are mass and angular momentum per unit mass of the black hole, respectively. $\Delta$ vanishes when $r = r_\pm = MG \pm \sqrt{\left(MG\right)^2 - a^2}$, while $g_{tt}$ vanishes when $r = r_{S\pm} = MG \pm \sqrt{\left(MG\right)^2 - a^2\cos^2\theta}$: they are not modified by GRw and the outer horizon or simply horizon is located at $r_+ = r_H$. Units in which $\hbar = c = k = 1$ are used throughout the paper.

## 2. GRw Entropy for the Kerr Black Hole

To discuss the entropy for a Kerr black hole we have two options: we can use a rest observer at infinity (ROI) or we can use a Zero Angular Momentum Observer

(ZAMO)[19,23]. The ROI frame is described by the line element (12) and the appropriate form of the free energy is the following

$$F = \frac{1}{\beta}\int_0^\infty dn\,(E)\ln\left(1-e^{-\beta(E-m\Omega_0)}\right). \tag{15}$$

It is immediate to see that when we use a ROI, the problem of superradiance appears when the free energy (15) is computed in the range $0 < E < m\Omega_0$. On the other hand when a ZAMO is considered, the free energy (15) becomes similar to the one used for a Schwarzschild black hole. Basically this happens because near the horizon the metric becomes

$$ds^2 = -\frac{N^2dt^2}{g_1^2\,(E/E_P)} + g_{\phi\phi}\frac{d\phi^2}{g_2^2\,(E/E_P)} + g_{rr}\frac{dr^2}{g_2^2\,(E/E_P)} + g_{\theta\theta}\frac{d\theta^2}{g_2^2\,(E/E_P)} \tag{16}$$

and the mixing between $t$ and $\phi$ disappears. Moreover when we use a ZAMO frame, the superradiance does not come into play because there is no ergoregion. Indeed since we have defined

$$N^2 = g_{tt} - \frac{g_{t\phi}^2}{g_{\phi\phi}} = -\frac{1}{g^{tt}} = -\frac{\Delta\sin^2\theta}{g_{\phi\phi}}, \tag{17}$$

$N^2$ vanishes when $r \to r_H$. The number of modes with frequency less than $E$ is given approximately by

$$n(E) = \frac{1}{\pi}\int_0^{l_{max}}(2l+1)\int_{r_H}^{R}\sqrt{k^2(r,l,E)}drdl. \tag{18}$$

Here it is understood that the integration with respect to $r$ and $l$ is taken over those values which satisfy $r_H \leq r \leq R$ and $k^2(r,l,E) \geq 0$. Thus one finds

$$\frac{dn(E)}{dE} = \frac{1}{8\pi^2}\int d\theta d\bar{\phi}\int_{r_H}^{R}dr\left(-g^{tt}\right)^{\frac{3}{2}}\sqrt{g_{rr}g_{\theta\theta}g_{\phi\phi}}\frac{1}{3}\frac{d}{dE}\left(h^3\,(E/E_P)\,E^3\right). \tag{19}$$

In proximity of the horizon, the free energy can be approximated by

$$F_{r_H} = \frac{1}{8\pi^2\beta}\int d\theta d\bar{\phi}\int_0^\infty \ln\left(1-e^{-\beta E}\right)\frac{d}{dE}\left(\frac{1}{3}h^3\,(E/E_P)\,E^3\right)H\,(r_H,r_1)\,dE \tag{20}$$

where we have defined

$$H\,(r_H,r_1) = \int_{r_H}^{r_1}dr\left(-g^{tt}\right)^{\frac{3}{2}}\sqrt{g_{rr}g_{\theta\theta}g_{\phi\phi}}. \tag{21}$$

$F_{r_H}$ can be further reduced to

$$F_{r_H} \simeq \frac{C\,(r_H,\theta)}{8\pi^2\beta}\int_0^\infty\frac{\ln\left(1-e^{-\beta E}\right)}{\sigma\,(E/E_P)}\frac{d}{dE}\left(\frac{1}{3}h^3\,(E/E_P)\,E^3\right)dE, \tag{22}$$

where

$$C\,(r_H,\theta) = \int d\theta d\bar{\phi}\left[\frac{\left(r_H^2+a^2\right)^4\sin\theta}{r_H\left(r_H-r_-\right)^2\Sigma_H}\right] \tag{23}$$

and where we have assumed that, in proximity of the throat the brick wall can be written as $r_0\left(E/E_P\right)=r_H\sigma\left(E/E_P\right)$ with

$$\sigma\left(E/E_P\right)\to 0, \qquad E/E_P\to 0. \tag{24}$$

With an integration by parts one finds

$$\begin{aligned} F_{r_H} &= -\frac{C\left(r_H,\theta\right)}{24\pi^2\beta}\int_0^\infty \frac{E^3h^3\left(E/E_P\right)}{\sigma\left(E/E_P\right)} \\ &\times\left[\frac{\beta}{\left(\exp\left(\beta E\right)-1\right)}-\frac{\ln\left(1-e^{-\beta E}\right)}{E_P\sigma\left(E/E_P\right)}\sigma'\left(E/E_P\right)\right]dE. \end{aligned} \tag{25}$$

It is possible to show that

$$\begin{aligned} F_{r_H} &= -\frac{C\left(r_H,\theta\right)}{24\pi^2\beta}\int_0^\infty\left[\frac{\beta E e^{-3E/E_P}}{\left(\exp\left(\beta E\right)-1\right)}-2e^{-3E/E_P}\ln\left(1-e^{-\beta E}\right)\right]dE \\ &= -\frac{C\left(r_H,\theta\right)}{24\pi^2\beta}\left[\zeta\left(2,1+\frac{3}{\beta E_P}\right)+\frac{\beta E_P}{3}\left(\gamma+\Psi\left(1+\frac{3}{\beta E_P}\right)\right)\right], \end{aligned} \tag{26}$$

where $\zeta\left(s,\nu\right)$ is the Hurwitz zeta function, $\Gamma\left(x\right)$ is the gamma function and $\Psi\left(x\right)$ is the digamma function. In the limit where $\beta E_P\gg 1$, at the leading order, one finds that the entropy can be approximated by

$$S=\beta^2\frac{\partial F_{r_w}}{\partial\beta}=\frac{E_P^2}{36\beta}\int d\theta d\bar{\phi}\left[\frac{\left(r_H^2+a^2\right)^4\sin\theta}{r_H\left(r_H-r_-\right)^2\Sigma_H}\right] \tag{27}$$

and even when rotation is included, the "*brick wall*" does not appear. Of course the entropy (27) can always be cast in the familiar form

$$S=\frac{A_H}{4G}, \tag{28}$$

where $A_H$ is the horizon area. To summarize, we have shown that the ability of Gravity's Rainbow to keep under control the UV divergences applies also to rotations. However the connection between a ROI and a ZAMO has to be investigated with care[24]. Indeed in the ROI frame, the superradiance phenomenon appears, while in the ZAMO frame does not. Once the connection is established nothing forbids to extend this result to other rotating configuration like, for example, Kerr-Newman or Kerr-Newman-De Sitter (Anti-De Sitter).

# Gravitational perturbation in holography between rotating black holes and conformal field theory

Masoud Ghezelbash

*www.usask.ca*

The holography for rotating black holes provides a description of black hole physics in terms of a certain two-dimensional conformal field theory (CFT). The first realization of the holography for rotating black holes was proposed for extremal Kerr black hole. The proposal states that the near horizon geometry of the extremal Kerr black hole does have a dual holographic description in terms of a two-dimensional chiral CFT. The proposal has been studied and extended extensively for other extremal or near extremal rotating black holes. For all extremal and near-extremal black holes in different dimensions, the physical quantities associated to black hole (such as the entropy or scattering cross section) are in agreement with the corresponding microscopic dual quantities in CFT. In this talk, we find the explicit form of two-point function for the conformal spin-2 energy momentum operators on the near horizon of a near extremal Kerr black hole by variation of a proper boundary action. In this regard, we consider an appropriate boundary action for the gravitational perturbation of the Kerr black hole. We consider the boundary action and calculate it on-shell to find the two-point functions for the spin-2 energy momentum tensor fields, on the near horizon region of the Kerr black hole. We show that the variation of the boundary action with respect to the boundary fields yields the two-point function for the energy momentum tensor of a conformal field theory. We find agreement between the two-point function and the correlators of the dual conformal field theory to the Kerr black hole.*

*Keywords*: Gravitational perturbation, Kerr black hole, Kerr/CFT correspondence.

## 1. Introduction

Inspired by the fact that near horizon region of a near extremal Kerr black hole contains a two dimensional copy of Anti de Sitter[1], a field theoretic calculation can be done to find the two-point correlation functions of conformal fields with different spin. Explicitly, in Ref. 2, the two-point correlation functions of spinor fields were constructed by calculating the on-shell gravitational action for the spinor fields with appropriate boundary condition. Though the on-shell bulk action for the spinor fields vanishes, however one can add a boundary term to the gravitational action which does not vanish on-shell[3]. The variation of the boundary action yields the proper two-point correlation functions for the conformal operators. In a recent article, Ref. 4, the authors used an appropriate boundary action for the vector fields to calculate the two-point functions of conformal vector fields. In this article, we derive the two-point function for the energy-momentum tensor fields in the

*This presentation is entirely based on published paper in the journal *Gen. Relativ. Gravit.* **48**, 102 (2016) by A.M. Ghezelbash.

background of Kerr black hole. The first step is to find an appropriate boundary action for the spin-2 fields. In this regard, we write the Einstein-Hilbert action as the summation of two actions. The first action is a bulk action that unlike the Einstein-Hilbert action depends only on the metric tensor and its first derivative. Although the bulk action is not a scalar under the general coordinate transformations, however it leads to the same Einstein's field equations. The second action is a boundary action that depends on the metric tensor and the Christoffel symbols. We consider the boundary action and calculate it on-shell to find the two-point functions for the spin-2 energy momentum tensor fields, on the near horizon region of the Kerr black hole. We then compare the result of our calculation to the correlation functions for spin-2 conformal operators in a conformal field theory.

## 2. The Gravitational Perturbations and the Boundary Action for Them in the Rotating Black Hole

We consider the gravitational action for a general four-dimensional curved spacetime $\mathcal{M}$ with a boundary $\partial M$ as $S = S_{EH} + S_{GH}$, where $S_{EH} = \frac{1}{16\pi}\int_{\mathcal{M}} d^4x\sqrt{-g}R$ and $S_{GH} = \frac{1}{8\pi}\int_{\partial\mathcal{M}} d^3x\sqrt{k}K$ is the Gibbons-Hawking boundary action. $k_{\mu\nu}$ is the induced metric on the boundary $\partial\mathcal{M}$ and $K = \nabla_\mu N^\mu$ is the trace of extrinsic curvature and $N^\mu$ is the unit normal vector to $\partial\mathcal{M}$. We may use the following identity

$$S_{EH} = S_1 + \frac{1}{16\pi}\int_{\partial M} d^3x\sqrt{-g}N_\mu\{g^{\mu\nu}\Gamma^\sigma_{\nu\sigma} - g^{\sigma\nu}\Gamma^\mu_{\sigma\nu}\}, \tag{1}$$

where

$$S_1 = \frac{1}{16\pi}\int_{\mathcal{M}} d^4x\sqrt{-g}g^{\mu\nu}\{\Gamma^\tau_{\mu\nu}\Gamma^\sigma_{\tau\sigma} - \Gamma^\tau_{\mu\sigma}\Gamma^\sigma_{\tau\nu}\}, \tag{2}$$

to write $S_{EH}$ as the summation of a bulk action that depends only on the metric field and the first order derivatives of the metric field and a boundary term. In fact, The bulk action $S_1$ clearly depends on the gravitational field and its first derivatives and resembles to the action for a scalar field or spinor or electromagnetic field that only depends on dynamical field and its first derivatives. We consider the gravitational action $\mathcal{S}$ for the four-dimensional curved spacetime $\mathcal{M}$ with a boundary $\partial\mathcal{M}$ as[5]

$$\mathcal{S} = \frac{1}{16\pi}\int_{\mathcal{M}} d^4x\sqrt{-g}g^{\mu\nu}\{\Gamma^\tau_{\mu\nu}\Gamma^\sigma_{\tau\sigma} - \Gamma^\tau_{\mu\sigma}\Gamma^\sigma_{\tau\nu}\} + S_B, \tag{3}$$

where

$$S_B = \frac{1}{16\pi}\int_{\partial\mathcal{M}} d^3x\sqrt{-g}N_r\{g^{r\nu}\Gamma^\sigma_{\nu\sigma} - g^{\sigma\nu}\Gamma^r_{\sigma\nu}\}. \tag{4}$$

We consider $\mathcal{M}$ as the near extremal Kerr black hole and use the boundary action (4) to calculate the two-point functions of spin 2 gravitational perturbation fields $\tilde{h}_{\mu\nu}$ on the near-horizon geometry of the near extremal black hole where $g_{\mu\nu} = g^{(0)}_{\mu\nu} + \epsilon\tilde{h}_{\mu\nu}$

and $g^{(0)}_{\mu\nu}$ describes the Kerr black hole which the line element in Boyer-Lindquist coordinates is given by

$$ds^2 = -\frac{\Delta}{\rho^2}\left(dt - a\sin^2\theta d\phi\right)^2 + \frac{\rho^2}{\Delta}dr^2 + \rho^2 d\theta^2 + \frac{\sin^2\theta}{\rho^2}\left(adt - \left(r^2+a^2\right)d\phi\right)^2, \quad (5)$$

where $\rho^2 = \bar{\rho}\bar{\rho}^*$, $\bar{\rho} = r + ia\cos\theta$ and $\Delta = r^2 + a^2 - 2Mr$. We should note that in (4), $\partial\mathcal{M}$ is the hypersurface $r = r_B$ which is the near-horizon of near-NHEK geometry for the Kerr black hole. Moreover the field $\tilde{h}_{\mu\nu}$ is the spin 2 field which represents the gravitational perturbation of the Kerr black hole (5). The explicit representation of the different components of $\tilde{h}_{\mu\nu}$ is given in Ref. 5. In fact, a detailed analysis of the gravitational perturbation fields shows that we can represent the fields $\tilde{h}_{\mu\nu}$ as the real parts of $\mathbf{h}_{\mu\nu}$, where[5]

$$\mathbf{h}_{\mu\nu}(t, r, \theta, \phi) = h_{\mu\nu}(r, \theta)e^{-i\omega t + im\phi}, \quad (6)$$

and

$$h^{\mu\nu} = \sum_{i,j=+,-} f^{\mu\nu}_{ij}(r, \theta)P_i(r)S_j(\theta), \quad (7)$$

where

$$f^{\mu\nu}_{ij} = f^{\mu\nu(-1)}_{ij}\Delta^{-1} + f^{\mu\nu(0)}_{ij}\Delta^0 + \cdots. \quad (8)$$

In equation (7), $P_\pm(r)$ and $S_\pm(\theta)$ are related to the radial and angular Teukolsky functions, respectively[5]. We notice that the presence of $\rho$ in all components of the graviton $h^{\mu\nu}$, makes the results (8) completely non-separable in terms of coordinates $r$ and $\theta$. However, in calculation of the boundary action, we consider a spherical boundary with radius $r_B$ as the boundary of the near-NHEK geometry. We set the radial coordinate in $\rho$ equal to $r_B$ and so $\rho_B = \rho(r = r_B)$ depends only on $\theta$. As a result, we check out explicitly that any single term in the expansion (7) is completely separable in terms of coordinates $r$ and $\theta$. In other words, we can re-write (7) as

$$h^{\mu\nu} = \sum_{i,j=+,-} \chi_i \sum_{\aleph} f^{\overline{\mu\nu}}_{1ij\aleph}(r) f^{\overline{\mu\nu}}_{2ij\aleph}(\theta)R_i(r)S_j(\theta), \quad (9)$$

where $\chi_+ = \Delta_B$, $\chi_- = 1$, the over-line means that there is no summation over superscripts $\mu$ and $\nu$. The summation index $\aleph$ in (9) shows all the individual terms that appear in expansion (8). After a long calculation, we can show that the only relevant terms in the boundary action (4) that lead to the proper two-point function are given by[5]

$$S^{(2)}_B = \int_{r=r_B} d^3x\sqrt{-g^{(0)}}N_r \left\{ g^{(0)r\nu}\Gamma^{(2)\sigma}_{\nu\sigma} + \Gamma^{(1)\sigma}_{\nu\sigma}\left(\frac{1}{2}g^{(0)r\nu}\tilde{h} - \tilde{h}^{r\nu}\right) + \Gamma^{(0)\sigma}_{\nu\sigma}\left(-\frac{1}{2}\tilde{h}\tilde{h}^{r\nu} + \frac{g^{(0)r\nu}}{8}(\tilde{h}^2 - \tilde{h}_{\rho\lambda}\tilde{h}^{\rho\lambda})\right)\right\}, \quad (10)$$

where $\Gamma^{(i)\rho}_{\mu\nu}$, $i=0,1,2$ are the expansion coefficients of the Christoffel affine connection in terms of $\epsilon$, as $\Gamma^{\rho}_{\mu\nu}=\Gamma^{(0)\rho}_{\mu\nu}+\epsilon\Gamma^{(1)\rho}_{\mu\nu}+\epsilon^2\Gamma^{(2)\rho}_{\mu\nu}$. After some substitutions and showing the $(t,\phi)$-dependence of the boundary fields by $\mathcal{H}^{\alpha\beta}_{B+}(t,\phi)$ and rewriting the boundary field $h^{\alpha\beta}_{B+}$ as

$$h^{\alpha\beta}_{B+}(t,\theta,\phi)=\mathcal{H}^{\overline{\alpha\beta}}_{B+}(t,\phi)\Theta^{\overline{\alpha\beta}}_{\pm}(\theta), \tag{11}$$

where $\mathcal{H}^{\overline{\alpha\beta}}_{B+}(t,\phi)$ is equal to $\Delta_B e^{-i\omega t+im\phi}R_{B+}$ for $\alpha,\beta=t,r,\theta,\phi$ and

$$\Theta^{\overline{\alpha\beta}}_{\pm}=\sum_{\aleph}[f^{\overline{\alpha\beta}}_{1+\pm\aleph}(r_B)f^{\overline{\alpha\beta}}_{2+\pm\aleph}(\theta)]S_{\pm}(\theta), \tag{12}$$

we find that the boundary action (10) becomes

$$S^{(2)}_B=\frac{1}{\Delta^2_B}\int_{r=r_B}d^3x\sqrt{-g}N_r\Big\{[F^{-+*}_{++}(\theta)\Theta^{\overline{\alpha\beta}*}_{+}+F^{--*}_{+-}(\theta)\Theta^{\overline{\alpha\beta}*}_{-}](\Psi_B)_{\alpha\beta\gamma\delta}(r_B,\theta)$$
$$\times[F^{-+}_{++}(\theta)\Theta^{\overline{\gamma\delta}}_{+}+F^{--}_{+-}(\theta)\Theta^{\overline{\gamma\delta}}_{-}]\frac{R^*_-(r_B)R_-(r_B)}{R^*_{B+}R_{B+}}\mathcal{H}^{\overline{\alpha\beta}*}_{B+}(t,\phi)\mathcal{H}^{\overline{\gamma\delta}}_{B+}(t,\phi)+c.c.\Big\}. \tag{13}$$

In equation (13), $(\Psi_B)_{\alpha\beta\gamma\delta}(r_B,\theta)$ denotes

$$(\Psi_B)_{\alpha\beta\gamma\delta}(r_B,\theta)=\Big\{-\frac{g^{rr}}{8}\partial_r(g_{\alpha\gamma}g_{\beta\delta})+\frac{g^{rr}(\beta+3/2)}{8r_B}$$
$$\times\left(\frac{1}{2}g_{\alpha\beta}g_{\gamma\delta}-g_{\alpha\gamma}g_{\beta\delta}-\frac{g^r_\alpha g^r_\beta g_{\gamma\delta}}{g^{rr}}\right)+\frac{1}{8}\left(g^r_\alpha g^r_\beta-\frac{1}{2}g^{rr}g_{\alpha\beta}\right)g_{\delta\gamma,r}$$
$$-\frac{1}{16}g^{\sigma\lambda}g_{\sigma\lambda,r}g_{\alpha\beta}g^r_\gamma g^r_\delta+\frac{g^{rr}}{64}g^{\sigma\lambda}g_{\sigma\lambda,r}(g_{\alpha\beta}g_{\gamma\delta}-g_{\alpha\delta}g_{\beta\delta})\Big\}|_{r=r_B}, \tag{14}$$

and the $\theta$-dependent functions $F^{-+}_{++}$ and $F^{--}_{+-}$ are give by

$$F^{-+}_{++}(\theta)=\frac{\sum_{\aleph}f^{\overline{\mu\nu}}_{1-+\aleph}(r_B)f^{\overline{\mu\nu}}_{2-+\aleph}(\theta)}{\sum_{\aleph}f^{\overline{\mu\nu}}_{1++\aleph}(r_B)f^{\overline{\mu\nu}}_{2++\aleph}(\theta)}, \tag{15}$$

and

$$F^{--}_{+-}(\theta)=\frac{\sum_{\aleph}f^{\overline{\mu\nu}}_{1--\aleph}(r_B)f^{\overline{\mu\nu}}_{2--\aleph}(\theta)}{\sum_{\aleph}f^{\overline{\mu\nu}}_{1+-\aleph}(r_B)f^{\overline{\mu\nu}}_{2+-\aleph}(\theta)}, \tag{16}$$

respectively[5]. We can find now the two-point function of the boundary energy-momentum tensor operators $\mathcal{O}_{\alpha\beta}$ by taking the functional derivative of the action (10) with respect to the rescaled boundary gravitational field $\hat{\mathcal{H}}^{\alpha\beta}_{B+}$ as $<\mathcal{O}_{\alpha\beta}\mathcal{O}_{\gamma\delta}>=\frac{\delta^2S^{(2)}_B}{\delta\hat{\mathcal{H}}^{\alpha\beta}_{B+}\delta\hat{\mathcal{H}}^{\gamma\delta}_{B+}}$. We get the result as

$$<\mathcal{O}_{\alpha\beta}\mathcal{O}_{\gamma\delta}>=\frac{\delta^2S^{(2)}_B}{\delta\hat{\mathcal{H}}^{\alpha\beta}_{B+}\delta\hat{\mathcal{H}}^{\gamma\delta}_{B+}}=r_B^{2\beta-8}\frac{\left(R^B_-\right)^*R^B_-}{\left(R^B_+\right)^*R^B_+}\mathcal{F}_{\alpha\beta\gamma\delta}, \tag{17}$$

where all the factors are given explicitly in Ref. 5. Using the explicit form of Teukolsky radial functions, we find

$$< \mathcal{O}_{\alpha\beta}\mathcal{O}_{\gamma\delta} >= M^8 r_B^{2\beta-8}\mathcal{F}_{\alpha\beta\gamma\delta}\left\{1+M^{-2\beta}\frac{\mathcal{N}}{\mathcal{C}}G_R^*+M^{-2\beta}\frac{\mathcal{N}}{\mathcal{C}^*}G_R+\mathcal{N}M^{-4\beta}|G_R|^2\right\}, \tag{18}$$

where the function $G_R$ is given by[5]

$$G_R = T_R^{2\beta}\frac{\Gamma(-2\beta)\Gamma(\beta-3/2-im)\Gamma(1/2+\beta-i(n-m))}{\Gamma(2\beta)\Gamma(5/2-\beta-im)\Gamma(1/2-\beta-i(n-m))}, \tag{19}$$

and $\mathcal{C}=(\bar{\lambda}-2m^2-2im\beta)(\bar{\lambda}-2m^2-2im\beta+2)$. As we notice, the second and third terms in bracket in equation (18) are complex conjugate of each other and so we find a real-valued two-point function for the boundary conformal operators. However according to similar analysis in References 2 and 4, we can drop the second term in (18) to find a complex-valued two-point function for the boundary conformal operators. The main physical reason to drop the second term in (18) and so find a complex-valued two-point function, is that we can find the absorption cross section of spin 2 fields (using the optical theorem), only from a complex-valued two-point function (19). We also notice that the coefficient $\frac{\mathcal{N}}{\mathcal{C}^*}$ of term $G_R\mathcal{F}_{\alpha\beta\gamma\delta}$ in (18) depends on the momentum. However it is not a part of the two-point function (19). Moreover, similar momentum-dependent coefficients have been found for the two-point functions of other spins, such as spin-1/2 operators[2] as well as spin-1 operators[4]. Moreover, we note that the first term in bracket in equation (18) is just a constant contact term, compared to the third term that is proportional to $G_R$. In general, such contact terms can be cancelled by adding a proper counter term to the boundary action. The effect of adding the counter term is just to cancel out the constant contact term in (18) and we do not expect any changes in the two-point function $G_R\mathcal{F}_{\alpha\beta\gamma\delta}$. The last term in (18) is very small compared to the third term, since the ratio of the last term to the third term is proportional to $(\frac{\tau_H}{M})^{2\beta}$ where $\tau_H \to 0$[5]. Hence we conclude that the field theoretical two-point function for spin-2 conformal operators $\mathcal{O}_{\alpha\beta}$ on the boundary can be described by $G_R\mathcal{F}_{\alpha\beta\gamma\delta}$. The retarded Green's functions for fields with different spins were proposed in References 6 and 7. We note that $G_R$, as a part of two-point function $G_R\mathcal{F}_{\alpha\beta\gamma\delta}$ for the boundary conformal operators, is in perfect agreement with the proposed retarded Green's function for spin-2 fields. We also find that the absorption cross section of fields (with spin 2) is in exact agreement with the result of Reference 8 if we apply the optical theorem to the retarded Green's function (19).

The finite temperature two-point function of scalars[6,7], spin-1/2 fermions[2] as well as spin-1 fields[4] are given by

$$\langle\mathcal{O}\mathcal{O}\rangle \sim \left(\frac{\pi T_R}{\sinh\left(\pi T_R t_{12}^+\right)}\right)^{2h_R}\left(\frac{\pi T_L}{\sinh\left(\pi T_L t_{12}^-\right)}\right)^{2h_L}, \tag{20}$$

by proper identification of left and right conformal weights $h_L$ and $h_R$, where $1/T_L$ and $1/T_R$ are the circumferences of two fundamental circles of a torus. The Fourier

transform of the two-point function (20) is given by

$$\mathcal{F}(\langle\mathcal{O}\mathcal{O}\rangle) \sim {T_R}^{2\beta} \frac{\Gamma(1-2h_R)\,\Gamma(1-2h_L)}{\Gamma(1-h_R-in_R)\,\Gamma(1-h_R+in_R)\,\Gamma(1-h_L-in_L)\,\Gamma(1-h_L+in_L)}, \tag{21}$$

where $n_R$ and $n_L$ stand for $\frac{i\omega_R}{2\pi T_R}$ and $\frac{i\omega_L}{2\pi T_L}$ respectively. If we consider the conformal weights $h_R = \beta + 1/2$ and $h_L = \beta - 3/2$ for spin-2 operators, we then find

$$\mathcal{F}(\langle\mathcal{O}\mathcal{O}\rangle) \sim {T_R}^{2\beta} \frac{\Gamma(-2\beta)\,\Gamma(1/2+\beta-in_R)\,\Gamma(\beta-3/2-in_L)}{\Gamma(1/2-\beta-in_R)\,\Gamma(-\beta+5/2-in_L)\,\Gamma(2\beta)}. \tag{22}$$

Moreover, we consider $n_L = m$ and $n_R = n - m$ in (22) and find an exact agreement with the retarded Green's function (19) that we found as a part of two-point function for spin-2 operators.

## 3. Conclusions and Acknowledgements

The energy-momentum tensor operator of the CFT that is dual to the near extremal Kerr black hole, couples to the gravitational boundary fields with spin-2, on the near horizon of near extremal Kerr black hole. Hence we can find the two-point function of the energy-momentum tensor operator, by finding the explicit form of a boundary action that is bilinear in the boundary fields. In this article, we construct explicitly such a boundary action and vary the action with respect to the boundary fields. We derive the explicit expression for the two-point function and note that the two-point function factorizes into two terms. We show that the result for the two-point function is in agreement with correlation functions of spin-2 conformal operators in a dual CFT. We also note that one part of the result heavily depends on the gauge choice, that we made on fixing some of the Weyl scalars. Investigation about the gauge dependence of the two-point function would be an interesting project. Moreover, deriving the two-point function of the energy-momentum tensor operator with the primary fields of the dual CFT would be useful to establish a stronger field-theoretic approach to Kerr/CFT correspondence. The authoe would like to acknowledge the financial support by the Natural Sciences and Engineering Research Council of Canada.

In this article, we will discuss a Lorentzian sector calculation of the entropy of a minimally coupled scalar field in the Schwarzschild black hole background using the brick wall model of G 't Hooft. In the original article, the Wentzel-Kramers-Brillouin (WKB) approximation was used. In this article, we will consider the entropy for a thin shell of matter field of a given thickness surrounding the black hole horizon. The thickness is chosen to be large compared with the Planck length and is of the order of the atomic scale. The corresponding leading-order entropy of the scalar field is found to be proportional to the area of the horizon and is logarithmically divergent. Thus, the entropy of a three-dimensional system in the near-horizon region is proportional to the boundary surface. The leading order entropy is a decreasing function of the the thickness of the thin shell. This is also valid for the sub-leading terms.

*Keywords*: Scwarzschild black hole, scalar field entropy, brick wall model, area law, logarithmic divergence, entropy bound.

## 1. Introduction

Since the four laws of black hole mechanics were formulated[1], there has been much effort to relate the laws of black hole mechanics to those of thermodynamics. The area theorem led Bekenstein to assign an entropy to a black hole[2]. Hawking established the thermodynamical aspects of black holes by showing that a black hole can radiate like a hot body at a temperature equal to a multiple of the surface gravity of the horizon[3]. The entropy of a black hole, considered as a thermodynamical system, was found to be $\frac{A}{4}$. Here $A$ is the area of the horizon.

We have to consider quantum field theory in curved spaces in most of the works related to black hole thermodynamics. In flat space, a uniformly accelerated observer detects a thermal spectrum when the field is in the Minkowski vacuum[4,5]. The temperature is dependent on the proper acceleration of the observer. A corresponding situation arises in the Schwarzschild black hole for a static observer outside the event horizon. The temperature is the same as that of the black hole if the static observer is at a large distance from the horizon[3,6]. In this article we will discuss the expression of the entropy of a minimally coupled massless scalar field in a Schwarzschild black hole in thermal equilibrium with the black hole. The expression is derived by us in a series of articles[7–9]. We have used a model proposed by G. 't Hooft known as the brick wall model and used the Wentzel−Kramers−Brillouin (WKB) approximation to count the states[10]. We can define a thermal equilibrium between a black hole and black body radiation of a massless scalar field surrounding the black hole at the same temperature as that of the black hole. The amount of radiation absorbed and emitted by the black hole is the same. Divergences appear

when we try to calculate the entropy of the scalar field[7,10]. This is associated with the continuous energy spectrum and unboundedness of the allowed angular quantum numbers in the near-horizon region. To regulate the divergence, 't Hooft proposed a boundary condition on the scalar field near the horizon[9]. He assumed the scalar field to be vanishing at a small distance away from the horizon. This radial parameter is known as the brick wall cut-off parameter. This boundary condition is a good model since in thermodynamic equilibrium there is no net interchange of particles between the black hole and the surrounding matter. The details can be found in[7,8]. The expression of the entropy is found to be logarithmically divergent in the brick wall cut-off parameter. The metric component $g_{rr}$ has a simple pole at the horizon. The WKB quantization rule indicates that the divergence is expected to be logarithmic. In the Schwarzschild black hole, we can also use the blueshift factor together with the form of the proper distance in the near-horizon region to understand this logarithmic divergence. The thickness of the thin shell takes care of the unbounded nature of the allowed angular quantum numbers. The expression of the entropy obtained by us is proportional to the area of the horizon when we take the temperature to be same as the Hawking temperature. The entropy is also found to be a decreasing function of the thickness of the thin shell. These aspects may be taken to be the semiclassical signs of a holography principle and entropy bound. Here the semiclassical theory refers to quantum field theory in a fixed background. The expressions obtained in this article are also significant in the context of entanglement entropy and the Euclidean approach to calculate the matter field entropy in a black hole background. We will discuss these aspects and the significance of the results obtained in this article in Sect. 2.

## 2. Entropy of a Thin Shell of Scalar Field in the Schwarzschild Black Hole

In this section we will consider the entropy of a minimally coupled scalar field in the Schwarzschild black hole. We will discuss the case of a massless field but the results can be easily extended for a massive case[7,8]. We will follow the method discussed in[7–9] and consider a thin shell of scalar field surrounding the horizon. We found earlier that in the spherical polar coordinates, the WKB approximation is suitable for a thin shell of scalar field[7,8]. Since the near-horizon region gives us interesting physics, we proceed to discuss the entropy of a thin shell of scalar field confined in the near-horizon region. The metric of the Schwaarzschild black hole is given by:

$$ds^2 = -\left(1 - \frac{2M}{r}\right) dt^2 + \frac{dr^2}{(1 - \frac{2M}{r})} + r^2(d\theta^2 + \sin^2\theta d\phi^2) \tag{1}$$

Here $M$ is the mass of the black hole defined with respect to an asymptotic observer. The wave equation of a minimally coupled massless scalar field in a curved space is given by the following expression:

$$(-g)^{-\frac{1}{2}} \partial_\mu [(-g)^{\frac{1}{2}} g^{\mu\nu} \partial_\nu \psi] = 0 \tag{2}$$

The wave equation is separable in the Schwarzschild black hole and we can take the basis function to be of the following form[7,8,10]:

$$f(l,m,E|x) = NR(r)P_l(\cos\theta)e^{im\phi}e^{-iEt} \tag{3}$$

Where, $l$ is the angular momentum quantum number and $E$ is the energy defined with respect to an asymptotic observer, $P_l(\cos\theta)$ are the Legendre polynomials and $R(r)$ satisfies the radial wave equation:

$$\left(1-\frac{2M}{r}\right)^{-1}E^2R(r)+\frac{1}{r^2}\partial_r[r(r-2M)\partial_rR(r)]-\frac{l(l+1)}{r^2}R(r)=0. \tag{4}$$

We use the WKB approximation to solve the above equation. This is a good approximation if we consider a thin shell of scalar field in the near-horrizon region[7–9]. We impose the brick wall boundary condition[10]:

$$R(2M+h)=0. \tag{5}$$

where, $h$ is a small radial parameter compared to $2M$ whose value will be discussed later. We can consider the scalar field to be confined in a half-infinite potential well in the near-horizon region[7,8]. The trial solutions are assumed to be of the form $\rho(r)\exp[iS(r)]$. The actual solutions are sinusoidal functions to satisfy the boundary conditions. In the near-horizon region, the radial wave function takes the following form:

$$R_l(r)\sim\exp\left[i\int k(r)dr\right] \tag{6}$$

Here, the $r$-dependent radial wave number is given by the following expression:

$$k(r)=\frac{1}{V(r)}\sqrt{E^2-\frac{V(r)}{r^2}l(l+1)} \tag{7}$$

To implement the thin shell boundary condition, we consider solutions that vanish at the brick wall and are stationary up to a certain value $'d'$ of the radial coordinate. We have the condition: $h << d << 2M$. The radial quantum number is given by the WKB quantization rule:

$$\pi n_d=\int_{2M+h}^{2M+d}dr\ k(r,l,E)\ . \tag{8}$$

To evaluate $n_d$, we have to ensure that the wave number is real throughout the range of the radial integral for each value of $E, l$ present in its argument. This gives an upper limit on the allowed values of $l$ given by[7,8]:

$$L(L+1)=\frac{E^2(2M+d+h)^3}{d+h}\approx\frac{8E^2M^3}{d} \tag{9}$$

The free energy of the thin shell can be obtained from the expression:

$$\pi\beta F = -\int_0^\infty \frac{\beta dE}{[\exp(\beta E)-1]} \int_{2M+h}^{2M+d} \frac{dr}{V(r)} \int_0^L dl(2l+1)\sqrt{E^2 - \frac{V(r)}{r^2}[l(l+1)]}. \tag{10}$$

The entropy of a scalar field confined within the near horizon region and as predicted by an observer at infinity is given by[8]:

$$S = \frac{1}{30}\ ln\left(\frac{\epsilon_d}{\epsilon_h}\right)\ \frac{A}{4\pi{\epsilon_d}^2}\ . \tag{11}$$

The corresponding expression in the Kerr black hole is given by the following expression[7]:

$$S' = \frac{1}{60}\ ln\left(\frac{\epsilon_d}{\epsilon_h}\right)\ \frac{A}{4\pi{\epsilon_d}^2}\ . \tag{12}$$

The temperature in both the cases are taken to be the Hawking temperature of the corresponding black holes. Here $\epsilon_x$ represents the proper radial variable: $\epsilon_x = \int_{r_h}^{r_h+x}\sqrt{g_{rr}}\ dr$, $r_h$ is the event horizon. 'A' represents the area of the horizon. The entropy of the scalar field in the Kerr black hole is half of the corresponding value in the Schwarzschild black hole. This is due to rotation and is consistent with the preferential emission of particles in the Kerr black hole with azimuthal angular momentum in the same direction as that of the black hole itself. The Lorentzian sector calculation of the scalar field entropy in the Kerr black hole is more significant since the corresponding Euclidean sector literature is not well formulated[11]. The expressions of the scalar field entropy contain two free parameters, the proper thickness of the thin shell and the proper brick wall cut-off parameter. We take the proper thickness of the thin shell to be of the order of atomic lengths. The other undetermined parameter is the proper brick wall cut-off. 't Hooft wanted to explain the black hole entropy in terms of the near horizon part of the matter field entropy and equated the two[9]. If we do so, the internal energy turns out to be finite: $U = \frac{3}{8}M$. This also determines the proper brick wall cut-off parameter. In the present case we then have:

$$\epsilon_h = (\epsilon_d)\exp\left[-30\pi\ \left(\frac{\epsilon_d}{l_p}\right)^2\right]. \tag{13}$$

Where, $l_p$ is the Plack length. If we take $\epsilon_d = 10^{-10}\ cm$, $\epsilon_h$ is given by the following expression in terms of the Planck length: $\epsilon_h \sim [10^{24}]\exp(-10^{50})(l_p)$. Thus, the brick wall is almost coincident with the horizon although the free energy is finite. This is expected since there exists solutions vanishing on the horizon[7,8]. These solutions are consistent with the brick wall boundary condition. We note that even in the extreme case of a thin shell of thickness comparable to the Planck length, the proper brick wall cut-off remains small compared to the thickness. However,

in this case the semiclassical theory of quantum fields in a fixed background may not be appropriate. The back reaction problem is discussed in detail by Candelas and is not much important in the present case[12]. These discussions may become significant in the context of an entropy bound discussed below.

The scalar field entropy in a Schwarzschild black hole with off mass shell temperature is given by:

$$S = \frac{32s\pi^3}{15{\epsilon_d}^2}(2M)^2\left(\frac{2M}{\beta}\right)^3 ln\left(\frac{\epsilon_d}{\epsilon_h}\right). \tag{14}$$

We find that the entropy is a decreasing function of the proper thickness even when the temperature is not given by the Hawking temperature. We now consider the subleading terms of the scalar field entropy. It can be seen that in the approximation $h << d << 2M$, the complete entropy is given by the following expression,[7]:

$$S = \frac{1}{30\pi{\epsilon_d}^2}\left[ln\left(\frac{\epsilon_d}{\epsilon_h}\right) - \chi\right]\frac{A}{4}, \tag{15}$$

where, $\chi = \frac{1}{4}[1 + \frac{1}{12} + ...] > 0$ and the temperature is given by the Hawking temperature. For $d >> h$, the second term is negligibly small compared with the first term. The complete expression is also a decreasing function of the proper thickness of the thin shell. The leading-order scalar field entropy in a Kerr black hole with off mass shell temperature is given by:

$$S = \frac{16\pi^3}{15}\ \frac{1}{\beta^3}\ \frac{({r_+}^2 + a^2)^4}{(r_+ - r_-)^3}\ \frac{1}{{\epsilon_d}^2}\ ln\left(\frac{\epsilon_d}{\epsilon_h}\right). \tag{16}$$

Where, $a$ is the angular momentum per unit mass, $r_+$ is the event horizon and $r_-$ is the inner horizon of the black hole. We again find that the entropy is a decreasing function of the proper thickness even when the temperature is not given by the Hawking temperature. The leading order entropy is a decreasing function of the proper thickness when the temperature is given by the corresponding Hawking temperature. This is obvious from Eq. (12).

We find that the entropy is a decreasing function of the proper thickness even when the temperature is not given by the Hawking temperature. Thus, we may conjecture that *the entropy of a scalar field in an asymptotically flat black hole background which is correlated with the horizon through the brick wall boundary condition has an upper bound and this upper bound is proportional to the horizon surface area when the temperature is taken to be the Hawking temperature.* It may require a quantum theory of gravity to fix the exact magnitude of the upper bound. In this article we have chosen the upper bound to be the same as the black hole entropy itself. This conclusion is expected to remain valid for the semiclassical theory of quantum fields in curved spaces where back reaction problem is not severe. We can further verify the validity of the present conclusion by considering the spectrum of the solutions of the wave equation defined throughout the manifold and satisfying the brick wall boundary condition. We can use numerical methods for this purpose. These discussions are also important to the holographic principle

in asymptotically flat spaces[13]. Similar discussions will remain valid in presence of the cosmological horizons. The event horizons are two dimensional fixed point sets of the Killing fields[14]. This aspect may be important to explain the results obtained in this article.

The logarithmic divergence in Eq. (11) and Eq. (12) is important to the Euclidean sector calculation of the scalar field entropy[11]. The logarithmic divergence is expected on physical grounds as discussed briefly in the introduction and in detail in[7,8]. The Euclidean sector method contains a parameter which can be fixed by comparing with the Lorentzian sector expression obtained in the present article. Lastly, we can consider the scalar field entropy to give quantum correction to the black hole entropy and use Eq. (11) and Eq. (12) to renormalize the gravitational constant[15].

**E-mail: christine.gruber@uni-oldenburg.de*

The thermodynamics of a self-gravitating gas cloud of particles interacting only via their gravitational potential is an interesting problem with peculiarities arising due to the long-ranged nature of the gravitational interaction. Based on our recent work on the properties of such a configuration, we extend the system to contain a central gravitational field in which the particles are moving, to mimic the potential of a central compact object exerting an external force on the gas cloud. After an introduction to the general problem, including the aforementioned peculiarities and possible solutions, we will discuss the particular properties of the self-gravitating gas in a central field and its thermodynamic analysis.

*Keywords*: Thermodynamics, statistical mechanics; self-gravitating system; central potential.

## 1. Introduction

The topic of thermodynamic systems in the presence of gravity has been discussed in many occasions and forms[1–3], and has raised many questions on how to deal with the long-range effects of gravity in the thermodynamic analysis of systems, where concepts such as the isolation of a system in one or the other regard are important. Non-stationary equilibrium situations, negative heat capacities or simply divergences in the thermodynamic limit have been plaguing the analyses, and the conventional, very successful thermodynamic framework of Boltzmann-Gibbs statistics had to be adapted and modified in order to account for the peculiarities of the thermodynamics of a gravitational system.

Based on a Boltzmann-Gibbs analysis of the self-gravitating gas[4], the statistical analysis and subsequent calculation of thermodynamic properties have been carried out[5] assuming a generalized framework intended to describe a system with non-extensive properties, due to the presence of long-range forces such as gravity. The adopted generalized framework, i.e., Tsallis generalized $q$-statistics, has been developed in order to consider non-extensive effects, entailing an additional parameter $q$ in the statistical analysis.

This work is an extension of these previous investigations which generalizes the self-gravitating gas to a more realistic system featuring a centrally placed compact object, like e.g. a black hole, around which the gas is extending. Due to some peculiarities and open questions, we will not continue using the non-extensive $q$-statistics, but rather return to the conventional Boltzmann-Gibbs statistics, in order to get a first impression of the results. Other generalizations can be thought of, which will be commented on in the last section.

## 2. Statistical mechanics and thermodynamics of a self-gravitating gas

I will briefly review the most important steps in the analysis of a self-gravitating gas[4,5], from the system's properties to the peculiarities of the thermodynamic analysis and some of its outcomes.

The governing force of the self-gravitating gas is the gravitational attraction between its $N$ identical constituent particles which are otherwise moving freely, and thus the Hamiltonian of the system is

$$\mathcal{H} = \mathcal{T} + \mathcal{U} = \sum_{i=1}^{N} \frac{p_i^2}{2m} - Gm^2 \sum_{1 \le i < j \le N} \frac{1}{|\mathbf{q_i} - \mathbf{q_j}|_A}\,, \tag{1}$$

where $G$ is the gravitational constant, $m$ the mass of an individual particle, and $A$ represents a short-range cutoff imposed in order to avoid the unphysical collapse of the system to a point. This Hamiltonian is the basis for a thermodynamic analysis which can be done in principle in different ensembles, like the microcanonical one, where the energy of the system is kept constant, or the canonical one, where instead the temperature is fixed, and energy can be exchanged with a reservoir. In the microcanonical ensemble, the most important thermodynamic quantity from which everything is derived is the entropy, i.e., the logarithm of this sum over microstates $\Omega(E, V, N)$,

$$S = k_B \ln \Omega(E, V, N)\,, \tag{2}$$

where

$$\Omega = \frac{(2\pi m)^{3N/2}}{N!\, h^{3N} \Gamma\left(\frac{3N}{2} + 1\right)} \int d^{3N}q \, \left[E - \mathcal{U}\right]^{3N/2-1}. \tag{3}$$

From the entropy, you can obtain important thermodynamic quantities such as the temperature of the gas, or the equation of state, i.e., the relation between pressure, temperature and volume.

In the case of the canonical ensemble, the starting point is the partition function, defined as

$$Z = \frac{1}{N! h^{3N}} \int d^{3N}q \, d^{3N}p \, \exp_q\left(-\beta \mathcal{H}(\mathbf{p}, \mathbf{q})\right), \tag{4}$$

and everything else is derived from that quantity, like the equation of state. The temperature in this ensemble is fixed, so it cannot be calculated.

Following the definition of these basic thermodynamic functions, calculations can be simplified by the assumption of a weak gravitational interaction, i.e., the gravitational contribution can be treated as a small correction to the ideal gas, and results can be obtained analytically in this case.

Under this additional assumption, further quantities that are of thermodynamic interest can be calculated, like the heat capacity and other response functions of the system. Both equation of state and heat capacity have been calculated and

compared in the framework of Tsallis statistics[5], and the details can be found there.

An important point for further investigations is the question of the statistical framework, which is closely connected to the choice of thermodynamic limit. Tsallis' non-extensive statistics naturally features a modification of the thermodynamic limit, in which the thermodynamic state variables result in convergent functions. In the case the conventional Boltzmann-Gibbs statistics, another modification of the thermodynamic limit has to be adopted[4] in order to obtain convergent results. In the following, we will employ Boltzmann-Gibbs statistics with the modified thermodynamic limit.

## 3. Addition of the central gravitational potential

As a modification to the basic setup of a simple self-gravitating gas many complications can be thought of. The simplest gase perhaps is the addition of a central potential, to model the situation of a self-gravitating gas around a black hole. We will start with the assumption of an external gravitational field caused by a mass $M$ of size $r_S = 2GM/c^2$ in the center of the configuration, restricting the movement of the gas between the radius of the innermost stable circular orbit (ISCO) at $r_{ISCO} = 3r_S$ and infinity. This will make a difference in the integrals contained in the sum over microstates and the partition function, respectively. Moreover, the central potential will have its influence on every particle in the gas. The generalized Hamiltonian thus reads

$$\mathcal{H} = \sum_{i=1}^{N} \frac{p_i^2}{2m} - Gm^2 \sum_{1\leq i<j\leq N} \frac{1}{|\mathbf{q_i} - \mathbf{q_j}|_A} - GmM \sum_{1\leq i<j\leq N} \frac{1}{|\mathbf{q_i} - \mathbf{r}|_A}\,, \qquad (5)$$

with $\mathbf{r}$ denoting the center of mass of the compact object. To simplify calculations, we choose $\mathbf{r} = 0$.

The computational procedures in order to extract the thermodynamic equation of state is fairly analogous to the case of a simple self-gravitating gas, and differs only in the restriction of the range of integration, due to the fact that we consider a ring-like structure, or even a flat two-dimensional disk shape. This restriction will manifest itself in the definition of the virial coefficients $b_i$, which will be slightly different.

The interesting question is whether the modification of the system will lead to differences in the thermodynamic limit, i.e., facilitate the calculation of otherwise divergent functions, or modify the qualitative dependence on the number of particles in the thermodynamic limit. Preliminary results indicate that this is not the case, and that modifications are limited to the virial coefficients of the problem.

## 4. Outlook

We have here discussed the thermodynamic properties of a self-gravitating gas under the influence of a central gravitational field caused by a heavy mass at the

center of the configuration. Basing on the analysis of a self-gravitating gas cloud consisting of ideal particles[4,5], an additional term accounting for the central gravitational potential was added to the analysis, and the resulting thermodynamic state variables were calculated. Preliminary results indicate slight modifications of the state variables, depending on the new parameter, the mass of the central object. The goal is to generalize the analysis of a simple self-gravitating gas to eventually be able to make predictions on the thermodynamic behavior of matter around a compact object, i.e., an accretion disk of sorts.

Besides the inclusion of a central compact object, the gas itself can be modified in its properties, e.g., by considering non-ideal interactions between the particles. This could be accounted for in an exact way by adding additional particle-particle interactions to the Hamiltonian, with the corresponding coupling constant, like for example an electromagnetic charge. The different strengths of gravity and any other interactions that may be added have to be weighed against each other, and approximations could be applied. Another possibility would be to include effective potentials which are used in condensed matter systems, Mie-type potential like the Lennard-Jones case or others, in order to describe different variations of the gas. Investigations in this direction would represent the first steps towards the description of non-ideal fluids in gravitational contexts - either gas clouds of interacting particles, or non-ideal fluids constituting accretion disks or clouds around a central compact object.

Further generalizations include rotation of the system, or charge of the central object. Importantly, these results should then be connected to results of other calculations on accretion disks, in particular the accretion of (charged) dust particles in a spherical shell or torus structure[6].

# Hawking radiation as quantum tunneling phenomenon

Wajiha J. and Rimsha B.

*Department of Mathematics, Division of Science & Technology, University of Education, Lahore-54590, Pakistan*
*wajiha.javed@ue.edu.pk; wajihajaved84@yahoo.com; rimsha.babar10@gmail.com*

We explore the Hawking radiation phenomenon as a tunneling process of charged spin particles through event horizons of some particular black holes. Using the semi-classical WKB approximation to the general covariant wave equations of charged particles, we evaluate the tunneling probabilities of outgoing charged particles. The Hawking temperatures corresponding to these black holes are recovered. By considering the back-reaction effects of the emitted spin particles from black holes, We calculate their corresponding quantum corrections to the radiation spectrum. It is found that this radiation spectrum is not purely thermal due to energy and charge conservation but has some corrections.

*Keywords*: Hawking Radiation; Spin-1 particles; Quantum Corrections.

## 1. Introduction

A realm of space where gravity is so intense that nothing not even light can escape is known as Black Hole (BH). This idea laid by the astronomical pioneer John Michell (1784).[1] The outer surface of a BH is known as *event horizon*. Stephen Hawking (1974) evoked that BHs are not totally black, but they emit thermal radiation,[2] known as *Hawking radiation*. The mass and energy of BH decreases due to the continuous emission of these Hawking radiation, as a result eventually BH evaporates, this phenomenon is know as BH evaporation.

A number of techniques have been introduced to investigate the Hawking radiation spectrum. By taking into account the semi-classical effects, the quantum tunneling approach[3,4] is the most convenient strategy to study these BHs radiation. Quantum tunneling is a process, by which particles have finite probability to cross the event horizon. In order to understand this process their are two main approaches, one of them is *null geodesic technique* proposed by Kraus & Wilczek,[5] while the other one is *Hamilton-Jacobi technique* propounded by Angheben et al.[6] These techniques gives the tunneling probability, i.e., the estimated rate of emitted particles accompanying the classically forbidden trajectories from inside to the outside region of the BH through event horizon. The tunneling probability, $\Gamma$, of outgoing radiated particles can be defined as

$$\Gamma = \exp\left(-\frac{2}{\hbar} Im\mathcal{S}\right), \tag{1}$$

where $\mathcal{S}$ stands for the action of radiated particle and $\hbar$ represents the Planck's constant. Sharif and Javed[7] studied the Hawking radiation process through the quantum tunneling phenomenon for fermion particles from various types of BHs, also they analyzed quantum corrections for regular BHs. The quantum gravity

effects by using generalized uncertainty principle (GUP) have been discussed in literature.[8–14] Javed and Babar[15] investigated Hawking temperature and corrected Hawking temperature for fermions particles. Moreover, Javed et al.[16] analyzed the corrected temperature for spin-0 and spin-1/2 particles for cubic and quartic interactions. In the continuation of previous work, we are going to provide a general formulation of vector particles tunneling for general spherically symmetric rotating BH and investigate its original and corrected Hawking temperature.

## 2. Charged Vector Particles Tunneling

The metric can be defined as

$$ds^2 = -Adt^2 + \frac{1}{B}dr^2 + Cd\theta^2 + Dd\varphi^2 - 2Fdtd\varphi, \tag{2}$$

where the metric functions $A, B, C, D$ and $F$ are depend upon $r$ and $\theta$. One can obtain the event horizon $r_+$ of this BH by considering the horizon equation, $A(r_+, \theta) = 0$. The angular velocity of BH at event horizon is given by

$$\Omega_H = \frac{F(r_+, \theta)}{D(r_+, \theta)}. \tag{3}$$

In order to calculate the tunneling probability of charged spin-1 particles at horizon $r_+$, the required Proca equation can be expressed as[17]

$$\frac{1}{\sqrt{-g}}\partial_\mu\left(\sqrt{-g}\Psi^{\nu\mu}\right) + \frac{\iota}{\hbar}e\tilde{F}^{\nu\mu}\Psi_\mu + \frac{\iota}{\hbar}eA_\mu\Psi^{\nu\mu} + \frac{m^2}{\hbar^2}\Psi^\nu = 0, \tag{4}$$

here $g$ is the determinant of the coefficient matrix and $m$ represents the mass of emitted particle, the $\Psi^{\mu\nu}$ and $\tilde{F}^{\nu\mu}$ are anti-symmetric & electromagnetic field tensors, respectively, which are given by

$$\Psi_{\nu\mu} = \partial_\nu\Psi_\mu - \partial_\mu\Psi_\nu - \frac{\iota}{\hbar}eA_\mu\Psi_\nu + \frac{\iota}{\hbar}eA_\nu\Psi_\mu\ , \qquad \tilde{F}^{\nu\mu} = \nabla^\nu A^\mu - \nabla^\mu A^\nu, \tag{5}$$

where $A_\mu$ is electromagnetic vector potential of the given BH, $e$ denotes the charge of the radiated $W$-bosons and $\nabla_\mu$ represents the geometry of covariant derivative. The equation of motion is same for both outgoing $W^+$ and incoming $W^-$ bosons, therefore the tunneling rate for both cases is also similar. Utilizing, the following WKB approximation for the given BH[6]

$$\Psi_\nu = c_\nu \exp\left[\frac{\iota}{\hbar}\mathcal{S}(t, r, \theta, \varphi) + \Sigma\hbar^n\mathcal{S}_n(t, r, \theta, \varphi)\right], \tag{6}$$

and the Proca equation (4), as well as by considering only the leading order terms in $\hbar$, we obtain the following set of equations

$$\begin{aligned}
DB\ & [c_1(\partial_1\mathcal{S})((\partial_0\mathcal{S})+eA_0)-c_0(\partial_1\mathcal{S})^2]+FB[c_3(\partial_1\mathcal{S})^2-c_1(\partial_1\mathcal{S})((\partial_3\mathcal{S})\\

-\ & BC^{-1}(BD+F)[c_2(\partial_1\mathcal{S})^2-c_1(\partial_1\mathcal{S})(\partial_2\mathcal{S})]=0, \qquad (9)\\
BF\ & [c_1(\partial_0\mathcal{S})(\partial_1\mathcal{S})-c_0(\partial_1\mathcal{S})^2+eA_0c_1(\partial_1\mathcal{S})]+FC^{-1}[c_2(\partial_0\mathcal{S})(\partial_2\mathcal{S})\\
-\ & c_0(\partial_2\mathcal{S})^2+eA_0c_2(\partial_2\mathcal{S})]-AB[c_3(\partial_1\mathcal{S})^2-c_1(\partial_1\mathcal{S})(\partial_3\mathcal{S})\\
-\ & eA_3c_1(\partial_1\mathcal{S})]-AC^{-1}[c_3(\partial_2\mathcal{S})^2-c_2(\partial_2\mathcal{S})(\partial_3\mathcal{S})-eA_3c_2(\partial_2\mathcal{S})]\\
+\ & eA_0[c_3(\partial_0\mathcal{S})-c_0(\partial_3\mathcal{S})+eA_0c_3-eA_3c_0]+[c_3(\partial_0\mathcal{S})^2\\
-\ & c_0(\partial_3\mathcal{S})(\partial_0\mathcal{S})+eA_0c_3(\partial_0\mathcal{S})-eA_3c_0(\partial_0\mathcal{S})]+FC^{-1}[c_2(\partial_0\mathcal{S})(\partial_2\mathcal{S})\\
-\ & c_0(\partial_2\mathcal{S})^2+eA_0c_2(\partial_2\mathcal{S})]+m^2[Fc_0-c_3A]=0. \qquad (10)
\end{aligned}$$

By considering the separation of variables technique, one can write the particle's action in the following form

$$\mathcal{S}=-(E-j\Omega_H)t+\mathcal{R}(r)+j\varphi+\Theta(\theta), \qquad (11)$$

here $j$ and $E$ are the angular momentum and energy of radiated particle, respectively. The above set of Eqs. (7)–(10) can be describe in the form of following $4\times4$ matrix equation, i.e.,

$$\bigwedge(c_0,c_1,c_2,c_3)^t=0. \qquad (12)$$

In order to obtain the following non-trivial solution, we take $|\bigwedge| = 0$

$$\mathcal{R}^{\pm} = \pm\sqrt{\frac{(E - j\Omega_H - eA_0)^2 + Y}{AB}}dr. \tag{13}$$

The above equation implies the imaginary part of radial component of particle's action, i.e.,

$$Im\mathcal{R}^{\pm} = \pm\pi\frac{(E - j\Omega_H - eA_0)}{\sqrt{A_r(r_+,\theta)B_r(r_+,\theta)}}, \tag{14}$$

where the function $Y$ is given as follows

$$Y = -AN^2C^{-1} - m^2A + BF(E - j\Omega_H) - AB\dot{\Theta} - eA_0BF - eA_3AB.$$

The tunneling rate of charged spin-1 particles can be calculated as

$$\Gamma = \exp\left[-\frac{4}{\hbar}Im\mathcal{R}^{+}\right] = \exp\left[\frac{-4\pi(E - eA_0 - j\Omega_H)}{\sqrt{A_r(r_+,\theta)B_r(r_+,\theta)}}\right]. \tag{15}$$

By utilizing Boltzmann formula $\Gamma_B = \exp[(E - eA_0 - j\Omega_H)/T_H]$, the expected Hawking temperature $T_H$ can be obtained as

$$T_H = \left[\frac{\sqrt{A_r(r_+,\theta)B_r(r_+,\theta)}}{4\pi}\right]. \tag{16}$$

## 3. Quantum Corrections

The GUP-corrected equation of motion of massive uncharged $W$ bosons is given by[18]

$$\partial_\mu(\sqrt{-g}\Psi^{\mu\nu}) - \sqrt{-g}\frac{m_W^2}{\hbar^2}\Psi^{\nu} + \tilde{\beta}\hbar^2\partial_0\partial_0\partial_0(\sqrt{-g}g^{00}\Psi^{0\nu}) - \tilde{\beta}h^2\partial_i\partial_i\partial_i(\sqrt{-g}g^{ii}\Psi^{i\nu}) = 0, \tag{17}$$

where $m_W$ is vector particle's mass, the modified anti-symmetric tensor $\Psi^{\mu\nu}$ is defined below

$$\Psi^{\mu\nu} = (1 - \tilde{\beta}\hbar^2\partial_\mu^2)\partial_\mu\Psi_\nu - (1 - \tilde{\beta}\hbar^2\partial_\nu^2)\partial_\nu\Psi_\mu.$$

Using coordinate transformation, the metric can be rewritten as follows

$$ds^2 = -Adt^2 + \frac{1}{B}dr^2 + Cd\theta^2 + Dd\varphi^2. \tag{18}$$

The WKB approximation for the vector field $\Psi^{\mu}$ is given by

$$\Psi^{\mu} = c_\mu(t, r, \theta, \varphi)\exp\left[\frac{\iota}{\hbar}\mathcal{S}(t, r, \theta, \varphi)\right]. \tag{19}$$

Substituting values from Eqs. (18) and (19) in Eq. (17) and neglecting the higher order terms in $\hbar$, we obtain the following set of equations

$$B\,[c_0(\partial_r\mathcal{S})^2P_1^2 - c_1(\partial_r\mathcal{S})(\partial_t\mathcal{S})P_1P_0] + \frac{1}{C}[c_0(\partial_\theta\mathcal{S})^2P_2^2 - c_2(\partial_\theta\mathcal{S})(\partial_t\mathcal{S})P_2P_0]$$
$$+\ \frac{1}{D}[c_0(\partial_\varphi\mathcal{S})^2P_3^2 - c_3(\partial_\varphi\mathcal{S})(\partial_t\mathcal{S})P_3P_0] + c_0m_W^2 = 0, \tag{20}$$
$$-\ \frac{1}{A}[c_1(\partial_t\mathcal{S})^2P_0^2 - c_0(\partial_t\mathcal{S})(\partial_r\mathcal{S})P_0P_1] + \frac{1}{C}[c_1(\partial_\theta\mathcal{S})^2P_2^2 - c_2(\partial_\theta\mathcal{S})(\partial_r\mathcal{S})P_2P_1]$$
$$+\ \frac{1}{D}[c_1(\partial_\varphi\mathcal{S})^2P_3^2 - c_3(\partial_\varphi\mathcal{S})(\partial_r\mathcal{S})P_3P_1] + c_1m_W^2 = 0, \tag{21}$$
$$-\ \frac{1}{A}[c_2(\partial_t\mathcal{S})^2P_0^2 - c_0(\partial_t\mathcal{S})(\partial_\theta\mathcal{S})P_0P_2] + B[c_2(\partial_r\mathcal{S})^2P_1^2 - c_1(\partial_r\mathcal{S})(\partial_\theta\mathcal{S})P_1P_2]$$
$$+\ \frac{1}{D}[c_2(\partial_\varphi\mathcal{S})^2P_3^2 - c_3(\partial_\varphi\mathcal{S})(\partial_\theta\mathcal{S})P_3P_2] + c_2m_W^2 = 0, \tag{22}$$
$$-\ \frac{1}{A}[c_3(\partial_t\mathcal{S})^2P_0^2 - c_0(\partial_t\mathcal{S})(\partial_\varphi\mathcal{S})P_0P_3] + B[c_3(\partial_r\mathcal{S})^2P_1^2 - c_1(\partial_r\mathcal{S})(\partial_\varphi I_1)P_2P_3]$$
$$+\ \frac{1}{C}[c_3(\partial_\theta\mathcal{S})^2P_2^2 - c_2(\partial_\theta\mathcal{S})(\partial_\varphi\mathcal{S})P_2P_3] + c_3m_W^2 = 0, \tag{23}$$

where

$$P_0 = 1 + \tilde{\beta}\frac{1}{A}(\partial_t\mathcal{S})^2, \quad P_1 = 1 + \tilde{\beta}B(\partial_r\mathcal{S})^2,$$
$$P_2 = 1 + \tilde{\beta}\frac{1}{C}(\partial_\theta\mathcal{S})^2, \quad P_3 = 1 + \tilde{\beta}\frac{1}{D}(\partial_\varphi\mathcal{S})^2. \tag{24}$$

According to the Hamilton-Jacobi method, the separation of variables technique provides the following form of particle's action, i.e.,

$$\mathcal{S} = -(E - j\Omega_H)t + \mathcal{R}(r) + \Theta(\theta,\varphi). \tag{25}$$

Using Eq. (25) in Eqs. (20)–(23), we get the following $4\times4$ matrix equation, i.e.,

$$\bigwedge(c_0, c_1, c_2, c_3)^t = 0. \tag{26}$$

By considering only the leading order term in $\tilde{\beta}$ and taking $\det\bigwedge = 0$, we determine the following form of imaginary part of particle's action

$$\mathrm{Im}\mathcal{R}^{\pm}(r) = \pm\frac{\pi(E - j\Omega_H)}{\sqrt{A_r(r_+,\theta)B_r(r_+,\theta)}} \times (1 + \tilde{\beta}\Pi). \tag{27}$$

The tunneling rate of emitted particles at horizon can be obtained as

$$\Gamma = \exp\left[-\frac{4}{\hbar}Im\mathcal{R}^+\right] = \exp\left[-\frac{4\pi(E - j\Omega_H)}{\hbar\sqrt{A_r(r_+,\theta)B_r(r_+,\theta)}} \times (1 + \tilde{\beta}\Pi)\right]. \tag{28}$$

For $\hbar = 1$ and $\Gamma_B = \exp[(E - j\Omega_H)/T_H']$, the effective Hawking temperature is evaluated as

$$T_H' = \frac{\sqrt{A_r(r_+,\theta)B_r(r_+,\theta)}}{4\pi(1 + \tilde{\beta}\Xi)} = T_H(1 - \tilde{\beta}\Pi), \tag{29}$$

where $T_H$ is the original Hawking temperature defined by Eq. (16).

## 4. Conclusion

In this paper, we have studied the tunneling rate and Hawking temperature for vector particles. By considering the Hamilton-Jacobi method and applying the WKB approximation, we have considered Proca equation for massive charged vector field. Later, we have investigated the corresponding Hawking temperature of vector particles tunneled through horizon, which preserved charge and energy. Moreover, by utilizing GUP modified Proca equation, the corrected Hawking temperature has been computed by considering quantum gravity effects. We have concluded that the correction term decelerates the increase in Hawking temperature.

The properties of Kerr black holes (**BHs**)and naked singularities (**NSs**) are investigated by using stationary observers and their limiting frequencies. We introduce the concept of **NS** Killing throats and bottlenecks for slowly spinning **NSs** to describe the frequency of stationary observers. In particular, we show the frequency on the horizon can be used to point out a connection between **BHs** and **NSs** and to interpret the horizon in terms of frequencies. The analysis is performed on the equatorial plane of the ergoregion.

*Keywords*: Black holes; Naked singularities; Killing horizons.

## 1. Introduction

We study the orbital angular frequencies of stationary observers in the Kerr spacetime. We introduce the concept of Killing throats that arise in the spacetime of **NSs** and can be interpreted as the "opening" and disappearance of Killing horizons. Killing bottlenecks are identified as "restrictions" of Killing throats that appear in the case of weak naked singularities[a] (**WNSs**) for which the spin-mass ratio is close to the value of the extreme **BH**. To explore these **NS** effects, and considering the dynamics of the zero angular momentum observers (**ZAMOs**), we introduce the concept of "metric bundles" and "extended planes". In this work, we limit the analysis of the equatorial plane of the Kerr spacetime. The generalization to the case of the Reissner-Nordström and Kerr-Newmann spacetimes is presented elsewhere[4].

We first analyze the behavior of the frequency of a stationary observer in terms of the radial distance and the spin parameter $a$ of the source. In this way, we find in the **NS** region a particular set of curves that we identify as the Killing throat. In the case of **WNSs**, for which $a/M \in ]1, 2]$, the Killing throats show "restrictions" identified as Killing bottlenecks. To explore the properties of the bottlenecks, we introduce the concept of extended plane which is a graph relating a particular characteristic of a spacetime in terms of the parameters entering the corresponding spacetime metric. Any curve on the extended plane represents, therefore, a metric bundle, i.e., a family of spacetimes defined by a characteristic photon orbital frequency $\omega$ and characterized by a particular relation between the metrics parameters. In the case of the Kerr spacetime, the extended plane turns out to establish a relation

[a]The concept of strong and weak **NSs**, defined through the values of the spin parameter, has been explored in several works[1–4]. However, they can also be defined as strong curvature singularities[5].

between **BHs** and **NSs**. As a consequence, **WNSs** turn out to be related to the appearance of (a portion of) the inner horizon, whereas strong naked singularities (**SNSs**) with $a > 2M$ are related to the outer horizon.

This work is organized as follows. In Sec. 2, we discuss the concept of stationary observers, introducing the concepts of Killing throats and Killing bottlenecks. A discussion of the significance of the Killing bottlenecks and their possible origin is presented in Sec. 2.0.1. In Sec. 3, we introduce a possible generalization of the Killing horizon definition in the extended plane. Finally, we discuss a possible connection between black holes and naked singularities, revisiting the definition of horizons and the role played by **NSs** in horizon construction. Final remarks follow in Sec. 4.

## 2. Stationary observers and light surfaces

Consider the Kerr spacetime in Boyer-Lindquist (BL) coordinates, $(t, r, \phi, \theta)$, with $M \geq 0$ as the mass parameter and $a \equiv J/M \geq 0$ as the *specific* angular momentum or *spin*, where $J$ is the *total* angular momentum of the gravitational source. The horizons and ergospheres radii are given by $r_\pm = M \pm \sqrt{M^2 - a^2}$ and $r_\epsilon^\pm = M \pm \sqrt{M^2 - a^2\cos^2\theta}$. *Stationary observers* are characterized by a four-velocity of the form

$$u^\alpha = \gamma(\xi_t^\alpha + \omega\xi_\phi^\alpha), \quad \gamma^{-2} \equiv -\kappa(\omega^2 g_{\phi\phi} + 2\omega g_{t\phi} + g_{tt}), \tag{1}$$

where $\gamma$ is a normalization factor with $\kappa = -g_{\alpha\beta}u^\alpha u^\beta$, $\xi_\phi$ is the rotational Killing field, $\xi_t$ is the time-translational Killing field, and $\omega$ is a uniform *angular velocity* (dimensionless quantity)[b]. In BL coordinates, in which the metric tensor depends on $(r, \theta)$ only; this means that $r$ and $\theta$ are constants along the worldline of each stationary observer (the observer does not see the spacetime changing along the trajectory). The spacetime causal structure of the Kerr spacetime can be also studied by considering stationary observers[6].

Timelike stationary particles have orbital frequencies in the range

$$\omega \in ]\omega_-, \omega_+[ \quad \text{where} \quad \omega_\pm \equiv \omega_Z \pm \sqrt{\omega_Z^2 - \omega_*^2}, \quad \omega_*^2 \equiv \frac{g_{tt}}{g_{\phi\phi}} = \frac{g^{tt}}{g^{\phi\phi}}, \quad \omega_Z \equiv -\frac{g_{\phi t}}{g_{\phi\phi}}, \tag{2}$$

where $\omega_Z$ is the orbital angular frequency of the zero angular momentum observers (ZAMOS) and $\omega_\pm$ are the limiting frequencies of photons orbits, which are solutions of the equation $g_{\alpha\beta}\mathcal{L}_\pm^\alpha\mathcal{L}_\pm^\beta = 0$ with $\mathcal{L}_\pm \equiv \xi_t + \omega_\pm\xi_\phi$. Killing vectors $\mathcal{L}_\pm$ are generators of Killing horizons. The Killing vector $\xi_t + \omega\xi_\phi$ becomes null at $r = r_+$, defining the frequency $\omega_+(r_+) = \omega_h$.

On the equatorial plane $\theta = \pi/2$ of the Kerr spacetime we have that

$$\omega_\pm \equiv \frac{2aM^2 \pm M\sqrt{r^2\Delta}}{r^3 + a^2(2M + r)}, \quad \Delta \equiv r^2 - 2Mr + a^2 \tag{3}$$

[b]The particular case $\omega = 0$ defines *static observers*; these observers cannot exist in the ergoregion.

with the asymptotic behavior

$$\lim_{r\to\infty}\omega_{\pm}=0,\quad \lim_{a\to\infty}\omega_{\pm}=0,\quad \lim_{r\to 0}\omega_{\pm}\equiv\omega_0=\frac{M}{a} \tag{4}$$

and the particular values

$$\omega_h\equiv\omega_{\pm}(r_+)=\omega_Z(r_+)=\frac{a}{2r_+},\quad \omega_\epsilon\equiv\omega_+(r_\epsilon^+)=\frac{aM}{2M^2+a^2}. \tag{5}$$

We can see that $\omega_-<0$ for $r>r_\epsilon^+$, and $\omega_->0$ inside the ergoregion, while $\omega_+>0$ everywhere. Moreover, since $\omega_+=\omega_-$ on the horizon, stationary observers cannot exist inside this surface. Therefore, $\omega_\pm$ are limiting angular velocities for physical observers. The behavior of the frequencies $\omega_\pm$ is depicted in Fig. 1. Notice that

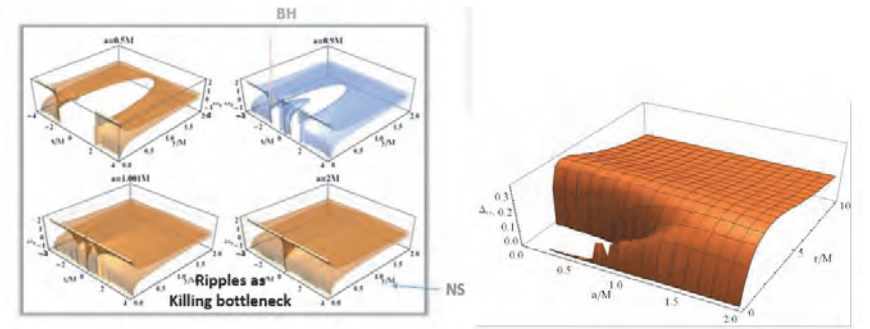

Fig. 1. Left panel: Plots of the frequency surfaces $\omega_\pm$ as functions of the radial distance $r$ in Cartesian coordinates $(x,y)$ for different spin values $a$, including **BH**s (upper plots) and **NS**s (bottom plots). Timelike stationary observers are defined in the region bounded by these planes. In the **BH** case, the horizons are clearly identified; as the spin increases, the horizons merge and, in the **NS** region, a rippled configuration (bottleneck) appears specially in the case of **WNSs** with $(a\in]M,2M[)$. Right panel: Plot of the frequency interval $\Delta\omega_\pm=\omega_+-\omega_-$ as a function of the radius $r/M$ and the spin $a/M$. The extrema $r_\Delta^\pm$ and $r_\blacksquare^\pm$ are solutions of the equations $\partial_r\Delta\omega_\pm=0$ and $\partial_a\Delta\omega_\pm=0$, respectively. Bottlenecks are shown explicitly[4].

instead of the spin parameter $a$, we could use the frequency $\omega_0$ or $\omega_h$ to parameterize the Kerr spacetime by using the relations

$$a=\frac{M}{\omega_0}\quad\text{or}\quad a=\frac{4M\omega_h}{1+4\omega_h^2}\ , \tag{6}$$

respectively, which can be prove to be $1-1$ relations. This simple observation has very important consequences. In fact, if we could measure all the values of $\omega_0\in]0,\infty[$ or $\omega_h\in]0,1/2]$, the entire Kerr family of spacetimes would be described by these frequencies. From a practical point of view, however, we can expect that the frequency on the (outer) horizon $\omega_h$ is a more suitable candidate for being measured. This, again, is an interesting fact that seems to be related to the well-known property that all the physical degrees of freedom of a black hole are encoded on the horizon.

The angular frequency $\omega_0$ ("frequency of the singularity") emerges as a relevant quantity in this analysis and, as it is clear from Fig. 1, it can be used to differentiate between low spin $a \in [0, M]$ sources, where the frequency gap $\Delta\omega_\pm = \omega_+ - \omega_-$ is larger, and **WNSs** and **SNSs**, where stationary observers are not defined (asymptotically, for large $a/M$, $\omega_0 \approx 0$ and $\Delta\omega_\pm \approx 0$ for a fixed orbit $r$).

The constant $\omega_h$ is also important in the context of **BH** thermodynamics. Indeed, from the fundamental Bekenstein-Hawking entropy equation, $S = \frac{1}{4}A_h$, where $A_h = A_h(r_+)$ is the area of the outer horizon, one can derive all the thermodynamic properties of a **BH**, including its temperature (surface gravity) and angular velocity at the horizon[c]. The frequency $\omega_h$ also determines the uniform (rigid) angular velocity on the horizon, representing the fact that the **BH** rotates rigidly. This quantity enters directly into the definition of the **BH** surface gravity and, consequently, into the formulation of the rigidity theorem. **BH** thermodynamics is established through the quantities $(r_+, \omega_h)$ and their variation (in $r > r_+$); consequently, from the point of view of the geometric laws of the **BH** thermodynamics considered here, the universe in the outer region, $r > r_+$, is regulated exclusively by the outer horizon $r_+$ (the region "inside" the black hole, i.e., $r < r_+$, does not directly enter in the outer region thermodynamics). This aspect will have a correspondence in the concept of inner horizon confinement (in the extended plane) that we will show in Sec. 3. The **BH** surface gravity is defined from the variation of the Killing field $\mathcal{L}$ norm on the outer **BH** horizon. In this analysis we study this norm and its variation on the equatorial plane of the Kerr geometries (i.e. $r > 0$ and $\theta = \pi/2$). We focus particularly on the ergoregion as the outer boundary of the ergosurface ($r_\epsilon^+ = 2M$) is a spin-independent quantity (in the static limiting metric, where $r_\epsilon^+ = 2M$, there is an event horizon associated to the Killing $\xi_t$–apparent, trapped, Killing and events horizons in stationary and static spacetimes coincide.). The relevance of this special feature of the outer ergosurface on the equatorial plane consists in the variation of the norm of the Killing field $\mathcal{L}$ with the dimensionless spacetime spin $a/M$. The off-equatorial case is instead considered in Ref. 7.

Since $S$ depends only on the radius of the outer horizon, which in turn depends only on $M$ and $a$, we can replace the spin parameter $a$ by the frequency parameter $\omega_h$, by using the $1-1$ relation (6). This means that $\omega_h$ can play the role of a thermodynamic variable for a **BH**. It would be interesting to investigate how the use of the frequency $\omega_h$, instead of the angular momentum $J = aM$, as a thermodynamic variable would affect the thermodynamics of the corresponding **BHs**.

**Killing vectors and Killing horizons**

It is convenient here to review some well-known facts about Killing horizons and Killing vectors. A **Killing horizon** is a *null* surface, $\mathcal{S}_0$, whose *null* generators

[c]In fact, one can write the Hawking temperature as $T_H = \hbar c\kappa/2\pi k_B$, where $k_B$ is the Boltzmann constant and $\kappa$ is the surface gravity. Temperature $T = \kappa/(2\pi)$; entropy $S = A/(4\hbar G)$, where $A =$ area of the horizon $A = 8\pi m r_+$; pressure $p = -\omega_h$; volume $V = GJ/c^2$ ($J = amc^3/G$); internal energy $U =$ GM ($M = c^2 m/G =$ mass) and $m$ is the mass.

coincide with the orbits of an one–parameter group of isometries (i.e., there is a Killing field $\mathcal{L}$ which is normal to $\mathcal{S}_0$). Therefore, it is a lightlike hypersurface (generated by the flow of a Killing vector) on which the norm of a Killing vector goes to zero. In static **BH** spacetimes, the event, apparent, and Killing horizons with respect to the Killing field $\xi_t$ coincide. In the Schwarzschild spacetime, therefore, $r = 2M$ is the Killing horizon with *respect* to the Killing vector $\partial_t$. The event horizons of a spinning **BH** are Killing horizons with respect to the Killing field $\mathcal{L}_h = \partial_t + \omega_h \partial_\phi$, where $\omega_h$ is defined as the angular velocity of the horizon (the event horizon of a stationary black hole must be a Killing horizon). In Ref. 7, we also consider the case of the Reissner–Nordström and Kerr-Newman spacetimes.

**Killing vectors and BH surface gravity**

The **surface gravity** of a **BH** may be defined as the *rate* at which the norm of the Killing vector vanishes from outside. The surface gravity for the Kerr **BH** metric, $\mathcal{SG}_{Kerr} = (r_+ - r_-)/2(r_+^2 + a^2)$, is a conformal invariant of the metric, but it re-scales with the conformal Killing vector. Therefore, it is not the same on all generators (but obviously it is constant along one specific generator because of the symmetries).

**Surface gravity and frequencies**

The Kerr **BH** surface gravity can be decomposed as $\kappa = \kappa_s - \gamma_a$, where $\kappa_s \equiv 1/4M$ is the Schwarzschild **BH** surface gravity, while $\gamma_a = M\omega_h^2$ is the contribution due to the additional component of the **BH** intrinsic spin; $\omega_h$ is, therefore, the angular velocity (in units of $1/M$) on the *event horizon*. The (strong) rigidity theorem connects then the event horizon with a Killing horizon, stating that, under suitable conditions, the event horizon of a stationary (asymptotically flat) solution satisfying suitable hyperbolic equations is a Killing horizon. The surface area of the **BH** event horizon is non-decreasing with time (which is the content of the second law of black hole thermodynamics). The **BH** event horizon of the stationary solution is a Killing horizon with constant surface gravity (zeroth law)[d]. Thus $\Lambda = \mathcal{L}^\alpha \mathcal{L}_\alpha$ is constant on the horizon. The surface gravity is then defined as the constant $\kappa : \nabla^\alpha \Lambda = -2\kappa \mathcal{L}^\alpha$ (on the outer horizon $r_+$). Alternatively, it holds that $\mathcal{L}^\beta \nabla_\alpha \mathcal{L}_\beta = -\kappa \mathcal{L}_\alpha$ and $L_{\mathcal{L}} \kappa = 0$, where $L_{\mathcal{L}}$ is the Lie derivative (a non affine geodesic equation). In other words, $\kappa$ is constant on the orbits of $\mathcal{L}$.

We here consider $\Lambda$ as a function of $(r, a)$ (as we are restricting the analysis to the equatorial plane). To analyze the dependence on $a$, we introduce the concept of the *extended plane* $\pi^+$ as the set of points $(a/M, \mathcal{Q})$, where $\mathcal{Q}$ is any quantity that characterizes the spacetime and depends on $a$. In general, the extended plane is an

[d]Progenitors, as stars or galaxies, have generally spin $a = J/(Mc)$ usually bigger than their mass $m = GM/c^2$. During the gravitational collapse, the body should lose mass and angular momentum, generating the Killing horizons, ending up as a black hole. Penrose Cosmic Censorship Hypothesis constrains the gravitational collapse from good (physically realistic) initial conditions for the progenitors to end up in a **BH**; this result, however, is still an hypothesis, strictly depending on the "physical" initial conditions.

$(n+1)$-dimensional surface, where $n$ is the number of independent parameters that enter $\mathcal{Q}$[7]. An example of an extended plane is plotted in Fig. 1, which corresponds to the 2D set of points $(a/M, \omega_\pm)$. The frequency $\omega_\pm$ shows "ripples", which emerge when the spin is within the interval $a \in ]M, 2M]$. The surfaces become connected and the two horizons disappear, leaving as "remnants" in the planes the "Killing bottlenecks". Those ripples appeared also in different analysis of the stationary observes[4].

2.0.1. *Light surfaces*

Light surfaces are determined by the solutions of the equation $g_{\alpha\beta}\mathcal{L}^\alpha_\pm \mathcal{L}^\beta_\pm = 0$, which in the case under consideration can be expressed as[4]

$$\frac{r_s^-}{M} \equiv \frac{2\beta_1 \sin\left(\frac{1}{3}\arcsin\beta_0\right)}{\sqrt{3}}, \quad \frac{r_s^+}{M} \equiv \frac{2\beta_1 \cos\left(\frac{1}{3}\arccos(-\beta_0)\right)}{\sqrt{3}} \tag{7}$$

$$\text{where} \quad \beta_1 \equiv \sqrt{\frac{1}{\omega^2} - \frac{1}{\omega_0^2}}, \quad \beta_0 \equiv \frac{3\sqrt{3}\beta_1\omega^2}{\left(\frac{\omega}{\omega_0}+1\right)^2}. \tag{8}$$

The surfaces $r_s = r_s^+ \cup r_s^-$ are represented for **BHs** and **NSs** in Fig. 2. In the **BH** case, we note the disconnection due to the presence of the horizons, which corresponds to the disconnection in the frequency planes of Fig. 1, where we limit the plots to the region $r_s < r_\epsilon^+$. Physical (timelike) observers are located between the inner cone and the outer cylinder surfaces of Fig. 2. As the spin increases into the **NS** regime, the surfaces merge at $a \geq M$, giving rise to a connected surface $r_s$ $(r_s^+ \cup r_s^-)$, the Killing throat (or tunnel). For spins $a \in ]0, 2M]$, the Killing bottleneck appears as restriction of the surface $r_s = r_s^+ \cup r_s^-$. We focus the analysis on the Killing bottleneck considering a $2D$ representation of the Killing throat versus the frequency $\omega$ at different spins, close to values where the bottleneck appears. Fig. 4 shows the behavior for **BHs** (gray region) and **NSs**. In the **BH** case, we do not consider the region inside the inner horizon (i.e. $r < r_-$). The outer horizon is the tangent point $r_+$ to the curve $r_s$ and the minimum (regular) point of the surface $r_s(\omega)$. For the extreme Kerr spacetime the horizon is a (non regular) cusp point in this representation. Each Killing throat is associated to one spacetime geometry.

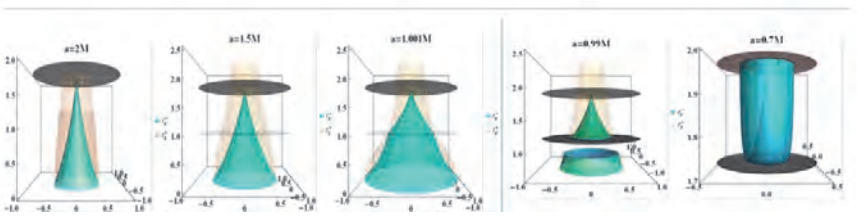

Fig. 2. Plots of the surfaces $r_s^\pm$ (in units of mass) versus the frequency $\omega$ for different spin values $a/M$, including **BH** and **NS** geometries. The Killing throat and bottleneck are plotted[4].

For example, the Killing throat defined for $a = 2M$ has a characteristic singularity frequency $\omega_0 = M/a = 0.5$, which is the limiting frequency at the singularity (note that the restriction of the throat approaching the singularity corresponds to a null frequency gap $\Delta\omega_\pm$, meaning that there are no physical stationary observers close to the singularity). At a fixed value $r_s(\omega)$, one orbit on a throat $a = 2M$, corresponds to two (positive) photon orbital frequencies $\omega_+$ and $\omega_-$ (a part on the singularity $r_s = 0$); viceversa, there can be two orbits $r_1(\omega) < r_2(\omega)$ on the surface $r_s$ (vertical lines in Fig. 2), where photons have equal orbital frequency (note that the photon orbital frequency $\omega_\pm$ are limiting frequencies for timelike particles; therefore, they determine also the range of possible values of $\omega$ for the physical stationary observers).

Killing bottleneck appears as restriction of the Killing throat in the light surfaces analysis and as ripples in the frequency planes of Fig. 1. We considered the possibility that these "horizons remnants" in **WNSs** were caused by failure of the **BL** coordinates "close" to the $a = M$, in the region near the horizon $r_+ = r_- = M$; nevertheless, Killing bottlenecks appear in the whole spin range $a \in ]M, 2M]$. To understand if the Killing bottlenecks are due to some known geometrical properties of the singularities, we focus our analysis on the spins $a \in ]M, 2M]$. Considering **ZAMOs** dynamical properties, we highlight some particular spin values of this range.

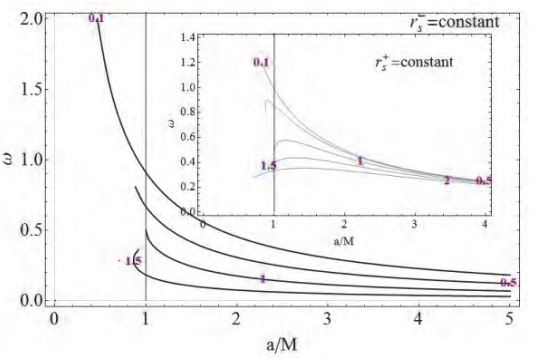

Fig. 3. Curves $r_s^-$ =constant and $r_s^+$ =constant (inside panel) in the plane $(\omega, a/M)$. The numbers denote the constant radii $r_s^\pm/M$ (light cylinders). The angular momentum and the velocity $(a, \omega)$ for $r_s^\pm(a, \omega) = 0$ are related by $\omega = M/a$.

**Zero Angular Momentum Observers**

Some properties of spacetimes with bottlenecks shown in Fig. 2 can be related to the dynamics of ZAMOs, which are defined by the condition

$$\mathcal{L} \equiv u_\alpha \xi^\alpha_{(\phi)} = g_{\alpha\beta}\xi^\alpha_\phi p^\beta = g_{t\phi}\dot{t} + g_{\phi\phi}\dot{\phi} = 0 \quad (d\phi/dt = -g_{\phi t}/g_{\phi\phi} \equiv \omega_Z = (\omega_+ + \omega_-)/2). \tag{9}$$

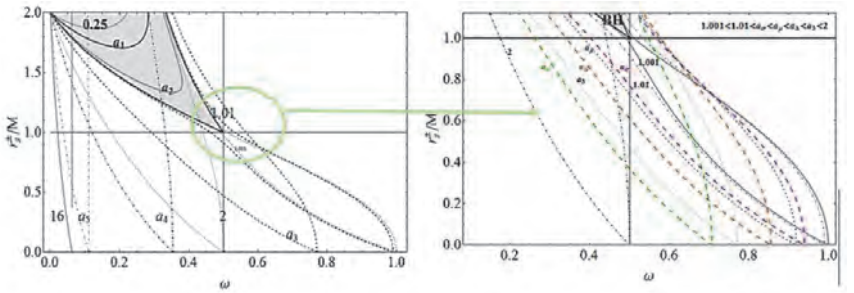

Fig. 4. The radii $r_s^{\pm}$ versus the frequency $\omega$ for different values of the spin $a/M$ (numbers close to the curves). The gray region is the only region allowed for the case of **BH** spacetimes. The surfaces $\hat{r}_{\pm}$ at $a = M$ (extreme-**BH**-case) are shown in black-thick (from Ref. 4).

The variation of the orbital frequencies of the ZAMOs with the spin, for different orbits, shows the existence of extreme orbits as shown in Fig. 6, $\partial_a \omega_Z|_{\pi/2} = 0$, $\omega_e \equiv \omega_Z(r_e)$, where

$$r_e \equiv \frac{\sqrt[3]{3}a^2 + \Upsilon^2}{3^{2/3}\Upsilon}, \quad \Upsilon \equiv \sqrt[3]{9Ma^2 + \sqrt{3}\sqrt{a^4\,(27M^2 - a^2)}}. \tag{10}$$

The relation between ZAMOs orbital frequency and light frequencies $\omega_{\pm}$ can be inferred from Eq. (2). In Figs. 5 and 6 some properties of the ZAMOs dynamics are shown, which follow from the analysis of the Killing bottleneck and the light surfaces, Fig. 4.

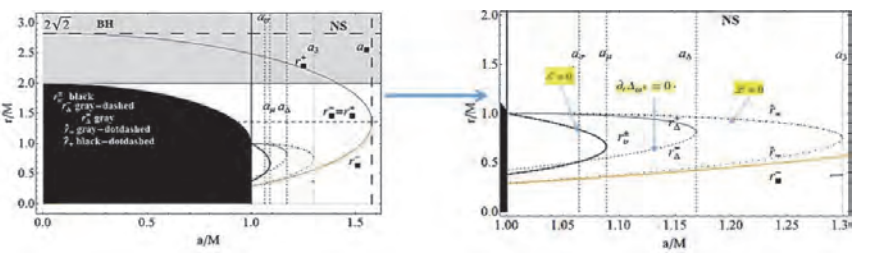

Fig. 5. The radius $r(a)$, solution of $\partial_r \Delta_{\omega_{\pm}} = 0$, i.e., it represents the critical points of the separation parameter $\Delta\omega_{\pm} \equiv (\omega_+ - \omega_-)|_{\pi/2}$ on the equatorial plane $\theta = \pi/2$. The radius $r_v^{\pm}$, where the orbital energy $\mathcal{E} = 0$, and the orbits $\hat{r}_{\pm}$, for which $\mathcal{L} = 0$, are also plotted. Dashed lines represent the spins $a_\sigma = 1.064306M$, $a_\mu = 4\sqrt{2/3}/3M \approx 1.08866M$, $a_\Delta = 1.16905M$ and $a_3 = 3\sqrt{3}/4M$. The black region corresponds to $r < r_+$. The radii $r_{\blacksquare}^{\pm} : \partial_a \Delta_{\omega_{\pm}} = 0$ are plotted as functions of $a/M$–from Ref. 4.

These spins are significant for the orbital properties of the ZAMOs which exist exclusively inside the ergoregion of **WNS** with $a \leq 1.31M$[e]. A more detailed

[e]The constant $\mathcal{L}$ and $\mathcal{E}$ shown in Figs. 5 and 6 are constant of motion associated respectively to $\xi_t$ and $\xi_\phi$ and compose the rotational version of the Killing fields i.e. the canonical vector fields

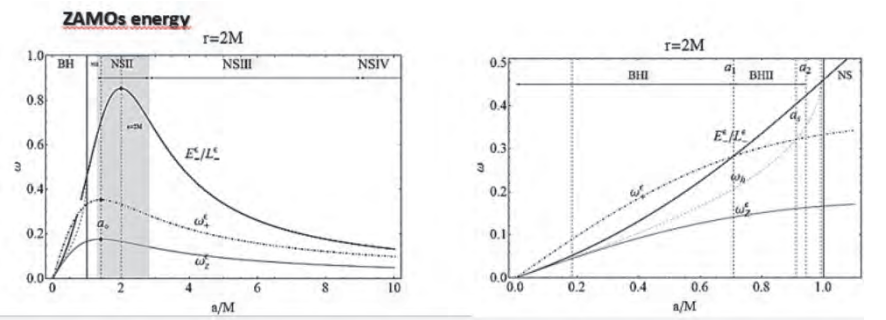

Fig. 6. Left panel: The ratio $\mathcal{E}^{\epsilon}_{-}/\mathcal{L}^{\epsilon}_{-}$ and the angular momentum of the ZAMOs $\omega^{\epsilon}_{Z}$ as a function of $a/M$ in the static limit $r = r^{+}_{\epsilon}$. The angular momentum $\omega^{\epsilon}_{+} \equiv \omega_{+}(r^{+}_{\epsilon})$ which is a boundary frequency for the stationary observer (outer light surface) is plotted (gray curve). The radius $r^{+}_{\epsilon}$ is defined by the condition $\omega_{-}(r^{+}_{\epsilon}) = 0$, $\omega_h$ is the ZAMOs angular velocity on $r = r_{+}$, i.e. $\omega_{\pm}(r_{\pm}) = \omega_h$. The maxima, related to the orbits $r_e(a)$, are denoted by points. A zoom of this plot in the **BH** region is in the right panel (from Ref. 4).

analysis is performed in Figs. 5 and 6. See also Ref. 4. From the analysis of Fig. 5 it follows that the radii connected with the the *frequency interval* $\Delta_{\omega_{\pm}} \equiv \omega_{+} - \omega_{-}$ are relevant to Killing bottlenecks:

$$
\begin{aligned}
& r^{+}_{\blacksquare} \equiv \eta \cos\left[\frac{1}{3}\arccos\left(-\frac{8a^2}{\eta^3}\right)\right], \quad r^{-}_{\blacksquare} \equiv \eta \sin\left[\frac{1}{3}\arcsin\left(\frac{8a^2}{\eta^3}\right)\right], \\
& \eta \equiv \frac{2\sqrt{8M^2 - a^2}}{\sqrt{3}}, \quad \text{for} \quad r \in ]0, 2\sqrt{2}M[ \\
& \text{where} \quad r^{\pm}_{\blacksquare} : \ \partial_a \Delta_{\omega_{\pm}}\big|_{r^{\pm}_{\blacksquare}} = 0 \quad (maximum \quad points).
\end{aligned} \tag{11}
$$

The plots of Fig. 5 show also the radii related to the frequency gap $\Delta\omega_{\pm}$. These radii are related to properties generally associated with so called "repulsive effects" of **NSs**. In this sense, the presence of ripples in the frequency sheets seem to be a related effect. It is also to be noted that the ripples are defined as a gap restriction in the frequency sheets; more precisely, they could be interpreted as due to the existence of two null orbits $r_1 \leq r_2$, where $\Delta\omega_{\pm}(r_1, r_2)$ is a minimum. That is, there is a pair of points $(r_1, r_2) \in r_s \times r_s$, on the light surface of a selected spacetime, where the photon orbital frequencies interval (range of possible timelike orbital frequency) is minimized. Clearly, the limiting case occurs for $r_1 = r_2 = r_* : \Delta\omega_{\pm}(r_*) = 0$, i.e., in $r_* \in \{0, r_{\pm}\}$. In this sense, the horizons and singularities can be interpreted

$\tilde{V} \equiv (r^2 + a^2)\partial_t + a\partial_\phi$ and $\tilde{W} \equiv \partial_\phi + a\sigma^2\partial_t$, $\sigma = \sin\theta$. The contraction of the geodesic four-velocity with $\tilde{W}$ leads to the non-conserved quantity $\mathcal{L} - \mathcal{E}a\sigma^2$, which on the equatorial plane reduces to the constant $\mathcal{L} - \mathcal{E}a$. Considering the principal null congruence $\gamma_{\pm} \equiv \pm\partial_r + \Delta^{-1}\tilde{V}$, there is the angular momentum $\mathcal{L} = a\sigma^2$, that is $\bar{\ell} = 1$ (and $\mathcal{E} = +1$, in proper units), every principal null geodesic is then characterized by $\bar{\ell} = 1$, with $\mathcal{L} = \mathcal{E} = 0$ on the horizon. In this analysis, the dimensionless radius $R \equiv r/a$ is relevant. For more discussions on the role of this ratio as $\bar{\mathcal{L}} = \mathcal{L}/a$ and $\bar{\ell} = \mathcal{L}/\mathcal{E}a$, see Ref. 4.

as the limiting cases of the Killing bottlenecks ("horizons remnants"). For more details see Ref. 7.

## 3. Horizon extension: Unveiling BH–NS connections

Figure 5 shows a bottleneck configuration for spins $a \in ]M, 1.31M]$. We now introduce the concept of metric bundle $g_\omega$ as the collection of Kerr metrics within the parameter range $a \in [a_0, a_g]$ with

$$a_\omega^\pm(r, \omega; M) \equiv \frac{2M^2\omega \pm \sqrt{r^2\omega^2\left[M^2 - r(r+2M)\omega^2\right]}}{(r+2M)\omega^2} \tag{12}$$

and a constant frequency $\omega$, which characterizes the bundle $g_\omega$. Any geometry of the bundle possesses two distinct lightlike orbits, $r_1 \leq r_2$, whose frequencies coincide with the characteristic frequency of the bundle, i.e., $\omega(r_1) = \omega(r_2) = \omega$, constrained within the limiting geometries with $a_0$ and $a_g$. Moreover, the orbital distance $(r_2 - r_1)$ reaches a maximum in the bundle and is null on the borders $a_0$ and $a_g$. *All and only* the geometries of that bundle share this property. From Fig. 7 we derive some general properties of the metric bundles: **1)** The vertical axis of the extended planes contains all the *origins* $a_0 \in ]0, \infty[$ of the metric bundles $g_\omega$. **2)** The curve $a_+$ represents the horizon in the extended plane $\pi^+$ and the boundary spin $a_g \in ]0, M]$ is associated to this curve. **3)** We can identify a correspondence between the inner horizon $r_-$ and outer horizon $r_+$ on the curve $a_+$, as shown in Fig. 7; we identify the **BH**-strip in the lower part of the panel and the **NS**-strip in the upper one as indicated. **4)** The metric bundles $g_\omega$ are closed as a consequence of the closing of the $\xi_\phi$ orbits. **5)** The metric bundles $g_\omega$ are tangent to the horizon. **6)** The metric bundle shown in Fig. 7 corresponds to the characteristic frequency $\omega = 0.5$ and origin $a_0 = 2M$, which is the upper limit of the spin region, where the Killing bottleneck appears. The bundle is tangent to the Killing horizon at the point $r_h = M$, corresponding to the spin $a_g = M$. This bundle is related also to the light surfaces with $\omega_0 = 0.5$ and $\omega_0 = 1$ as seen in Fig. 4. We note that this special metric bundle, corresponding to the spin $a_g = M$, is regular on the point

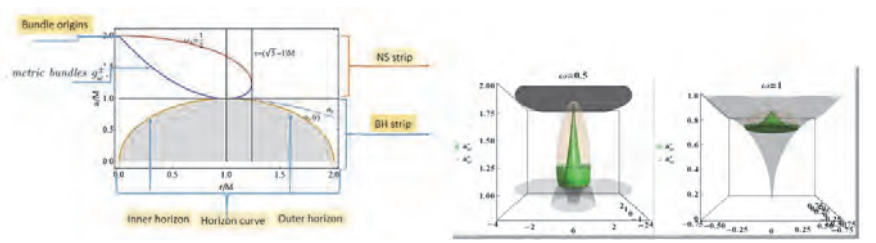

Fig. 7. The metric bundle $g_\omega$ for the spin $\omega_\pm = \omega_h = 1/2$ and bundle origin $a_0 = 2M$. The horizon curve $(a_+(r) \equiv \sqrt{r(2M-r)})$ and $a_\gamma$, solution of $r = r_\gamma$ where $r_\gamma \in \Sigma_\epsilon^+$ is the photon orbit in the ergoregion of the Kerr **BH**, are also plotted. The right panel shows a confinement of the metric bundle in the region bounded by the inner horizon and the bundle at $\omega = 0.5$.

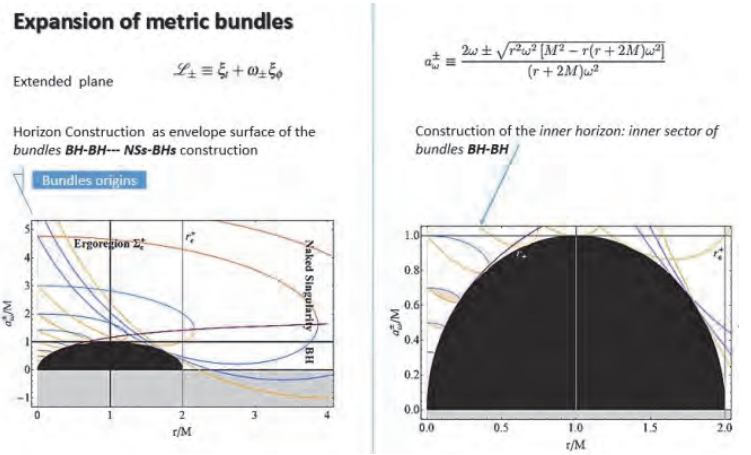

Fig. 8. The metric bundle $g_\omega$ with origins $a_0 > 0$. The horizon appears as the envelope surface.

on the horizon for the extreme Kerr **BH** and relates the spin-origin $a_0$ and the tangent point $r_h$ on the horizon with the spin $a_g$ defined by the tangent point. It is clear that the horizon curve on the extended plane corresponds to a unique horizon frequency $\omega_H$. It is possible to show that the correspondence $(a_0, a_g, \omega_H)$ can be set as a bijection.

Translating the bundle origin $a_0$ in all the range $a_0 > 0$ in Fig. 8, some relevant properties of the metric bundles and the Killing horizon appear: **i)** All the metric bundles are tangent to the horizon. **ii)** The metric bundles do not penetrate the horizon. **iii)** The space subtended by the horizon curve in the extended plane is not described by any metric of any bundle (in the sense of our analysis).

From the above properties, we can derive the following consequences: **1)** The frequencies $\omega$ of each bundle $g_\omega$ (and on every point $r$ of each bundle) are all and only those of the horizon frequency $\omega_H$. It is, therefore, sufficient to know the horizon frequency $\omega_H$ in the extended plane to fix the photon orbital frequencies (and therefore the physical observer frequency range) in each point of any **BH** or **NS** geometry of the Kerr spacetime family. **2)** The horizon arises as the *envelope surface* of all the metric bundles. **3)** The part of the horizon curve corresponding to the inner horizon in $\pi^+$ is built partially by metric bundles all contained in the region inside the inner horizon, i.e., confined in $a_g \in [0, M]$, $r \in [0, M]$ and $a_0 \in [0, M]$. These bundles have origins in $a_0 \in [0, M]$. However, these special bundles are not sufficient to construct, as envelope surface, the whole inner horizon in the extended plane. **4)** The bundles necessary for the construction of the other part of the the inner horizon in $\pi^+$ have origin in $a_0 \in [M, 2M]$, i.e., in the **WNS** geometries, where the Killing bottleneck appear. **5)** The Killing bottleneck appears to be related to the properties of these special metric bundles, which are involved in the construction of the inner horizon as envelope surface. **6)** The portion of the horizon curve corresponding to the outer Killing horizon on the equatorial plane is constructed by metric bundles with origins $a_0 > 2M$, which we identify as **SNS**.

We close this section noting that the whole set of photon limiting orbital frequencies $\omega_\pm$ (or alternatively the light surfaces $r_s^\pm$) of a single Kerr geometry with spin $\bar{a}$ (and therefore the range of orbital frequencies for the physical observers) in the extended plane, is given by the collection of points of all the metric bundles on the horizontal lines $\bar{a}$ =constant in Figs. 7 and 8. These frequencies are all and only those of the horizon frequency $\omega_H$. We discuss the interpretation of this result in the next conclusive section. Finally, we mentioned above that the internal bundles with origin in $a_0 \in [0, M]$ are all confined in the region of the inner horizon in $\pi^+$, i.e., in $a_g \in [0, M]$. This can be shown in several ways. In particular, considering again the horizon frequencies $\omega_h^\pm$, we introduce the radii $r_\mp^\mp$, defined as

$$r_-^- = \frac{1}{2}\left(\sqrt{\frac{32r_-}{a^2} - a^2 + 6\sqrt{1-a^2} - 22} - r_-\right) : \omega_-(r_-^-) = \omega_-(r_-) = \omega_h^- \quad (13)$$

$$r_+^+ = \frac{1}{2}\left(\sqrt{\frac{32r_+}{a^2} - a^2 - 6\sqrt{1-a^2} - 22} - r_+\right) : \omega_+(r_+^+) = \omega_+(r_+) = \omega_h^+, \quad (14)$$

$$\text{where} \quad (r_-^- < r_-) < (r_+ < r_+^+),$$

where we have used dimensionless units. The radii $(r_+^+, r_-^-)$ correspond to photon orbits with frequencies $\omega_\pm$ of the **BH** horizons $\omega_h^\pm$. The orbital frequency of the inner horizon has a replica on an orbit $r_-^- \in [0, r_-]$- "inner horizon frequency confinement". This result is in agreement with the **BHs** thermodynamic properties discussed in Sec. 2. Also, the relation $(a_g, a_0, r_h)$, where $r_h$ is obtained through $\omega_h$, has been mentioned to be bijective. We can show this through the relation between $(a_g, a_0)$ [7]

$$\forall\, a_0 > 0, \quad a_g \equiv \frac{4a_0M^2}{a_0^2 + 4M^2} \quad \text{where} \quad a_g \in [0, M] \quad \text{and} \quad (15)$$

$$\lim_{a_0\to 0} a_g = \lim_{a_0\to\infty} a_g = 0, \quad a_g(a_0 = 2M) = M. \quad (16)$$

This relation also allows us to formalize the **BH-BH** correspondence (construction of the inner horizon as an envelope surface in $\pi^+$), the **BH-WNS** relation (inner horizon construction) and the **BH-SNS** relation (construction of the outer horizon). Particularly, the horizon relates in the extended plane **BHs** with **NSs** (through the origins of the metrics bundles $a_0$ and $a_g$). In this sense, the **NSs** can be interpreted as necessary for the construction (as envelope surface) of the inner and outer horizons in the extended plane. Note that the static case of the Schwarzschild geometry, $a = 0$, can be seen as the limiting case in Figs. 7 and 8, where the horizon $a_g = 2M$ is in correspondence with the limiting **SNS** bundle with origin $a_0 = +\infty$. The plane $\pi^+$ in Figs. 7 and 8 have several symmetries. Note that in Fig. 8 negative values of $a_0$ and $a_g$ are possible in the metric bundles and are related to $\omega_\pm < 0$ frequencies, which are possible outside the ergoregion $(r > r_\epsilon^+)$. The quantity $\mathcal{A}_{r_\pm}^+ = \pi/2$ is the area of the region of $\pi^+$ bounded by the horizon (dimensionless quantities); $\mathcal{A}$ is the area of the regions in the extended plane $\pi^+$

bounded by the curves $a^{\pm}_{\omega}$, defining the metric bundles $g_{\omega}$. $\mathcal{A}$ is a decreasing function of the frequency $\omega$, shrinking at the origins $a_0 < M$, i.e. $\omega_0 = M/a > M$, where $g^{\pm}_{\omega}$ are all bounded by the inner horizons; viceversa, the region areas grow as the spin-mass ratio increases in the **NS** geometries. We repeated this analysis in the case of Reissner-Nordström and Kerr-Newman spacetimes and similar results are found.

## 4. Final remarks

In this work, we investigated the properties of stationary observers on the equatorial plane of the Kerr spacetime. The generalization to the off-equatorial case as well as the Reissner-Nordström and Kerr-Newman spacetimes is presented elsewhere[7]. We focused on the behavior of the frequency of stationary observers. To emphasize its peculiarities, we introduced the concept of Killing throats and bottlenecks. If we consider the frequency as a function of the spin, certain features appear that are better explained by introducing the concepts of extended planes and metric bundles. In the case of the Kerr metric on the equatorial plane, the extended plane is essentially equivalent to the function that relates the frequency with the spin.

Metric bundles and horizons remnants appear related to the concept of pre-horizon regimes. There is a pre-horizon regime in the spacetime when there are mechanical effects allowing circular orbit observers to recognize the close presence of an event horizon. This concept was introduced in Ref. 8 and detailed for the Kerr geometry in Refs. 13, 14, 9. The analysis of the pre-horizon structure led to the conclusion that a gyroscope would observe a memory of the static case in the Kerr metric. It is clear that this aspect could have an essential relevance in the investigation of the collapse[10–12]–see also[15].

In the extended plane of the Kerr metric, the frequency on the horizons determines a set of metrics, a metric bundle, describing in general **BHs** and **NSs**, and also the limiting frequencies for stationary observers, which correspond to light-like orbits. This fact can be interpreted as determining a connection between **BHs** and **NSs**. In the extended plane, the **NS** solutions have a clear meaning in relation to the construction as envelope surface of portions of the horizon in $\pi^+$. The inner **BH** horizon is connected to the origin of **BH** bundles and the outer horizon establishes **BHs-SNSs** correspondence. Moreover, the horizon in the extended plane can be interpreted as the envelope surface of all metric bundles. On the other hand, the metric bundles are all defined by all and only the frequency of the horizon. In this sense, the corresponding inner horizon in $\pi^+$ is partially constructed by **BHs** metric bundles. The inner horizon is completed by bundles including **BHs** and **WNSs**. This property appears related with the Killing bottlenecks appearing in the light surfaces. Interestingly, the outer horizon in $\pi^+$ is generated by **SNSs** metric bundles. It is then possible to argue that this result could be of interest for the investigation of the gravitational collapse. Indeed, suppose that the collapse is a quasi-stationary process in which each state is described by a Kerr spacetime. Since

rotating astrophysical compact objects are characterized by spin parameters, which correspond to **NS** configurations ($a/M > 1$), the formation of a **BH** ($a/M \leq 1$) would necessarily imply passing through a series of states with spin parameters in the **NS** regime. In this case, the extended plane of the Kerr metric as described above could contain the different states which are necessary for the formation of a **BH**. This fact has the interesting consequence that only horizon frequencies in extended plane determine the frequencies $\omega_{\pm}$ at each point, $r$, on the equatorial plane of a Kerr **BH** or **NS** geometry. All the frequencies $\omega_{\pm}(r)$ on the equatorial planes are only those of the horizon in $\pi^{+}$. Another relevant aspect connected with this fact is the confinement of the horizon in the sense of the frequencies given in Eq. (13). These aspects are currently under investigation.

We formulate a description of 3+1 dimensional gravitational phenomena in terms of a relativistic fluid living on the 2+1 dimensional timelike boundary of an arbitrary bulk region of spacetime, called a *gravitational screen*. We establish a consistent dictionary between the geometric variables describing the evolution of the screen and the thermodynamic variables describing a relativistic viscous fluid, and discuss the interpretation. We also examine the construction of gravitational screens in different spacetimes and analyze the properties of the fluids they realize.

*Keywords*: Gravity; thermodynamics; quasilocal; holography; hydrodynamics.

## 1. Introduction

One of the greatest theoretical developments in modern physics has been the anti-de Sitter/conformal field theory correspondence (AdS/CFT), which conjectures an equivalence between a theory of gravity in a bulk region of spacetime, and a quantum field theory on the boundary of that spacetime[1]. AdS/CFT has illuminated many aspects of string and field theory, giving key insights into what a quantum theory of gravity might look like, having also provided us with powerful tools for studying a broad range of strongly coupled systems, such as fluids near quantum critical points and quark-gluon plasmas. This notion of a bulk/boundary duality is also manifest in the membrane paradigm[2], where the interior of a black hole is replaced with a relativistic fluid living near the event horizon, and the celebrated fluid/gravity correspondence[5], where the long wavelength limit of Einstein's equations are mapped to fluid dynamics on the boundary of AdS. These ideas are all, in essence, a statement of the holographic principle; the fundamental idea that all of the information contained in a bulk region of spacetime can be encoded in the boundary of that region.

These approaches offer a limited perspective however, since we are usually constrained to situations where knowledge of the boundary of space or the end of time is required. AdS/CFT and the fluid/gravity correspondence makes reference to the boundary of anti-de Sitter space at infinity, while standard formulations of black hole thermodynamics, as well as the membrane paradigm, relate quantities to the event horizon, which is teleological and can only be located by knowing the entire future history of the universe. From a practical point of view this is unsatisfactory; as local observers we are generally unable to access these types of boundaries.

Recent progress in moving beyond these restricted classes of boundaries has led to the concept of a *gravitational screen*[4], a 2+1 dimensional timelike hypersurface representing the time evolution of the 2D boundary of a bulk region of spacetime. In this paradigm, Einstein's equations in the bulk are mapped to equations governing the non-equilibrium thermodynamics of a viscous fluid living on the screen, with all of the gravitational dynamics present inside the screen being encoded in the boundary fluid. This quasilocal approach is reminiscent of the membrane paradigm and fluid/gravity correspondence, but can be formulated on arbitrary timelike surfaces, without the aforementioned restrictions. It also bears some resemblance to other quasilocal approaches, such as the original work of Brown and York[3] and rigid quasilocal frames[7], though no fluid interpretation is given in those.

In this work, we present the fully relativistic generalization of the gravitational screen[a]. Whereas the original work considered a correspondence between Einstein's equations in the bulk and the non-relativistic Navier-Stokes equations on the boundary, here we promote the boundary theory to a fully covariant one, placing it on equal footing with the bulk theory. We clarify the interpretation of the fluid pressure as the screen's normal acceleration, finding that the correct bulk/viscous splitting must include an expansion-dependent term. We also construct examples of gravitational screens both in Minkowski and Schwarzschild backgrounds and examine the properties of the corresponding holographic fluids. Finally, we examine how the fluid entropy can be linked to the curvature of spacetime, and remark on the salient features of the correspondence.

## 2. Screens as hypersurfaces

The gravitational screen $\Sigma$ is a 2+1 dimensional hypersurface which is the time evolution of a 2D boundary $\mathcal{S}$ of some 3D bulk connected region of interest. The screen is topologically $\mathbb{R}\times S^2$, admitting a smooth codimension-one foliation by the leaves $\mathcal{S}$, which are level sets of some time function $t(x)$ inherited from the bulk foliation. We consider spherically symmetric boundaries only, though the screen geometry can in principle be chosen arbitrarily. The screen is defined by $s^a$, the outward pointing spacelike unit normal vector to $\mathcal{S}$, and $u^a$, the timelike unit vector tangent to $\Sigma$. By construction $s_a s^a = 1$, $u_a u^a = -1$, and $s_a u^a = 0$.
The metrics on $\Sigma$ and $\mathcal{S}$ in terms of the bulk metric $g_{ab}$ are

$$\Sigma: \quad h_{ab} = g_{ab} - s_a s_b \qquad\qquad \mathcal{S}: \quad q_{ab} = h_{ab} + u_a u_b \ , \tag{1}$$

with the associated extrinsic curvatures $H_{ab} = h_a{}^c h_b{}^d \nabla_c s_d$ and $\Theta_{\mathbf{u}ab} \equiv q_a{}^c q_b{}^d \nabla_c u_d$. The junction conditions[6] then lead to a surface stress-energy tensor

$$\tilde{S}_{ab} = \frac{1}{8\pi G} S_{ab} = \frac{1}{8\pi G}\big([H]h_{ab} - [H_{ab}]\big) \ , \qquad H \equiv h^{ab} H_{ab} \ . \tag{2}$$

[a]These proceedings serve as a brief summary of the current work. A more detailed and complete presentation, along with numerous examples, will be available in a future publication.

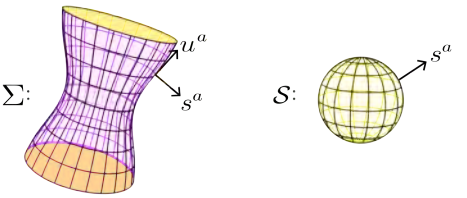

Fig. 1. A gravitational screen $\Sigma$ and the spatial boundary $\mathcal{S}$.

Square brackets represent the discontinuity of a quantity across the boundary. We will interpret this as the stress-energy tensor of a relativistic fluid living on the surface $\Sigma$. We adopt a holographic point of view, where the fluid stress-energy tensor (supported entirely on $\Sigma$) and the equations governing its evolution map to the geometry and dynamics within the screen. To this end, we let $[H_{ab}] \to H_{ab}$ and $[H] \to H$ giving

$$S_{ab} = Hh_{ab} - H_{ab} \ . \tag{3}$$

This is in the same spirit as the membrane paradigm [2], where the stretched horizon is taken to be the boundary of the spacetime and the stress energy tensor on the surface is chosen so that field lines terminate at the boundary. To arrive at a precise correspondence, we take Einstein's equations in the 4D space with zero cosmological constant, $R - \frac{1}{2}Rg_{ab} = T_{ab}$, and project them onto the timelike membrane $\Sigma$ via the Gauss-Codazzi equations, the first of which is the momentum constraint

$$D_b S^{ba} = T_{cb} s^c h^{ba} \tag{4}$$

where $D_a V_b = h_a{}^c h_b{}^d \nabla_c V_d$ is the covariant derivative on $\Sigma$. Equation (4) can further be projected into the spatial direction as $(D_b S^{ba}) q_{ac} = T_{\mathbf{s}c}$, where $T_{\mathbf{s}c} \equiv s^a T_{ac}$ and it is understood that the index $c$ represents components tangent to $S$. This equation expresses conservation of momentum on $\Sigma$, with $T_{\mathbf{s}c}$ representing the momentum flux density across the screen. Using (3) and inserting the factor $(8\pi G)$ gives:

$$(8\pi G) T_{\mathbf{s}c} = D_c(\gamma_{\mathbf{u}} + \tfrac{1}{2}\theta_{\mathbf{s}}) - \theta_{\mathbf{s}} \mathrm{a}_{\mathbf{u}c} - (\tfrac{3}{2}\theta_{\mathbf{u}} q_{bc} + \tilde{\Theta}_{\mathbf{u}bc} + \epsilon_{bc})\omega^b - D_{\mathbf{u}}\omega_c - D_b \tilde{\Theta}^b_{\mathbf{s}c}. \tag{5}$$

Here, $\mathrm{a}_{\mathbf{u}c} \equiv u^b \nabla_b u_c$ is the acceleration of screen observers, $\omega_a \equiv q_a{}^b (s_c \nabla_b u^c)$ is the normal one-form, $\gamma_u \equiv s_b u^a \nabla_a u^b$ is the normal acceleration, $\tilde{\Theta}_{\mathbf{u}bc}$ is the symmetric trace-free part of $\Theta_{\mathbf{u}bc}$, $\epsilon_{bc}$ is the antisymmetric part of $\Theta_{\mathbf{u}bc}$ (which vanishes if $u^a$ is hypersurface orthogonal) and $\theta$ is the expansion. Projecting (4) along $u^a$ instead gives conservation of energy on the screen

$$(8\pi G) T_{\mathbf{su}} = (D_u + \theta_{\mathbf{s}})\theta_{\mathbf{u}} - (\gamma_{\mathbf{u}} + \tfrac{1}{2}\theta_{\mathbf{s}})\theta_{\mathbf{u}} - \tilde{\Theta}^{ab}_{\mathbf{s}} \Theta_{\mathbf{s}ab} + (\mathrm{d}_a + 2\mathrm{a}_{\mathbf{u}a})\omega^a \ , \tag{6}$$

where $T_{\mathbf{su}} \equiv s^a u^b T_{ab}$ represents the energy flux density flowing across the screen and we have defined the covariant derivative on $\mathcal{S}$ as $\mathrm{d}_a V_b = q^c{}_a q^b{}_d \nabla_c V_d$.

## 3. Relativistic hydrodynamics

We consider now the equations governing a relativistic viscous fluid living on a 2+1 dimensional surface with topology $S^2 \times \mathbb{R}$. The conservation equations are

$$\nabla_a T^{ab} = 0 \ , \tag{7}$$

where in the general case we consider non-perfect (non-equilibrium) fluids with stress-energy tensors of the form

$$T^{ab} = e u^a u^b + (p+\pi) q^{ab} + u^a q^b + u^b q^a + \Pi^{ab} \ . \tag{8}$$

$u^a$ is the fluid 4-velocity, $e$ is the internal energy density of the fluid, $p$ is the isotropic pressure, $q^{ab}$ is the metric on $\mathcal{S}^2$, $\Pi^{ab}$ is the anisotropic stress tensor, $q^a$ is the heat flux, and $\pi$ is the dynamic pressure (the difference between the total pressure and pressure at equilibrium). $\Pi^{ab}$, $q^a$, and $\pi$ are thermodynamic fluxes that capture the deviations from a perfect fluid, and are given in this case by

$$\Pi^{ab} = q^a{}_c q^b{}_d T^{cd} - (p+\pi) q^{ab} \ , \qquad q^a = -q^a{}_c T^{cb} u_b \ , \qquad p + \pi = \frac{1}{2} q_{ab} T^{ab} \ . \tag{9}$$

As in the gravity picture, we project (7) in the directions parallel and orthogonal to $u^a$, giving the analogue of the Gauss-Codazzi equations but with $T_{ab}$ playing the role of $S_{ab}$. Projecting in directions orthogonal to $u^a$ gives conservation of momentum,

$$0 = \dot{u}_c (e + p + \pi) + \mathrm{d}_c (p + \pi) + (\mathrm{d}_a + \dot{u}_a) \Pi^a{}_c + q_{cb} \dot{q}^b + \left( \omega_{ac} + \sigma_{ac} + \tfrac{3}{2} \theta q_{ac} \right) q^a \ , \tag{10}$$

while the projection in the direction of $u^a$ gives conservation of energy,

$$0 = -\dot{e} - (e + p + \pi) \theta - (\mathrm{d}_a + 2 \dot{u}_a) q^a + \Pi^{ab} \sigma_{ab} \ . \tag{11}$$

## 4. The dictionary

We can now construct the map between the geometric variables describing the boundary evolution, and the thermodynamic variables governing the evolution of the relativistic fluid. Remarkably, this can be done consistently in the relativistic case just as in the Newtonian case considered in Ref. 4. Comparing the conservation of momentum (10) and energy (11) equations for the fluid to the gravity equations (5) and (6) leads to the following identifications:

$$e = -\frac{\theta_{\mathbf{s}}}{8\pi G} \ , \qquad p + \pi = \frac{\gamma_{\mathbf{u}} + \frac{1}{2}\theta_{\mathbf{s}}}{8\pi G} \ , \qquad \theta = \theta_{\mathbf{u}} \ , \qquad \omega_{ab} = \epsilon_{ab} \tag{12}$$

$$\Pi_{ab} = -\frac{\tilde{\Theta}_{\mathbf{s}ab}}{8\pi G} \ , \qquad \sigma_{ab} = \Theta_{\mathbf{u}ab} \ , \qquad q_a = -\frac{\omega_a}{8\pi G} . \tag{13}$$

We initially took the hydrodynamic conservation laws (7) to be source-free, resulting in the vanishing left hand side of (10) and (11). It is clear now that a non-zero $T_{\mathbf{su}}$ or $T_{\mathbf{s}c}$ manifest themselves as non-zero source terms in (7).

In this picture, the fluid energy density $e$ is related to the rate of expansion of outgoing radial null geodesics at the boundary. Our choice of sign leads to a negative energy density which increases with the mass of the screened region. Positivity of entropy and temperature for the screen fluid requires the presence of a negative chemical potential $\mu$ for the fluid. The 2D fluid pressure $p$ is now identified with $\gamma_{\mathbf{u}}+\frac{1}{2}\theta_{\mathbf{s}}$, in contrast to both the membrane paradigm and the non-relativistic screen formalism, where it is simply $\gamma_{\mathbf{u}}$. The pressure can thus vanish for non-trivial screen geometries leading to complex thermodynamic behaviour. The fluid expansion $\theta$ is directly related to the expansion in the time direction $\theta_t$ of the screen. The intuition is clear; the fluid expands as the 2D volume of the boundary increases with time.

A new feature appearing in our work is the fluid twist or kinematic vorticity $\epsilon_{ab}$ which maps to the twist $\omega_{ab}$ of the screen observers. The fluid twist measures rigid rotations of fluid lines with respect to the local inertial rest frame. Traditionally, quasilocal approaches to studying gravitational thermodynamics use shell observers whose 4-velocities are hypersurface orthogonal [7], and therefore have vanishing twist. In hydrodynamics however, $\epsilon_{ab}$ plays an important role in establishing the Kelvin-Helmholtz and Bernoulli theorems [8], as well as modelling turbulence, and is therefore a critical ingredient in understanding the full non-linear dynamics of gravity in hydrodynamic terms. With this dictionary in place, well-known results from relativistic hydrodynamics as well as the laws of thermodynamics can be used to study gravitational phenomena.

## 5. Thermodynamics of screen fluids

The thermodynamic system governed by (6) has more degrees of freedom than constraints, requiring additional information to complete. In hydrodynamics, this comes in the form of an equation of state $e(p)$ which characterizes the fluid. From the gravity point of view, $e \sim \theta_u$ and $p \sim \gamma_s$, so it is the screen evolution/geometry which fixes the equation of state of the fluid. We are also interested in relating the temperature $T$ and entropy $S$ of the boundary fluid to the internal geometry. These quantities are determined by assuming quasistatic equilibrium and employing the first law and Euler relation for a (charge-free) relativistic fluid,

$$de = Tds + \mu dn \ , \qquad e + p = Ts + \mu n \ . \tag{14}$$

A natural question that arises is "Which screen evolutions give rise to physical equations of state?". As an example, one can construct[b] a static, spherically symmetric screen in Minkowski space, whose boundary fluid has the simple equation of state

$$e(p) = -2p \ , \tag{15}$$

which has the form $p(e) = \omega e$ with $\omega = -1/2$. Such equations of state appear in cosmology as models of dark energy fluids, which satisfy the strong energy condition

[b] We omit the details of the construction for brevity. All of the relevant quantities can be calculated from the definitions given in Section 2.

but do not support classical perturbations. This fluid requires a negative chemical potential in order to have a positive entropy and temperature, suggesting that the underlying microscopic constituents are bosonic in nature.

Another example is a static, spherically symmetric screen centered in a Schwarzschild background, lying outside of the event horizon. In this case the fluid has an equation of state

$$e(p) = \frac{-4\,p\left(1 - 32\pi mp + \sqrt{1 - 32\pi mp}\right)}{\left(1 + \sqrt{1 - 32\pi mp}\right)^2} \ , \tag{16}$$

where $m$ is the ADM mass. The fluid retains its barotropic nature, but can now support classical perturbations (the speed of sound is positive) and has an entropy which increases monotonically with the screen radius, allowing one to map the fluid entropy to the curvature of the space enclosed by the screen.

These simple examples of screens demonstrate some of the salient features of the dictionary, and illustrate the subtleties involved in constructing screens which have interpretations in terms of physical fluids. It is also interesting to consider fixing the properties of the boundary fluid first, and ask what dynamics are required of the screen to realize that fluid. Indeed, we would eventually like to classify all possible physical screen evolutions and boundary fluids. Moving forward, we aim to further apply this formalism to dynamic backgrounds (which generically lead to time-dependent equations of state) and better understand how phenomena like gravitational waves in the bulk manifest in the boundary fluid. We would also like to leverage the power of the bulk/boundary map to shed light on dissipative phenomena in relativistic hydrodynamics, where exact solutions are generally unavailable.

We consider spherically-symmetric black holes in semiclassical gravity. For a collapsing radiating thin shell we derive a sufficient condition on the exterior geometry that ensures that a black hole is not formed. This is also a sufficient condition for an infalling test particle to avoid the apparent horizon of an existing black hole and approach it only within a certain minimal distance. Taking the presence of a trapped region and its outer boundary — the apparent horizon — as the defining feature of black holes, we explore the consequences of their finite time of formation according to a distant observer. Assuming regularity of the apparent horizon we obtain the limiting form of the metric and the energy-momentum tensor in its vicinity that violates the null energy condition (NEC). The metric does not satisfy the sufficient condition for horizon avoidance: a thin shell collapses to form a black hole and test particles (unless too slow) cross into it in finite time. However, there may be difficulty in maintaining the expected range of the NEC violation, and stability against perturbations is not assured. On the other hand, expansion of a trapped region that was formed in a finite time of a distant observer leads to a firewall that contradicts the quantum energy inequality.

*Keywords*: Black holes; null energy condition; thin shells.

## 1. Introduction

Event horizon — the null surface that bounds the spacetime region from which signals cannot escape — is the defining feature of black holes in classical general relativity[1–3]. Nevertheless, it is a global teleological entity that is in principle unobservable[4,5]. Theoretical, numerical and observational studies therefore focus on other characteristic features of black holes[3,6]. A local expression of the idea of the absence of communications with the outside world is provided by the notion of a trapped region. It is a domain where both outgoing and ingoing future-directed null geodesics emanating from a spacelike two-dimensional surface with spherical topology have negative expansion[1,3,6,7]. The apparent horizon is defined as the

evolving outer boundary of the trapped region[1,6]. According to classical general relativity the apparent horizon is located inside the event horizons if the matter satisfies energy conditions[1,8].

However, quantum states can violate energy conditions[8]. Black hole evaporation proceeds precisely because $T_{\mu\nu} = \langle \hat{T}_{\mu\nu} \rangle$ violates the null energy condition (NEC): there is a null vector $k^\mu$ such that $T_{\mu\nu}k^\mu k^\nu < 0$. In this case the apparent horizon is outside the event horizon. In fact, the very existence of the latter is uncertain[9,10]. While existence of spacetime singularities is no longer prescribed, their appearance without the horizon cover ("naked") is not excluded either. This situation motivated the introduction of many models of non-singular ultra-compact objects[5].

We consider the formation of a trapped region with a non-singular boundary in the finite time of a distant observer as a definition of existence of a black hole. Working in the framework of semiclassical gravity with spherical symmetry[11] we derive the condition that allows an infalling observer to avoid horizon crossing. We then show that if the apparent horizon is regular, the energy-momentum tensor and the metric in its neighbourhood are determined by the Schwarzschild radius $r_g$ and its rate of change. Finally, we discuss intriguing implications of these results.

## 2. Spherical symmetry. Sufficient condition for horizon avoidance

A general spherically symmetric metric in Schwarzschild coordinates is given by

$$ds^2 = -e^{2h(t,r)} f(t,r) dt^2 + f(t,r)^{-1} dr^2 + r^2 d\Omega. \tag{1}$$

The function $f(t,r) = 1 - C(t,r)/r$ is coordinate-independent[12], where the function $C(t,r)$ is the Misner-Sharp mass[3,13]. In an asymptotically flat spacetime $t$ is the physical time of a distant observer.

Trapped regions exist only if the equation $f(t,r) = 0$ has a root[7]. This root (or, if there are several, the largest one) is the Schwarzschild radius $r_g(t)$. Apparent horizons are in general observer-dependent entities. However they are unambiguously defined in the spherically symmetric case for all spherical-symmetry preserving foliations[13]. In this case the apparent horizon is located at $r_g$. In the Schwarzschild spacetime $C(t,r) = 2M$ and $h = 0$, hence $r_g = 2M$.

Radial infall of non-gravitating massive or massless point particle and thin shell collapse[2] are the simplest models that elucidate the near-horizon geometry and its dynamics. In thin shell models the geometry inside the shell is given by the flat Minkowski metric. The matter content of the shell is given by the surface energy-momentum tensor. The trajectory of a massive shell or particle is parametrized by its proper time $\tau$ and expresses as $\big(T(\tau), R(\tau)\big)$ in the exterior Schwarzschild coordinates. Initially the shell is located outside its gravitational radius, $R(0) > r_g$. Its dynamics is obtained by using the so-called junction conditions[2,14].

The first junction condition is the statement that the induced metric $h_{ab}$ on the shell $\Sigma$ is the same on both sides $\Sigma^\pm$, $ds^2_\Sigma = h_{ab} dy^a dy^b = -d\tau^2 + R^2 d\Omega$. Since for

massive particles the four-velocity $u^\mu$ satisfies $u_\mu u^\mu = -1$, their trajectory obeys

$$\dot{T} = \frac{\sqrt{F + \dot{R}^2}}{e^H F}, \tag{2}$$

where $\dot{A} = dA/d\tau$, $H = h(T, R)$, $F = f(T, R)$. This condition is used to identify the radial coordinate of the shell in interior and exterior coordinates, $R_- \equiv R$.

Discontinuity of the extrinsic curvature $K_{ab}$ is described by the second junction condition[2,14] that relates it to the surface energy-momentum tensor. Given the exterior metric the junction conditions result in the equations of motion for the shell. The classical collapse in vacuum, and the resulting equation for $R(\tau)$, is simple enough to have an analytic solution $\tau(R)$, leading to the finite proper time $\tau(r_g)$ and infinite time $T(r_g)$.

This equation of motion is modified for a general exterior metric. Its solution for the collapsing shell and for a particle that falls into a formed black hole has some remarkable features[15–17]. Here we focus on the possibility of crossing the Schwarzschild sphere of an evaporating black hole ($dr/dt = r_g'(t) < 0$) in finite proper time. For a finite evaporation time $t_E$ the finite proper crossing time is equivalent to having a finite time $t_g$ of a distant observer. By monitoring the gap between the shell and the Schwarzschild radius[11,18],

$$X(\tau) := R(\tau) - r_g\big(T(\tau)\big), \tag{3}$$

we discover the sufficient condition for a thin shell to never cross its Schwarzschild radius. The same condition applies to the study of an infalling test particle into an existing black hole. The analysis is generalized to null shells and test particles[16].

The rate of approach to the Schwarzschild radius behaves as $\dot{X} = \dot{R} - r_g'(T)\dot{T}$. Close to the Schwarzschild radius we have $\dot{T} \approx -\dot{R}e^{-H}/F$, and hence

$$\dot{X} \approx \dot{R}(1 - |r_g'|e^{-H}/F). \tag{4}$$

If for a fixed $t$ the function $\exp(h)f$ goes to zero as $x := r - r_g \to 0$, then there is a stopping scale $\epsilon_*(\tau)$. If the shell comes to the Schwarzschild radius closer than $\epsilon_*$ the gap has to increase, $\dot{X} > 0$, evidently indicating in this case that the shell never collapses to a black hole.

The collapse outcome depends on the metric choice: the outgoing Vaidya metric with decreasing mass (and thus positive energy density) prevents formation of the horizon, but the shell either becomes superluminal[15] or develops a surface pressure[16]. On the other hand, the metric functions of Eqs. (5) and (6) below lead to horizon formation in finite time according to both infalling and distant observers.

## 3. Metric outside an apparent horizon

Using only one additional assumption it is possible to obtain the explicit form of the metric near $r_g$. In fact this metric satisfies the sufficient condition for the horizon avoidance. We consider an evaporating black hole that is formed at some distant

observer's finite time, i.e. its apparent horizon radius $r_g(t)$ is a decreasing function of time. In addition we assume that the horizon is regular (the standard "no drama at the horizon" postulate[19], where the established regularity of the classical results is assumed to hold in the quantum-dominated regime). The regularity is expressed by finite values of the curvature scalars that can be directly expressed in terms of the energy-momentum tensor[20], $\mathrm{T} := T^{\mu}{}_{\mu}$ and $\mathfrak{T} := T^{\mu\nu}T_{\mu\nu}$.

The existence of an apparent horizon and regularity assumptions strongly constrain the energy-momentum tensor, and consistency with the known results on the background of an eternal black hole[21,22] specify its limiting form uniquely. The leading terms in the $(tr)$ block of the energy-momentum tensor are determined by a single function $a(t)$ (that for evaporating black holes is identified below), and the functions $C(t)$ and $h(t)$ take the following form[20],

$$C = r_g(t) - a(t)\sqrt{x} + \frac{1}{3}x \ldots . \tag{5}$$

and

$$h = -\ln\frac{\sqrt{x}}{\xi_0(t)} + \frac{4}{3a}\sqrt{x} + \ldots , \tag{6}$$

where $x = r - r_g$. The function of time $\xi_0(t)$ is determined by the choice of the time variable and the asymptotic behaviour of the solutions of the Einstein equations. The metric takes a particularly simple form in ingoing Vaidya coordinates[20].

The energy-momentum tensor that corresponds to this metric violates the null energy condition in the vicinity of the apparent horizon[20]. The comoving density and pressure at the apparent horizon of an evaporating black hole are negative,

$$\rho = p = -\frac{r_g'^2}{16\pi\dot{R}^2 r_g^2}, \tag{7}$$

where $R$ is the radial coordinate of the comoving observer[17]. We focus on the question of horizon avoidance. Return first to a collapsing thin shell problem where the exterior metric is given now by Eq. (1) with the metric functions that are given in Eqs. (5) and (6) above. Expanding Eqs. (5) and (6) for $X \to 0$ the rate of approach is

$$\dot{X} = -\left(\frac{2|\dot{R}|}{a} - \frac{a}{2|\dot{R}|r_g}\right)\sqrt{X} + \ldots , \tag{8}$$

which is independent of the function $\xi_0$. Hence if a test particle is in the vicinity of the apparent horizon, $X \ll a^2$, it will cross the horizon unless $|\dot{R}| < a/(2\sqrt{r_g})$.

For the evaporating case we match the $r_g'$ that is obtained as a consistency requirement on the functions of $C$ and $h$ from the Einstein equations[20], with the known results[21] for the quasi-static mass loss $r_g' = -\kappa/r_g^2$. In Planck units $\kappa \sim 10^{-3} - 10^{-4}$, and we obtain

$$\xi_0 \approx \sqrt{\frac{\kappa}{2r_g}} \approx \frac{a}{2}. \tag{9}$$

We have seen that the violation of the NEC is necessary for the existence of a black hole. Such violations, however, are bounded by quantum energy inequalities (QEI). Adapting the QEI of Ref. 24 we obtain that the region where the NEC is violated is bounded by

$$x_{\max} < \frac{11}{960\pi |r_g'| r_g^2} \sim 1, \tag{10}$$

that is obtained by ignoring the sub-Planckian features of the bound[11]. Even this estimate fails short of the conventional estimate $x_{\max} \sim r_g$. Our results indicate either that the required negative energy density for having a Schwarzschild sphere at finite time $t_S$ cannot be maintained or the trapped regions forms at a much later stage of the collapse. Alternatively, the domain of validity of the self-consistent metric is much narrower than that of the approximate metric that is obtained by taking the backreaction into account[21]. If the black hole was formed in the finite time of a distant observer and is subsequently accreting, the situation is would more radical: on approaching the apparent horizon the comoving density, pressure and flux diverge as $1/X$, while the curvature invariants remain finite[17]. We see that growth of the trapped region leads a falling-in observer to encounter a firewall at its boundary that, moreover, violates the NEC.

Both scenarios may indicate that the semiclassical approximation and its associated classical notions are modified already at the horizon or larger scales. A rigourous analysis of this situation is in order.

Another question results from two properties we discussed above. On the one hand, existence of the apparent horizon requires violation of the NEC. Test particles cross it in finite time unless moving too slow. It is not clear how the apparent horizon that requires NEC violation for its existence reacts to a perturbation by infalling normal matter. Given that collapsing thin shells are known to cross the apparent horizon and form a black hole with nearly all their rest mass intact[23], it is possible that the answer will involve considerable adjustment of our concept of black holes.

The well known Schwarzschild black hole entropy is depicted in terms of trapped gravitons within the event horizon. A discrete spectrum for the so trapped gravitons is obtained and used to calculate thermodynamic quantities. The semi-classical expression for the black hole entropy is obtained with a temperature proportional to the usual Bekenstein-Hawking one and as a result a pressure term arises in the first law of thermodynamic. My approach is an attempt to obtain the semi-classical black hole entropy in terms of degrees of freedom stored inside (but 'near') the event horizon. Moreover, it is also shown that by modifying the internal energy by a term motivated by quantum Planckian fluctuations, a phase transition emerges during evaporation process with a vanishing specific heat at Planckian scales, thus representing the end of the evaporation process.

*Keywords*: Black Hole Thermodynamics; Black Hole Entropy; Trapped Gravitons.

## 1. Black Hole Entropy from Trapped Gravitons

As well known[1], black holes in asymptotically flat spacetimes are equipped with a non vanishing entropy given by $S_{BH} = \frac{A_h}{4L_P^2}$ and temperature $T_h = \frac{c\hbar}{4\pi K_B R}$ $(r \to \infty)$. Open questions are:

- What is the physical origin of the degrees of freedom implying $S_h$?
- Where is the lost information during evaporation?
- Where is the $PdV$ term in the first law?
- How can we obtain the log. corrections to the BH entropy?

In usual approaches (String, Loop quantum gravity) one quantize the area of the black hole: nevertheless the physical (statistical) origin of the BH entropy degrees of freedom is still obscure.

Moreover, what is the fate of the matter-radiation falling inside the event horizon?

In[2,3], I have proposed a possible description of the Black Hole entropy in terms of massless excitations provided by gravitons trapped inside the event horizon located at proper areal radius $R = 2GM/c^2$, with $M$ the ADM mass of the Black Hole.

The Bekenstein-Hawking (B-H) entropy is a semi-classical formula obtained with arguments involving classical general relativity with ordinary quantum mechanics. In this regard, the B-H entropy is 'phenomenological' and universal since it does not assume an underlying quantum gravity proposal, and for this reason it is expected to

hold in any physically sound quantum gravity theory. In particular, it is expected in low energy regime of the quantum gravity theory. Moreover, logarithmic corrections are expected to arise when quantum Planckian fluctuations in a full quantum gravity regime come into action.

To star with, we must obtain a suitable approximate formula for trapped gravitons within a box of radiaus $R$. Consider a gravitational wave in the vacuum and then put this in a spherical box, not a simple task!

Fortunately, we can use the well known perturbation formalism of the general relativity (Regge-Wheeler 1957, Zerilli $\sim$ 1970, Chandrasekhar 1984) on a Minkowskian spacetime $\eta_{ik} = diag(-1, +1, +1, +1)$ (Cartesian coordinates), perturbed by $h_{ik}$:

$$g_{ik} = \eta_{ik} + h_{ik}, \quad |h_{ik}| << |\eta_{ik}|.$$

After imposing Dirichelet boundary conditions on the Regge-Wheeler or Zerilli (In a Minkowski spacetime equations are the same) equation

$$Z^{(a,p)}_{\ell m,r,r} + \omega^2 Z^{(a,p)}_{\ell m} = \frac{\ell(\ell+1)}{r^2} Z^{(a,p)}_{\ell m},$$

at $r = R$ we get the following approximate formula for the allowed angular frequencies:

$$\omega_{\ell n} \simeq \frac{c}{2R}\,(2 + \ell + 2n)\,\pi, \;\; \ell \geq 2, \;\; n \in \mathbb{N}, \tag{1}$$

where $n$ is the radial quantum number and $\ell$ is interpreted as a species index (quadrupolar, sextupolar...gravitons). With the (1), we can build the ordinary statistical mechanics by calculating the partition function for $N$ oscillators[2]: we obtain the correct equation of state expected for radiation, i.e. $PV = \frac{U}{3}$, where $P$ is the pressure and $U$ the internal energy. In this way the pressure, missing in the usual treatment with respect to an external observer, emerges from the interior of the black hole. The first law of thermodynamics requires that $T_i = \alpha T_h = \frac{\alpha c\hbar}{4\pi K_B R}$, $\alpha \in (0, \infty)$. For a radiation field from the integrated first law we expect $\alpha = 2$. For the entropy we thus obtain the expression:

$$S = K_B Y(\alpha) \frac{A_h}{4L_P^2}, \;\; A_h = 4\pi R^2,$$

$$Y(\alpha) = \frac{b}{\alpha\pi^2\left(3 + e^{\frac{2\pi^2}{\alpha}}\right)} \tag{2}$$

$$b = -\alpha e^{\frac{4\pi^2}{\alpha}} \ln\left(1 - e^{-\frac{2\pi^2}{\alpha}}\right) - \alpha e^{\frac{4\pi^2}{\alpha}} \ln\left(1 - e^{-\frac{4\pi^2}{\alpha}}\right) + 6\pi^2 +$$

$$+ 2\pi^2 e^{\frac{2\pi^2}{\alpha}} + \alpha \ln\left(1 - e^{-\frac{2\pi^2}{\alpha}}\right) + \alpha \ln\left(1 - e^{-\frac{4\pi^2}{\alpha}}\right). \tag{3}$$

Hence $S = S_h$ iff. $Y(\alpha) = 1$ with a unique solution $\alpha \simeq 2.2$. If a summation over the azimuthal index $m$ is performed, we obtain $\alpha \simeq 8.48 \rightarrow$ that must be ruled out because too large with respect to the approximations made.

In[4] also the logarithmic corrections have been obtained by considering quantum Planckian fluctuations motivated by a quantum spacetime[6–8]. It is also interesting to note that, by taking the internal energy 'dressed' with Planckian fluctuations, i.e. $U(R) = \frac{c^4}{2G}R + \frac{C_1 c^4 L_P^2}{2GR}$, $\{C_1\} \in \mathbf{R}^+$, evaporation stops[3] at the radius $R = R_0 > R_c = \sqrt{C_1}L_P$: as expected, Planckian fluctuations act as a repulsive force thus opposing to the gravitational one.

## 2. Remarks

We have obtained a statistical description of the black hole entropy in terms of trapped gravitons: why gravitons and not photons? First of all, the B-H bentropy has been obtained with semi-classical considerations concerning general relativity and quantum mechanics. Since the Schwarzschild metric is a vacuum solutions of Einstein's equations, we expect that, thanks to the equivalence principle, only gravitons can survive inside the horizon. In fact, any other matter-energy is equipped with a non vanishing energy momentum tensor $T_{\mu\nu}$, and in a quantum context it will appear the mean value of $T_{\mu\nu}$ in some quantum state, i.e. $< T_{\mu\nu} >$, in the field equations, and as a consequence a non vacuum solution emerges.

It should be noticed that we have obtained the B-H entropy only with two reasonable assumptions. First of all, we have assumed for the internal energy the expression $U_h = U_i = Mc^2$, where $M$ is the ADM mass. This is a rather natural assumption. In practice, from the interior point of view the black hole is equipped with the same mass-energy as seen by an external observer with the entropy $S_h = \frac{K_B A_h}{4L_P^2}$. This entropy is interpreted in different ways. The external observer measures the Hawking radiation at spatial infinity with temperature $T_h$ and thus associates a non vanishing entropy to this radiation: the external observer cannot see the interior of the black hole and thus cannot have direct experience of the degrees of freedom giving the black hole entropy. Conversely, from the interior point of view, gravitons are stored inside and provide the degrees of freedom leading to the B-H entropy. In some sense, the point of view of the interior is 'dual' to the one present from the exterior.

The second assumption is the validity of the first law of thermodynamics. The application of the first law implies that the internal temperature is proportional to the one at the exterior $T_h$ by a factor 2: in this way a pressure term naturally arises in the first law.

We have obtained for $\alpha$ a numerical value, $\sim 2.2$, that is near the true value $\alpha = 2$ within the approximations made. To this purpose, note that the function $Y(\alpha)$ in[3] is strongly sensitive to $\alpha$ and therefore our consistent check is far from trivial.

An interesting property of our construction is that we have not used an underlying quantum gravity theory and thus our approach, according to the aim of the Hawking drivation, is 'phenomenological' and thus it is expected to be physically sound, since we used only sound arguments of general relativity, quantum mechanics

and statistical mechanics. In this regard is rather intriguing the fact that, as a consequence of the two assumptions depicted above, we obtain that $N \sim A$. This means that we obtain a result according to the holographic principle without assuming it from the onset: this results is a simple exact consequence of the fact that the mass of the black hole is the ADM one and the validity of the first law, no other assumptions are necessary.

In[5] we have extended the results in[2–4] for any massless excitations. This open the doors to a physical description of the cosmological constant.

## 1. Introduction

Black holes in gravity models with a negative cosmological constant are of considerable interest because of their fundamental role in the Anti-de Sitter/Conformal Field Theory (AdS/CFT) correspondence[1,2], in which an equivalence between classical gravitational solutions with AdS asymptotics in $D-$dimensions and field theory strongly coupled states in $(D-1)-$dimensions is proposed.

In this context the solutions of five dimensional $\mathcal{N}=4$ $SO(6)$ gauged supergravity are of special interest, since this theory is thought to be a consistent truncation of type IIB supergravity on $AdS_5 \times S^5$ [3,4]. The simplest version of the model corresponds to the bosonic sector of the theory, which results in Einstein-Maxwell (EM) theory with a Chern-Simons (CS) term and a negative cosmological constant. The action for $D=5$ minimal gauged supergravity is the following

$$I=-\frac{1}{16\pi}\int_{\mathcal{M}} d^5\mathrm{x}\sqrt{-g}\left[R+\frac{12}{L^2}-F_{\mu\nu}F^{\mu\nu}-\frac{2\lambda}{3\sqrt{3}}\varepsilon^{\mu\nu\alpha\beta\gamma}A_\mu F_{\nu\alpha}F_{\beta\gamma}\right]. \quad (1)$$

Here $R$ is the curvature scalar, $L$ is the AdS length scale (related with the cosmological constant $\Lambda=-6/L^2$) and $A_\mu$ is the $U(1)$ gauge potential with corresponding field strength tensor $F_{\mu\nu}=\partial_\mu A_\nu-\partial_\nu A_\mu$. Note that $\lambda$ is the CS coupling constant, but in the minimal gauged supergravity case this is fixed to $\lambda=1$.

The field equations of this model is a generalized version of the Einstein-Maxwell equations,

$$R_{\mu\nu}-\frac{1}{2}Rg_{\mu\nu}-\frac{6}{L^2}g_{\mu\nu}=2F_{\mu\rho}F^{\rho}{}_{\nu}-\frac{1}{2}F^2g_{\mu\nu}\ ,\ \ \nabla_\nu F^{\mu\nu}=\frac{-\lambda}{2\sqrt{3}}\varepsilon^{\mu\nu\alpha\beta\gamma}F_{\nu\alpha}F_{\beta\gamma}\ . \quad (2)$$

This model has a number of interesting solutions. For instance, static and spherically symmetric black holes (the Schwarzschild-Tangherlini solution), stationary vacuum black holes (the Myers-Perry-AdS solution, with two different angular momenta in general), or the static, spherically symmetric and electrically charged configuration (the Reissner-Nordström-AdS black hole). More interesting are the stationary and electrically charged configurations (the Chong-Cvetic-Lü-Pope solution). These solutions possess four global charges: the mass, two angular momenta, and the electric charge[5]. The symmetry can be enhanced when the two angular momenta are equal in magnitude. This particular case was obtained by Cvetič, Lü and Pope (CLP)[6,7]. They possess a regular extremal limit, which contains a subset of solutions that preserves a fraction of supersymmetry[8]. Several generalizations of the CLP solution have been presented in[16–18].

In this paper we will review a particular family of solutions that generalize the CLP black hole. We will see that these new solutions, in addition to the mass, angular momentum and charge, are characterized by some non-trivial asymptotics (magnetization and squashing of the AdS boundary). These solutions are motivated by similar configurations studied in simpler settings, such as in Einstein-Maxwell-AdS theory in 4 dimensions[9–11], or static configurations (black holes with a solitonic limit) that are supported by a purely magnetic gauge field[12]. The box-like behaviour of AdS space-time, when combined with some nontrivial asymptotical multipolar behavior of the electromagnetic field at the boundary can be used to obtain new classes of regular solitons, that can be combined with a horizon to construct black holes. We will present the properties of the magnetized configurations with $AdS_5$ asymptotics[13], and of the more general squashed and magnetized solutions[14,15], which possess only a locally-AdS boundary, but allow for the existence of a new family of supersymmetric black holes in the extremal limit.

## 2. Ansatz, asymptotic behavior and charges

Since we are interested in configurations with equal angular momenta, spherical topology of the horizon, and asymptotical AdS behavior, we can propose the following Ansatz for the line element,

$$ds^2 = -f(r)\left(1+\frac{r^2}{L^2}\right)dt^2 + \frac{m(r)dr^2}{f(r)\left(1+\frac{r^2}{L^2}\right)} + \frac{r^2 m(r)}{4f(r)}(d\theta^2+\sin^2\theta d\phi^2) + \frac{r^2 n(r)}{4f(r)}\left(d\psi+\cos d\theta d\phi - \frac{2\omega(r)}{r}dt\right)^2 , \qquad (3)$$

where $r$ and $t$ are the radial and temporal coordinates, and $\theta$, $\phi$, $\psi$ are the Euler angles on $S^3$. The gauge field compatible with this line element (3) contains in general an electric and a magnetic potential, $A = a_0(r)dt + a_k(r)(d\psi+\cos d\theta d\phi)/2$.

A first requirement to the solutions we are going to consider is the existence of a non-trivial magnetic field on the AdS boundary[13], $\Phi_m = \frac{1}{4\pi}\int_{S^2_\infty} F = -c_m/2$ which can be understood as the magnetic flux passing through the base space $S^2$ of the $S^1$ fibration.

In addition, we can relax the asymptotical behaviour of the line element so that the boundary space is no longer a global $AdS_5$ manifold, but a space with only the local AdS symmetries. We refer to this as a squashed AdS boundary.

These two requirements on the asymptotical behaviour of the configuration impose the following expansion on the functions when close to the boundary:

$$f(r) = 1 + \frac{4}{9}(1-v^2)\left(\frac{L}{r}\right)^2 + \dots \ , \quad m(r) = 1 - \frac{1}{9}(1-v^2)\left(\frac{L}{r}\right)^2 + \dots \ ,$$
$$n(r) = v^2\left(1 + \frac{17}{9}(1-v^2)\left(\frac{L}{r}\right)^2\right) + \dots \ , \quad w(r) = \hat{j}\frac{1}{r^3} + \dots \ ,$$
$$a_0(r) = -\frac{q}{r^2} + \dots \ , \quad a_k(r) = c_m + \left(\mu - 2c_m L^2 v^2 \log\left(\frac{r}{L}\right)\right)\frac{1}{r^2} + \dots \ . \quad (4)$$

The full asymptotic expansion can be found in [14,15]. It depends on the squashing parameter $v$ (where $v = 1$ for the standard $AdS_5$ asymptotics) and the magnetization parameter $c_m$, apart from other standard parameters that are related with the angular momentum ($\hat{j}$), electric charge ($q$) and magnetic moment ($\mu$) (the parameters related with the mass appear only in the next order of the expansion, which is not shown here for simplicity).

This expansion has important consequences for the total charges of the configuration [14,15]. For instance, now we have to distinguish between the Page charge and the holographic charge, calculated with the boundary flux formalism. It is possible to see that

$$Q^{(p_0)} = \frac{1}{4\pi}\int_{S^3_\infty} d\Sigma_3(\sqrt{-g}F^{rt} - p_0\frac{\lambda}{\sqrt{3}}\varepsilon^{abc}A_a F_{bc}) = -\pi\left(qv - p_0\frac{2\lambda}{\sqrt{3}}c_m^2\right) \ , \quad (5)$$

corresponds to the Page charge for $p_0 = 1$ (whose conservation is implied by the field equations (2)), and to the holographic charge for $p_0 = 2/3$ (which is calculated using the boundary counterterms of the action (1) and the corresponding stress-energy tensor at the boundary [14,15]). Note that both charges coincide in the absence of magnetic flux at the boundary.

In addition to this far-field expansion, it is possible to study perturbatively the properties of solutions with a horizon (in which case the horizon charges can be computed, such as the area, horizon mass, horizon angular momentum, etc). It is also possible to find perturbatively regular solitonic solutions, but only in the case that the Page charge of such solutions vanishes [14,15]).

Despite the existence of these perturbative analytical solutions, the full construction of the black holes and the solitons extending up to the AdS boundary has to be performed numerically. In the next sections we will discuss the properties of such solutions.

## 3. Magnetized and squashed configurations

Let us start with the simplest case, in which the squashing parameter is $v = 1$, but the solutions possess some non-trivial magnetization $c_m \neq 0$.

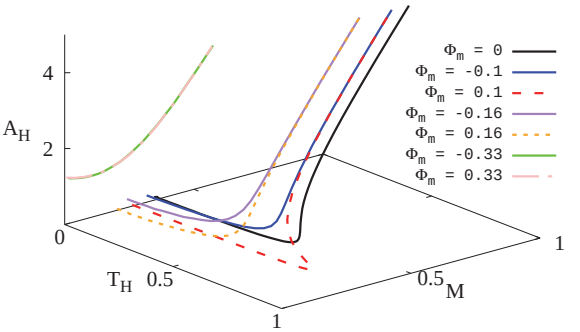

Fig. 1. Area ($A_H$) versus horizon temperature $T_H$ and total mass $M$ for the magnetized black holes. In black, the family CLP solutions with angular momentum $J = 0.003$, and (holographic) charge $Q = 0.044$. In colors, families of magnetized solutions with the same angular momentum and holographic charge, but different values of the magnetic flux at the $AdS_5$ boundary.

In Figure 1 we show the relation between the horizon area ($A_H$), horizon temperature ($T_H$) and total mass ($M$) of the magnetized black holes, for several values of the magnetization at the boundary ($\Phi_m$). Note that in general, the behavior of the magnetized solutions is very similar to the standard CLP black hole: one can see that there is a regular extremal limit (zero temperature), and that depending on the ratio between the different parameters, the families can possess a local maximum of the temperature (a phase transition between small and large black holes).

Apart from the previous families which possess an extremal limit, it is also possible to obtain families of black holes that asymptotically deform to magnetic solitons. To do so, one has to require the Page charge to vanish, and only then it is possible to continuously decrease the horizon size (as compared to the AdS length). In such a case the horizon shrinks and vanishes. We construct numerically the full solitonic configuration and compare this solution to the asymptotical behavior of the shrinking black holes, obtaining a perfect match. A more detailed discussion of all these configurations can be found in here[13].

It is possible to obtain numerically the squashed generalizations of the previous magnetized CLP black holes, by introducing the new parameter $v$ in the asymptotical behaviour of the metric functions. Such solutions were first presented in[14,15]. The space of solutions has very similar properties to what we show in Figure 1, but now with an extra parameter (the squashing $v$). Similar solitonic solutions can be constructed, and the black holes possess a regular extremal limit as well.

## 4. Supersymmetric solutions

More interesting is the existence of supersymmetric solutions contained in certain limits of the previous squashed and magnetized configurations. Some of them are well known (the Gutowski-Reall black hole[8], which is contained in the extremal limit of the CLP black hole, and hence it is unmagnetized and the AdS boundary is

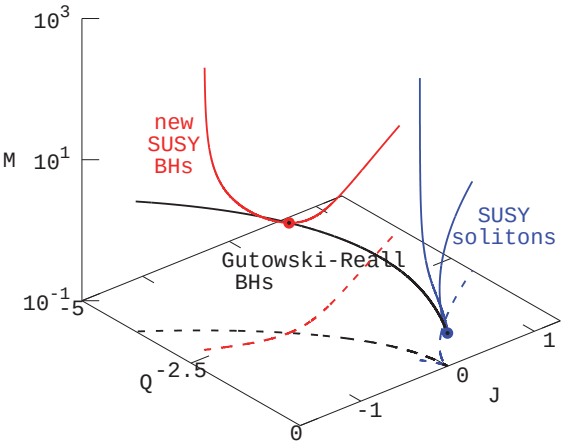

Fig. 2. Mass ($M$) versus holographic charge $Q$ and angular momentum $J$ for three families of supersymmetric solutions: in black, the Gutowski-Reall black holes; in blue the supersymmetric magnetized solitons with squashing of the boundary; in red the new squashed and magnetized supersymmetric black holes.

not deformed), or supersymmetric solitons[19] (which are both squashed and magnetized). In references[14,15] it was shown that an additional family of supersymmetric solutions, both squashed and magnetized, exist and branches off from a particular Gutowski-Reall configuration. In fact, all the supersymmetric solutions have a fixed relation between magnetization and squashing. The black holes can be connected to the supersymmetric solitons of Cassini and Martelli[19] only by increasing the black hole temperature, meaning they are connected by a family of non-extremal black holes (and hence non-supersymmetric).

In Figure 2 we show the mass, holographic charge and angular momentum for these three families of supersymmetric solutions. Interestingly, the new black holes (in red) have a 'frozen' horizon: although they form a one parameter family of solutions as it can be seen in the Figure, they all share the same near-horizon geometry (for instance, the same as the particular Gutowski-Reall black hole from which they branch off). They also share the same Page charge, but not the holographic charge, because of the non-trivial magnetization of the boundary.

## 5. Conclusions

We have presented here a summary of the properties of the new classes of magnetized and squashed black holes that generalize the CLP black hole by allowing for non-trivial asymptotics. In addition, the new black holes can be deformed continuously into solitons, without horizon. The black holes possess a regular extremal limit, and a particular subset of these extremal black holes turn out to be supersymmetric. Recently, further generalizations of these black hole solutions have been studied in more general settings[20–23].

# Non-linear perturbation of black branes at large $D$

Umpei Miyamoto

*RECCS, Akita Prefectural University, Akita 015-0055, Japan*
*E-mail: umpei@akita-pu.ac.jp*

The Einstein equations describing the black-brane dynamics both in Minkowski and AdS background were recently recast in the form of coupled diffusion equations in the large-$D$(imension) limit. Using such results in the literature, we formulate a higher-order perturbation theory of black branes in time domain and present the general form of solutions for arbitrary initial conditions. For illustrative purposes, the solutions up to the first or second order are explicitly written down for several kind of initial conditions, such as a Gaussian wave packet, shock wave, and rather general superposed sinusoidal waves. These could be the first examples describing the non-trivial evolution of black-brane horizons in time domain. In particular, we learn some interesting aspects of black-brane dynamics such as the Gregory-Laflamme (GL) instability and non-equilibrium steady state (NESS). The formalism presented here would be applicable to the analysis of various black branes and their holographically dual field theories.

*Keywords*: Black holes in higher dimensions; Gregory-Laflamme instability; AdS/CFT correspondence.

## 1. Introduction

It is important to understand the dynamics of higher-dimensional black objects, since it tells us much about the nature of higher-dimensional gravitational theories and their holographically dual quantum field theories. The strong non-linearity of gravity, however, usually prevents us from understanding the dynamical properties of black objects beyond the linear-perturbation regime without highly sophisticated skills of numerical computation.

The Gregory-Laflamme (GL) instability[1], which is a universal instability of higher-dimensional black objects, is a good example to see the above situation. Though the GL instability in the non-linear regime is quite interesting, its analysis needs sophisticated skills of numerical relativity[2]. While there exists a semi-analytic higher-order perturbation method[3], it seems applicable only to static problems.

Recently, Emparan, Suzuki, and Tanabe showed that the Einstein equations describing the horizon dynamics of black branes in both Minkowski and Anti-de Sitter (AdS) background are recast in the form of coupled non-linear diffusion-type equations when the number of spatial dimensions is large[4]. This result provides us with a unique approach to the non-linear dynamics of black objects in higher dimensions. The authors indeed showed that the unstable black strings converge to non-uniform black strings (NUBSs), which had been predicted to happen above a critical dimension[5], by solving the diffusion equations numerically with a few lines of *Mathematica* code.

Once the simple diffusion equations were obtained[4], it is natural to ask if the non-linear properties of black-brane dynamics can be understood analytically. In this work, we develop a systematic non-linear perturbation theory of asymptotically

flat and AdS black branes, allowing the perturbations to be dynamical. Using the Fourier and Laplace transformation to solve the partial differential equations (PDEs), the perturbation equations are solved order by order for given arbitrary initial conditions up to the integration associated with the inverse transformation.

While the formulation is so general that it would be applicable to various problems, we pick up several examples as the initial conditions, which are a Gaussian wave packet, a step-function like shock configuration, and quite general discretely superposed sinusoidal waves. For these examples, the integration associated with the inverse transformation is completed up to the first or second order, and the properties of solutions are examined. Through these examples, one will see the validity of formalism itself and some unknown, or yet-to-be-confirmed, non-linear properties of black-brane dynamics. In particular, in the case of asymptotically flat black branes, an interesting non-liner property of GL instability resulting from the mode-mode coupling is unveiled at the second order. In the case of shock propagation on asymptotically AdS black branes, the analytic description of non-equilibrium steady state (NESS), which was recently discussed in the Riemann problem of relativistic fluid mechanics and field theories[6], is presented.

In this article, we present the formulation and a few results in the asymptotically flat case. In the original paper Ref. 7 and talk, the results in the asymptotically AdS case are presented.

## 2. Perturbation equations and general form of solutions

In the large-$D$(imension) approach, the horizon dynamics of vacuum black branes without a cosmological constant are described by two functions, $m(t,z)$ and $p(t,z)$, where $t$ is time and $z$ is the spatial coordinate along which the horizon extends[4]. $m$ and $p$ represent the mass and momentum distributions along the horizon, respectively. $m \to +0$ corresponds to the pinching off of the horizon. The equations of motion for these quantities take form of coupled non-linear diffusion equations,

$$(\partial_t - \partial_z^2)m + \partial_z p = 0, \quad (\partial_t - \partial_z^2)p - \partial_z m = -\partial_z \left(\frac{p^2}{m}\right). \tag{1}$$

A uniform black-brane solution corresponds to $m(t,z) \equiv 1$ and $p(t,z) \equiv 0$. Since we are interested in the dynamical deformation of such a uniform solution, we introduce one-parameter families of $m(t,z)$ and $p(t,z)$, and expand them around the uniform black-brane solution,

$$m(t,z;\epsilon) = 1 + \sum_{\ell=1}^{\infty} m_\ell(t,z)\epsilon^\ell, \quad p(t,z;\epsilon) = \sum_{\ell=1}^{\infty} p_\ell(t,z)\epsilon^\ell, \tag{2}$$

where $\epsilon$ is a constant parameterizing the families. Substituting these expansions into Eq. (1), we obtain the equations of motion at $O(\epsilon^\ell)$ ($\ell \in \mathbb{N}$),

$$\dot{m}_\ell - m_\ell'' + p_\ell' = 0, \quad \dot{p}_\ell - p_\ell'' - m_\ell' = \psi_\ell, \tag{3}$$

where the dot and prime denote the derivatives with respect to $t$ and $z$, respectively. The right-hand side of right equation in (3), $\psi_\ell(t,z)$, which we call a source term, is a polynomial of the lower-order perturbations and their first spatial derivatives. For example, the source terms for $\ell=2$ and $\ell=3$ are given by

$$\psi_2 = -2p_1p_1', \quad \psi_3 = 2m_1p_1p_1' + m_1'p_1^2 - 2p_1p_2' - 2p_1'p_2. \tag{4}$$

We are looking for the general form of solutions to the perturbation equations (3), combining the Fourier and Laplace transformations. A similar technique is found to be used in Ref. 8 to analyze the higher-order perturbation of surface-diffusion equation, which is a single non-linear PDE. Before starting to solve Eq. (3), let us introduce the notations associated with the Fourier and Laplace transformations. For a given function, say $f(t,z)$, we shall denote its Fourier transformation with respect to $z$ by $\bar{f}(t,k)$, and its Laplace transformation with respect to $t$ by the corresponding capital letter $F(s,z)$. Namely,

$$\bar{f}(t,k) := \mathcal{F}[f(t,z)] = \int_{-\infty}^{\infty} f(t,z)e^{-ikz}dz, \tag{5}$$

$$F(s,z) := \mathcal{L}[f(t,z)] = \int_{0}^{\infty} f(t,z)e^{-st}dt. \tag{6}$$

With the notations introduced above, the Fourier-Laplace transformed version of Eq. (3) is written as coupled algebraic equations in a matrix form,

$$\boldsymbol{A}\begin{pmatrix}\bar{M}_\ell(s,k)\\ \bar{P}_\ell(s,k)\end{pmatrix} = \begin{pmatrix}\bar{m}_\ell(0,k)\\ \bar{p}_\ell(0,k)+\bar{\Psi}_\ell(s,k)\end{pmatrix}, \tag{7}$$

$$\boldsymbol{A} := \begin{pmatrix}s+k^2 & ik\\ -ik & s+k^2\end{pmatrix}. \tag{8}$$

The solution to Eq. (3) is obtained after multiplying Eq. (7) by $\boldsymbol{A}^{-1}$ from left and inversely transforming it,

$$\begin{pmatrix}m_\ell(t,z)\\ p_\ell(t,z)\end{pmatrix} = (\mathcal{F}^{-1}\circ\mathcal{L}^{-1})\left[\boldsymbol{A}^{-1}\begin{pmatrix}\bar{m}_\ell(0,k)\\ \bar{p}_\ell(0,k)+\bar{\Psi}_\ell(s,k)\end{pmatrix}\right]. \tag{9}$$

By simple algebra, the inverse matrix $\boldsymbol{A}^{-1}$ is found to be decomposed into two parts,

$$\boldsymbol{A}^{-1} = \sum_{\sigma=+,-}\frac{1}{s-s_\sigma(k)}\boldsymbol{B}_\sigma, \tag{10}$$

$$\boldsymbol{B}_\sigma := \frac{1}{2}\begin{pmatrix}1 & -\sigma i\\ \sigma i & 1\end{pmatrix}, \quad s_\sigma(k) := k(\sigma 1 - k). \tag{11}$$

After this decomposition, one can perform the inverse Laplace transformation $\mathcal{L}^{-1}$ in Eq. (9) to obtain

$$\begin{pmatrix}m_\ell(t,z)\\ p_\ell(t,z)\end{pmatrix} = \sum_{\sigma=+,-}\boldsymbol{B}_\sigma\begin{pmatrix}\mathcal{F}^{-1}[e^{s_\sigma(k)t}\bar{m}_\ell(0,k)]\\ \mathcal{F}^{-1}[e^{s_\sigma(k)t}\bar{p}_\ell(0,k)+e^{s_\sigma(k)t}*\bar{\psi}_\ell(t,k)]\end{pmatrix}, \tag{12}$$

where $*$ denotes the convolution with respect to time.

Equations (12) is exactly what we wanted, namely, the general form of solutions to the perturbation equations (3) for given arbitrary initial conditions, $m_\ell(0,z)$ and $p_\ell(0,z)$ ($\ell \in \mathbb{N}$).

## 3. Example of initial conditions: Superposed sinusoidal waves

As an example, we consider the situation where the black brane is initially given an $O(\epsilon)$ perturbation being a superposition of an arbitrary number of sinusoidal waves. This example is simple but interesting enough to see what happens in the non-linear regimes. We set the following initial conditions,

$$m_1(0,z) = \sum_{n=1}^{N} a_n \cos(k_n z + \varphi_n), \quad p_1(0,z) = m_1'(0,z), \tag{13}$$

$$m_\ell(0,z) = p_\ell(0,z) = 0 \quad \text{for all} \quad \ell \geq 2, \tag{14}$$

where $a_n$, $k_n$, and $\varphi_n$ ($n = 1, 2, \cdots, N$) are real constants. We shall compute the right-hand side of Eq. (9) order by order for these initial conditions.

Since we have no source term at $O(\epsilon)$, $\psi_1 \equiv 0$, we see from Eq. (9) that what to compute is only the inverse Fourier transformation of the initial spectra, $\bar{m}_1(0,k)$ and $\bar{q}_1(0,k)$, multiplied by $e^{s_\sigma(k)t}$. Then, we obtain the first-order solutions,

$$m_1(t,z) = \frac{1}{2}\sum_{n=1}^{N} a_n[(1+k_n)e^{s_+(k_n)t} + (1-k_n)e^{s_-(k_n)t}]\cos(k_n z + \varphi_n), \tag{15}$$

$$p_1(t,z) = -\frac{1}{2}\sum_{n=1}^{N} a_n[(1+k_n)e^{s_+(k_n)t} - (1-k_n)e^{s_-(k_n)t}]\sin(k_n z + \varphi_n). \tag{16}$$

Since we are considering linear equations of motion, there is no mode-mode coupling appearing in non-linear regime, and therefore Eqs. (15) and (16) allow simple interpretation. The factor of $\cos(k_n z + \varphi_n)$ in Eq. (15) represents the time-dependent amplitude of the initially given mode $\cos(k_n z + \varphi_n)$. Each mode evolves independently according to its growth or damping rate determined by $e^{s_+(k_n)t}$ and $e^{s_-(k_n)t}$. From the concrete form of $s_\pm(k)$ in Eq. (11), one can see that if $k_n \in (-1, 0)$ (resp. $k_n \in (0, 1)$), such a mode grows exponentially due to $e^{s_-(k_n)t}$ (resp. $e^{s_+(k_n)t}$), which represents the GL instability.

Since we assume that the initial perturbations vanish at $O(\epsilon^2)$, $m_2(0,z) = p_2(0,z) = 0$, we see from Eq. (9) that what to compute at the second order is the inverse Fourier transformation of the convolution between $e^{s_\sigma(k)t}$ and the Fourier spectrum of source term $\bar{\psi}_2(t,k)$.

Although the second-order solutions can be written down analytically, let us omit writing them down here since the space is restricted (see the original paper Ref. 7 for the explicit form of solutions). At the second order, the non-linear source term involves the mode-mode coupling, which is absent at the linear order. This coupling

excites the terms of $\cos[(k_n \pm k_{n'})z]$ and $\sin[(k_n \pm k_{n'})z]$. For example, one can find that both $\cos[(k_n + k_{n'})z]$ and $\cos[(k_n - k_{n'})z]$ terms involve the following three kind of time dependence,

$$e^{s_+(k_n+k_{n'})t}, \quad e^{s_-(k_n+k_{n'})t} \quad \text{and} \quad e^{s_+(k_n-k_{n'})t}, \quad e^{s_-(k_n-k_{n'})t}. \tag{17}$$

Thus, the second-order solutions exhibit a variety of dispersion given by the exponents of (17).

Let us consider the meaning to investigate the higher-order perturbations from the stability point of view. The asymptotically flat black brane we consider here is essentially unstable. Namely, if the initial perturbation contains any mode of which wave number $k_n \in (-1, 1) \setminus \{0\}$, such a mode grows unboundedly. However, we consider the black brane in the large-$D$ limit, namely, above the critical dimension[5]. Thus, the GL instability initially grows but it gradually damps in non-linear regimes, and eventually the horizon converges to non-uniform configuration[4].

A black brane that is linearly stable can become unstable at the second order. If the initial perturbation does not contain any unstable mode, the initial perturbation will damp exponentially at linear level. However, the second-order perturbation involves various time dependence as seen in Eq. (17). In order to see directly this situation, let us focus on a simple case as follow.

Suppose that the initial perturbation is the superposition of two modes $k_1$ and $k_2$ both of which are stable modes, $k_1 > k_2 > 1$. In addition, assume that their difference is smaller than unity, $k_1 - k_2 \in (0, 1)$. In this case, the term of $C_{21}^{(+)(-)}(t)\cos[(k_1 - k_2)z + (\varphi_1 - \varphi_2)]$ in $m_2(t, z)$ includes terms having growing factor $e^{s_+(k_1-k_2)t}$. Thus, the perturbation does not grow at $O(\epsilon)$ but does at $O(\epsilon^2)$.

The above phenomenon is an interesting aspect of the GL instability, which was revealed for the first time by the present non-linear perturbation theory in time domain. It is intuitively understandable. The superposition of the two modes forms the beat. For simplicity, assume $a_1 = a_2$ ($\neq 0$), then the superposed wave is written as

$$2a_1 \cos\left[\frac{(k_1 + k_2)z + (\varphi_1 + \varphi_2)}{2}\right] \cos\left[\frac{(k_1 - k_2)z + (\varphi_1 - \varphi_2)}{2}\right]. \tag{18}$$

This exhibits the fast spatial oscillation with the large wave number $\frac{k_1+k_2}{2}$ which is enveloped by the slow oscillation with the small wave number $\frac{k_1-k_2}{2}$, which is called the beat phenomenon especially when the difference of the wave numbers is rather small $k_1 - k_2 \ll k_1 + k_2$. This slow oscillation is nothing but the origin of the GL instability at the second order. One can observe that the beat formed by the superposition of two modes at $t = 0$. As soon as the dynamics starts, such an initial wave rapidly damps as predicted by the first-order perturbation. As the time proceeds, however, the waves of which scale is the same order as that of the beat begin to grow and eventually diverge.

# Unitary evaporation via modified Regge-Wheeler coordinate

Aizhan Myrzakul* and Michael R.R. Good†

*Physics Department,*
*Nazarbayev University,*
*Astana, Kazakhstan*

Constructing an exact correspondence between a black hole model, formed from the most simple solution of Einstein's equations, and a particular moving mirror trajectory, we investigate a new model that preserves unitarity. The Bogoliubov coefficients in 1+1 dimensions are computed analytically. The key modification limits the origin of coordinates (moving mirror) to sub-light asymptotic speed. Effective continuity across the metric ensures that there is no information loss. The black hole emits thermal radiation and the total evaporation energy emitted is finite without backreaction, consistent with the conservation of energy.

## 1. Introduction

The Hawking effect [1] has an exact correspondence [2] with the moving mirror. [3,4] The specific and analytically known accelerated boundary condition on the quantum field, $\psi$, located at the origin of coordinates, $r = 0$, corresponding to the location of the black hole singularity, depends explicitly on the form of the tortoise coordinate, $r^*$. The moving mirror perfectly reflects the field modes and accelerates with the precise trajectory, $t(x)$.

The physical effect of the mirror is that it arouses quantum field fluctuations reflecting virtual particles into real ones. The black mirror,[2] which is the aforementioned tortoise coordinate associated boundary condition, extracts energy indefinitely and does not preserve unitarity. However, we present a summary of a modified model [5] — "a drifting black mirror" — which resolves these two problems. It was demonstrated recently [6] that the new corresponding coordinate to $r^*$ is the generalized or giant tortoise coordinate (GTC). The giant tortoise coordinate results in unitarity preservation and finite energy emission of the black hole during evaporation.

In this MG15 proceedings contribution, first, the usual tortoise coordinate, $r^*$, and its relation to the moving mirror, $t(x)$, is briefly considered. Then we generalize this coordinate to the giant tortoise coordinate and investigate the correspondence between the black hole and the moving mirror in the context of the GTC. We find no information loss, finite evaporation energy, thermal equilibrium, analytical beta coefficients, and a left-over [7] remnant.

## 2. The Tortoise Coordinate and the Black Mirror

In this section the textbook matching solution[8] for the outside and inside of the black hole over the shock wave is derived.

Let us start from the usual tortoise coordinate, (the Regge-Wheeler $r^*$):

$$r^* \equiv r + 2M \ln\left(\frac{r}{2M} - 1\right). \tag{1}$$

Requiring the metric to be the same on both sides of the shock wave, $v_0$:

$$r(v_0, u_{\rm in}) = r(v_0, u_{\rm out}), \tag{2}$$

where

$$r(v_0, u_{\rm in}) = \frac{v_0 - u_{\rm in}}{2}, \qquad \text{and} \qquad r^*(v_0, u_{\rm out}) = \frac{v_0 - u_{\rm out}}{2}, \tag{3}$$

the tortoise coordinate, Eq. (1), can be rewritten as:

$$r(v_0, u_{\rm out}) + 2M \ln\left(\frac{r(v_0, u_{\rm out})}{2M} - 1\right) = \frac{v_0 - u_{\rm out}}{2}. \tag{4}$$

Solving this for the red-shift function $u_{\rm out}$ yields:

$$u_{\rm out} = u_{\rm in} - 4M \ln\frac{|v_H - u_{\rm in}|}{4M}. \tag{5}$$

The $u_{\rm out} = +\infty$ limit corresponds to the formation of a black hole event horizon location, $v_H \equiv v_0 - 4M$. Eq. (5) is exactly the matching solution[8] for the Eddington-Finkelstein background (exterior) to the Minkowski background (interior) with a strict event horizon.

Substituting $u_{\rm out} \equiv t(x) - x$ and $u_{\rm in} \equiv t(x) + x$ into Eq. (5), and solving for $t(x)$ gives the time-space trajectory of the black mirror[a]:

$$t(x) = v_H - x - 4Me^{x/2M}, \tag{6}$$

as investigated[b] in Good-Anderson-Evans (2016).[2] The range of the coordinates are: $0 < r < \infty$ and $-\infty < x < \infty$. Eq. (6) is transcendentally invertible and is an analytic relation between the black hole matching solution, Eq. (5), and the space-time trajectory of its moving mirror, $x(t)$.

## 3. The Giant Tortoise Coordinate and the Drifting Black Mirror

We impose a strong restriction on the maximum speed of the black mirror: it must always travel slower than light, even asymptotically.[c] That is, in any coordinate system the origin of the black hole, $r = 0$, should not speed away to null-future

[a] The black mirror, which is not eternally thermal,[9] is called Omex for short, due to the **Om**ega constant, $\Omega e^{\Omega} = 1$, and **ex**ponent argument.[2]

[b] See also the proceedings of the MG14 meeting[10,11] and the 2nd LeCosPA Symposium.[12]

[c] An exception in a different model can give finite energy and preserve information if the acceleration asymptotes to zero sufficiently fast.[13]

infinity, $\mathscr{I}^+$. This is highly restrictive and gives a new time-space trajectory[5] of the origin of coordinates (an asymptotically drifting mirror):

$$t(x,\xi) = v_H - \frac{x}{\xi} - 4Me^{\frac{x}{2M\xi}}. \tag{7}$$

Here $\xi$ is the asymptotic drifting speed which lies in the range $0 < \xi < 1$. The corresponding matching condition can be easily derived and is:

$$u_{\rm out} = u_{\rm in} - 4M\xi \ln\left[\frac{1-\xi}{2}\mathcal{W}\left(\frac{2e^{\frac{v_H - u_{\rm in}}{2M(1-\xi)}}}{1-\xi}\right)\right], \tag{8}$$

where $\mathcal{W}$ is the product log. When $\xi \to 1$, the matching solution Eq. (8) is equivalent to Eq. (5), meaning that one has operative formation of an effective event horizon. Thus the modest modification in Eq. (7) safeguards the formation of a black hole[d] that occur with Eq. (6).

Eq. (8) represents the world line of the origin. It is easy to see that this origin is a perfectly reflecting boundary as nothing can go behind $r = 0$ into the $r < 0$ space. Therefore we use the generalized matching solution Eq. (8) in order to find the giant tortoise coordinate (analogous to going backwards from Eq. (5) to Eq. (1)),

$$r^*(\xi) \equiv r + 2M\xi \ln\left[\frac{1-\xi}{2}\mathcal{W}\left(\frac{2e^{\frac{r-2M}{M(1-\xi)}}}{1-\xi}\right)\right]. \tag{9}$$

It is a crucial fact that these two coordinates, $r^*$ and $r^*(\xi)$, are effectively the same when $\xi \approx 1$. The distinction is that there is no singularity at $r = 2M$ in Eq. (9) as in Eq. (1) when $\xi \neq 1$: $r^*(\xi)_{r=2M} = 2M\left[1 - \xi\mathcal{W}(2/\epsilon)\right]$, where $\epsilon \equiv 1 - \xi$. The user may define the free parameter $\xi$ as close to $\xi \approx 1$ (for effective continuity) as is arbitrarily desired as long as strictly, $\xi < 1$ (for unitarity).

## 4. Unitarity: Finite Asymptotic Entanglement Entropy

Qualitatively, the black mirror correspondence demonstrates information loss by the acceleration horizon which prohibits some left-movers from hitting the mirror and becoming right-movers. We can say these modes are lost forever in the black hole. However, the drifting black mirror has an asymptotic approach to time-like future infinity, $i^+$, rather than null future infinity, $\mathscr{I}_L^+$ and all the left-movers hit the mirror and become right-movers, preserving information to an observer at $\mathscr{I}_R^+$.

Quantitatively, we see this result by the von-Neumann entanglement entropy[17] for the black mirror:[5]

$$S(t) = \frac{1}{6}\tanh^{-1}\left(\frac{1}{\mathcal{W}(2e^{2\kappa(v_H - t)}) + 1}\right), \tag{10}$$

[d]For more information on whether any type of horizon is formed during gravitational collapse taking into account quantum effects see, e.g. Ref. 14 (for horizonless models see Refs. 15, 16).

whose limit in the far future diverges:

$$S_f \equiv \lim_{t\to\infty} S(t) = \infty, \tag{11}$$

signaling information loss (see e.g. the entropy divergence in Ref. 18). Here $\kappa \equiv 1/4M$, the surface gravity for Schwarzschild background. In contrast, the drifting black mirror has entropy,

$$S_\xi(t) = \frac{1}{6}\tanh^{-1}\left(\frac{\xi}{\mathcal{W}(2e^{2\kappa(v_H-t)})+1}\right), \tag{12}$$

whose limit is

$$S_f \equiv \lim_{t\to\infty} S_\xi(t) = \frac{1}{6}\tanh^{-1}(\xi) = \frac{\eta}{6} \neq \infty. \tag{13}$$

The final asymptotic entropy is the drifting rapidity and its measure as a finite constant signals information preservation. To achieve effective equilibrium ($\xi \approx 1$), the final asymptotic entropy will be very large ($\eta \ggg 1$), but finite.

## 5. Finite Evaporation Energy

A prime advantage of the GTC, Eq. (9), is that during the collapse the global energy emission of the black hole is finite and analytic. The consistency of the result with the analytically computed beta Bogolubov coefficient can be shown via a numerical verification of the stress-energy tensor[5,19] whose total energy production is,

$$E = \frac{1}{96\pi M}\left(\gamma^2 + \frac{\eta}{\xi}\right), \tag{14}$$

where $\gamma \equiv 1/\sqrt{1-\xi^2}$ is the final drifting Lorentz factor, $\eta \equiv \tanh^{-1}\xi$ is the final drifting rapidity, with $\xi < 1$ corresponding to the final drifting speed. For high drifting speed (thermality), $\xi \approx 1$, then $\gamma^2 \gg \eta/\xi$, and:

$$E = \frac{\gamma^2}{96\pi M}. \tag{15}$$

One immediately sees that the energy diverges as the origin moves to the speed of light, (i.e. mirror drift, $\xi \to 1$ and $\gamma \to \infty$). Eq. (15) is the final expression for the energy emission of the thermal black hole which is finite and consistent with the conservation of energy. Finite energy is anticipated to be a primary result of backreaction,[8] yet, we have obtained consistency by restricting origin speed, $\xi < 1$.

## 6. Temperature and the Giant Tortoise Coordinate

Using the GTC, a constant energy flux plateau is apparent (high drifting speeds, $\xi \approx 1$). During equilibrium, $F = \pi T^2/12$. Expanding the temperature as a function of maximum energy flux (where the radiation is closest to equilibrium) gives the temperature of the black hole:[5]

$$T(\epsilon, M) = \frac{1}{8\pi M}\left[1 - 3\left(\frac{3}{4}\right)^{1/3}\epsilon^{2/3} + O(\epsilon)\right], \tag{16}$$

to lowest order in $\epsilon$ where $\epsilon \equiv 1 - \xi$. The first term in this expression corresponds to the equilibrium temperature of the unmodified black mirror model which uses the usual tortoise coordinate. The other terms correspond to the deviation due to sub-light speed drift, $\xi < 1$, which are negligible for small $\epsilon$. The modification of Eq. (6) to Eq. (7) still results in a constant energy flux plateau and effective long-term thermal equilibrium of Eq. (16) for $\xi \approx 1$. This confirms the robustness of the GTC model for describing Planckian distributed particle creation from a black hole.

## 7. The Beta Bogoliubov Coefficient

The particle spectrum,

$$\langle N_\omega \rangle \equiv \langle 0_{in} | N_\omega^{out} | 0_{in} \rangle = \int_0^\infty |\beta_{\omega\omega'}|^2 d\omega', \tag{17}$$

requires knowing the GTC beta Bogoliubov coefficient which is a simple integral to compute analytically[5] with result:

$$\beta_{\omega\omega'}(\xi) = -\frac{\xi\sqrt{\omega\omega'}}{2\pi\kappa\omega_p}\left(\frac{i\kappa}{\omega_p}\right)^A \Gamma(A), \tag{18}$$

where $\Gamma(x)$ is the gamma function, $A \equiv \frac{i}{2\kappa}[(1+\xi)\omega + (1-\xi)\omega']$ and $\omega_p \equiv \omega + \omega'$. The integrand[5] of Eq. (17) is Planckian using Eq. (18) with $\xi \approx 1$ and $\omega' \gg \omega$, which is consistent with Eq. (16).

## 8. Summary

| Quantity | Tortoise | Giant Tortoise |
|---|---|---|
| $r^*$ | $r^* \equiv r + 2M\ln\left(\frac{r}{2M} - 1\right)$ | $r^*(\xi) \equiv r + 2M\xi\ln\left[\frac{\epsilon}{2}\mathcal{W}\left(\frac{2}{\epsilon}e^{\frac{r-2M}{M\epsilon}}\right)\right]$ |
| $t(x)$ | $t = -x - 4Me^{x/2M}$ | $t(\xi) = -x/\xi - 4Me^{x/2M\xi}$ |
| $u_{\rm out}$ | $u_{\rm out} = u_{\rm in} - 4M\ln\frac{\lvert v_H - u_{\rm in}\rvert}{4M}$ | $u_{\rm out}(\xi) = u_{\rm in} - 4M\xi\ln\left[\frac{\epsilon}{2}\mathcal{W}\left(\frac{2}{\epsilon}e^{\frac{v_H - u_{\rm in}}{2M\epsilon}}\right)\right]$ |
| $S_f$ | $\infty$ | $S_f(\xi) = \eta/6$ |
| $E$ | $\infty$ | $E(\xi) = \frac{1}{96\pi M}\left(\gamma^2 + \frac{\eta}{\xi}\right)$ |
| $T$ | $T = \frac{1}{8\pi M}$ | $T(\xi) = \frac{1}{8\pi M} + \mathcal{O}(1-\xi)$, for $\xi \approx 1$ |
| $\beta$ | $\beta_{\omega\omega'} = -\frac{\sqrt{\omega\omega'}}{2\pi\kappa\omega_p}\left(\frac{i\kappa}{\omega_p}\right)^{\frac{i\omega}{\kappa}}\Gamma(\frac{i\omega}{\kappa})$ | $\beta_{\omega\omega'}(\xi) = -\frac{\xi\sqrt{\omega\omega'}}{2\pi\kappa\omega_p}\left(\frac{i\kappa}{\omega_p}\right)^A\Gamma(A)$ |

We have presented an overview[20] of a unitary black hole evaporation model that, without backreaction, manages to produce a finite total energy emission. Exact

analytic results for several important corresponding quantities are found: the beta Bogoliubov coefficients, the finite total energy emission, the matching condition for the modes and the generalized tortoise coordinate.

The model[e] relaxes uncompromising continuity across the shock wave in the metric in exchange for preserving information.[f] Arbitrary precision in continuity is permitted with arbitrary fast sub-light drifting speeds for the origin of coordinates (the moving mirror must travel at speeds less than light). As long as this requirement is met, the information is preserved and the energy emitted is finite. With ultra-relativistic, sub-light speeds the black hole emits particles in a Planck distribution with constant energy flux at equilibrium temperature.

# Equal-spin limit of the Kerr–NUT–(A)dS spacetime

Eliška Polášková and Pavel Krtouš

*Institute of Theoretical Physics, Faculty of Mathematics and Physics, Charles University, V Holešovičkách 2, 180 00 Prague 8, Czech Republic*
**E-mail: eli.polaskova@email.cz, Pavel.Krtous@utf.mff.cuni.cz*

We summarize properties of the Kerr–NUT–(A)dS spacetime in a general dimension. We also investigate a limit when several rotational parameters in the metric are set equal and study geometry of the resulting spacetime. In dimension $D = 6$, we found a suitable Killing vector basis, whose algebraic structure proves that symmetries of the spacetime after the limit are further enhanced.

*Keywords*: Black holes; higher dimensions; rotation; NUT charges; symmetries.

## 1. Introduction

In four dimensions, the Plebański–Demiański metric[1] represents a large family of algebraic type D vacuum spacetimes. For example, it includes the rotating Kerr black hole, the Taub–NUT solution with one NUT parameter as well as accelerating black holes described by the C-metric.

In higher dimensions, the most general spacetime metric known so far is called the *Kerr–NUT–(A)dS metric*[2]. It includes rotational and NUT parameters as well as the cosmological constant, however, a solution with acceleration and charge is yet to be discovered.

The Kerr–NUT–(A)dS metric can describe various geometries, such as maximally symmetric spaces, a so-called Euclidean instanton and black hole solutions[3]. It also admits explicit and hidden symmetries that can be generated from a single object — a closed conformal Killing–Yano tensor, which we call the principal tensor[4,5]. Moreover, the principal tensor uniquely determines canonical coordinates in which the Hamilton–Jacobi, Klein–Gordon[6] and Dirac[7] equations are fully separable, and therefore the geodesic motion is completely integrable[8].

The main focus of our work is a limit of the metric when several rotational parameters are set equal. Other limit cases have already been studied, such as the limit with some of the black hole's rotations switched off[9] or the limit when particular roots of the metric function $X_\mu$ degenerate[10]. These papers have demonstrated that not only can performing various limits of the general metric shed light on the role of NUT charges, but it can also result in new interesting geometries.

## 2. Kerr–NUT–(A)dS Spacetime

This section introduces the general Kerr–NUT–(A)dS spacetime and describes some of its interesting properties. Firstly, the metric in its general form is discussed and subsequently, we show how to obtain a black hole geometry from the general metric as a special case.

For simplicity, we restrict ourselves to even dimensions $D = 2N$. Note that the generalization to odd dimensions is straightforward — a corresponding term is added to the metric.

### 2.1. *Metric*

A metric describing the Kerr–NUT–(A)dS geometry can be written in the form[2]

$$\boldsymbol{g} = \sum_{\mu} \left[ \frac{U_\mu}{X_\mu} \mathbf{d}x_\mu^2 + \frac{X_\mu}{U_\mu} \left( \sum_k A_\mu^{(k)} \mathbf{d}\psi_k \right)^2 \right] , \tag{1}$$

with greek and latin indices going over slightly different ranges

$$\begin{aligned} \mu, \nu &= 1, \dots, N \,, \\ k, l &= 0, \dots, N-1 \,, \end{aligned}$$

unless stated otherwise explicitly in the sum.

The functions $U_\mu$ and $A_\mu^{(k)}$ that appear in the metric are defined as polynomials in coordinates $x_\mu$

$$U_\mu = \prod_{\substack{\nu \\ \nu \neq \mu}} \left( x_\nu^2 - x_\mu^2 \right) , \qquad A_\mu^{(k)} = \sum_{\substack{\nu_1, \dots, \nu_k \\ \nu_1 < \dots < \nu_k \\ \nu_i \neq \mu}} x_{\nu_1}^2 \dots x_{\nu_k}^2 \,. \tag{2}$$

Each function $X_\mu = X_\mu(x_\mu)$ is dependent on a single coordinate $x_\mu$ and if it is left unspecified, the metric is then referred to as *off-shell*. On the other hand, if the function $X_\mu$ is also defined as a polynomial, namely

$$X_\mu = \lambda \mathcal{J}\big(x_\mu^2\big) - 2b_\mu x_\mu \,, \tag{3}$$

where $\mathcal{J}\big(x_\mu^2\big)$ reads

$$\mathcal{J}\big(x_\mu^2\big) = \prod_{\nu} \left( a_\nu^2 - x_\mu^2 \right) , \tag{4}$$

then the metric (1) satisfies the Einstein equations in vacuum and we refer to it as *on-shell*.

The coordinates we used are divided into two sets. In the black hole case, which is discussed in detail in Sec. 2.2, the coordinates $x_\mu$ represent radius and latitudinal angles whereas the coordinates $\psi_k$ represent time and longitudinal angles. Moreover, since the metric functions are independent of $\psi_k$, they are also the *Killing coordinates*.

The on-shell metric is described by several parameters, but only $\lambda$ can be interpreted easily — it is related to the cosmological constant $\Lambda$ as

$$\Lambda = (2N-1)(N-1)\lambda \,. \tag{5}$$

Regarding the others, in general we can say that the parameters $a_\mu$ somehow describe rotations and the parameters $b_\mu$ encode mass and NUT charges. However,

their interpretation strongly depends on specific other choices that can be made. This will be demonstrated in the next subsection where a black hole geometry that can be obtained from the general metric is discussed.

Instead of $\psi_k$, we can also use a more convenient set of angular coordinates $\phi_\alpha$ defined as

$$\phi_\alpha = \lambda a_\alpha \sum_k \mathcal{A}^{(k)}_\alpha \psi_k \,, \qquad \psi_k = \sum_\alpha \frac{\left(-a_\alpha^2\right)^{N-1-k}}{\mathcal{U}_\alpha} \frac{\phi_\alpha}{\lambda a_\alpha} \,, \tag{6}$$

where the functions $\mathcal{U}_\mu$ and $\mathcal{A}^{(k)}_\mu$ are defined similarly to $U_\mu$ and $A^{(k)}_\mu$ in (2), only $x_\mu$ is replaced with $a_\mu$

$$\mathcal{U}_\mu = \prod_{\substack{\nu \\ \nu\neq\mu}} \left(a_\nu^2 - a_\mu^2\right) \,, \qquad \mathcal{A}^{(k)}_\mu = \sum_{\substack{\nu_1,\dots,\nu_k \\ \nu_1<\dots<\nu_k \\ \nu_i\neq\mu}} a^2_{\nu_1} \dots a^2_{\nu_k} \,. \tag{7}$$

The metric (1) then obtains the form

$$\boldsymbol{g} = \sum_\mu \left[ \frac{U_\mu}{X_\mu} \mathbf{d}x_\mu^2 + \frac{X_\mu}{U_\mu} \left( \sum_\alpha \frac{J_\mu\left(a_\alpha^2\right)}{\mathcal{U}_\alpha} \frac{1}{\lambda a_\alpha} \mathbf{d}\phi_\alpha \right)^2 \right] \,, \tag{8}$$

where $J_\mu\left(a_\alpha^2\right)$ reads

$$J_\mu\left(a_\alpha^2\right) = \prod_{\substack{\nu \\ \nu\neq\mu}} \left(x_\nu^2 - a_\alpha^2\right) \,. \tag{9}$$

Since $\phi_\alpha$ are simply linear combinations of $\psi_k$, they are the Killing coordinates as well.

### 2.2. *Black hole*

The metric (8) can have both Euclidean and Lorentzian signatures, depending on the coordinate ranges and values of the parameters. Detailed discussion of geometries with the Euclidean signature, such as maximally symmetric spaces and Euclidean instantons, can be found in Ref. 3.

In order to obtain the Lorentzian signature, some of the coordinates and parameters need to be Wick-rotated, namely

$$x_N = ir \,, \qquad \phi_N = \lambda a_N t \,, \qquad b_N = iM \,. \tag{10}$$

Moreover, we use a one-parametric gauge freedom in rescaling parameters and set

$$a_N^2 = -\frac{1}{\lambda} \,. \tag{11}$$

We also assume that $a_{\bar\mu}$ are ordered

$$0 < a_1 < \ldots < a_{\bar N - 1} < a_{\bar N} \,, \tag{12}$$

where $\bar{N} = N - 1$ and barred indices go over the ranges

$$\bar{\mu}, \bar{\nu} = 1, \dots, \bar{N}\,,$$
$$\bar{k}, \bar{l} = 0, \dots, \bar{N} - 1\,.$$

This notation is used to separate the temporal and radial coordinates from the angular ones.

The metric (8) then becomes

$$\begin{aligned}
\boldsymbol{g} = &- \frac{\Delta_r}{\Sigma}\left(\prod_{\bar{\nu}}\frac{1+\lambda x_{\bar{\nu}}^2}{1+\lambda a_{\bar{\nu}}^2}\mathbf{d}t - \sum_{\bar{\nu}}\frac{\bar{J}\big(a_{\bar{\nu}}^2\big)}{a_{\bar{\nu}}\,(1+\lambda a_{\bar{\nu}}^2)\,\bar{\mathcal{U}}_{\bar{\nu}}}\mathbf{d}\phi_{\bar{\nu}}\right)^2 \\
&+ \frac{\Sigma}{\Delta_r}\mathbf{d}r^2 + \sum_{\bar{\mu}}\frac{\big(r^2+x_{\bar{\mu}}^2\big)\,\bar{U}_{\bar{\mu}}}{\Delta_{\bar{\mu}}}\mathbf{d}x_{\bar{\mu}}^2 \\
&+ \sum_{\bar{\mu}}\frac{\Delta_{\bar{\mu}}}{\big(r^2+x_{\bar{\mu}}^2\big)\,\bar{U}_{\bar{\mu}}}\left[\frac{1-\lambda r^2}{1+\lambda x_{\bar{\mu}}^2}\prod_{\bar{\nu}}\frac{1+\lambda x_{\bar{\nu}}^2}{1+\lambda a_{\bar{\nu}}^2}\mathbf{d}t + \sum_{\bar{\nu}}\frac{\big(r^2+a_{\bar{\nu}}^2\big)\,\bar{J}_{\bar{\mu}}\big(a_{\bar{\nu}}^2\big)}{a_{\bar{\nu}}\,(1+\lambda a_{\bar{\nu}}^2)\,\bar{\mathcal{U}}_{\bar{\nu}}}\mathbf{d}\phi_{\bar{\nu}}\right]^2,
\end{aligned} \tag{13}$$

with the metric functions $\Delta_r$, $\Delta_{\bar{\mu}}$, $\Sigma$ and $\bar{J}\big(a_{\bar{\mu}}^2\big)$ defined as

$$\begin{aligned}
&\Delta_r = -X_N = \big(1-\lambda r^2\big)\prod_{\bar{\nu}}\big(r^2+a_{\bar{\nu}}^2\big) - 2Mr\,, \qquad && \Sigma = U_N = \prod_{\bar{\nu}}\big(r^2+x_{\bar{\nu}}^2\big)\,, \\
&\Delta_{\bar{\mu}} = -X_{\bar{\mu}} = \big(1+\lambda x_{\bar{\mu}}^2\big)\,\bar{\mathcal{J}}\big(x_{\bar{\mu}}^2\big) + 2b_{\bar{\mu}}x_{\bar{\mu}}\,, && \bar{J}\big(a_{\bar{\mu}}^2\big) = \prod_{\bar{\nu}}\big(x_{\bar{\nu}}^2 - a_{\bar{\mu}}^2\big)
\end{aligned} \tag{14}$$

and the functions $\bar{U}_{\bar{\mu}}$, $\bar{\mathcal{U}}_{\bar{\mu}}$, $\bar{J}_{\bar{\mu}}\big(a_{\bar{\nu}}^2\big)$ and $\bar{\mathcal{J}}\big(x_{\bar{\mu}}^2\big)$ defined in the same way as their unbarred counterparts in Sec. 2.1, only with modified sets of coordinates and parameters (i.e. without $x_N$ and $a_N$).

Let us now discuss suitable ranges of the coordinates $x_{\bar{\mu}}$. For vanishing NUT parameters (and non-zero mass), i.e. $b_{\bar{\mu}} = 0$, the metric is non-singular and has the desired signature if we assume that the coordinates are ordered as

$$-a_1 < x_1 < a_1 < x_2 < a_2 < \ldots < x_{\bar{N}} < a_{\bar{N}}\,. \tag{15}$$

For non-vanishing NUT charges, the coordinate ranges change only slightly — we assume that they are restricted by

$$a_{\bar{\mu}-1} < {}^{-}x_{\bar{\mu}} < x_{\bar{\mu}} < {}^{+}x_{\bar{\mu}} < a_{\bar{\mu}} \tag{16}$$

with the only exception being ${}^{-}x_1$ since ${}^{-}x_1 < -a_1$. Figure 1 shows the discussed ranges.

The horizon structure is given by the roots of the metric function $\Delta_r$ defined in Eq. (14). For $\lambda \leq 0$, there exist at most two horizons — an inner and an outer one. The two horizons can also coincide, thus forming a single extremal horizon, or we can obtain a naked singularity in case there are no horizons. For $\lambda > 0$, there exists one additional cosmological horizon.

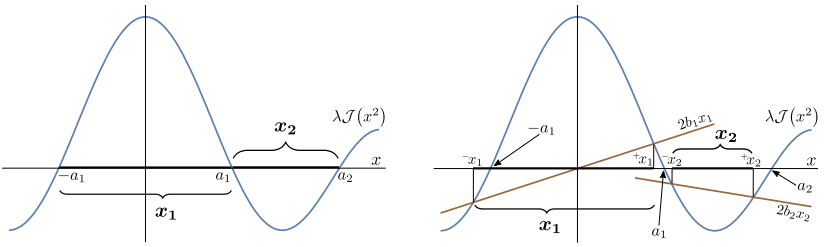

Fig. 1. Ranges of the coordinates $x_{\bar{\mu}}$ for (a) zero and (b) non-zero NUT parameters $b_{\bar{\mu}}$.

As for the interpretation of the metric parameters, for zero NUT charges $b_{\bar{\mu}} = 0$, $a_{\bar{\mu}}$ can be identified with the rotational parameters of the black hole. On the other hand, when the NUT parameters are non-trivial, then both $a_{\bar{\mu}}$ and $b_{\bar{\mu}}$ deform the geometry, however, their exact role remains elusive. This is where studying various limit cases might prove useful as they can help clarify this issue.

## 3. Equal-spin limit in $D = 6$

In general, performing the limiting procedure is not trivial — since some of the coordinate ranges and metric parameters degenerate, it is necessary to rescale them using an appropriate parametrization. Moreover, we expect the symmetry of the resulting spacetime to be enhanced, therefore we also need to find new Killing vectors or another proof of such enhanced symmetry.

For simplicity, we assume that the cosmological constant and NUT charges vanish, i.e. $\lambda = 0 = b_{\bar{\mu}}$. We are interested in the black hole form of the metric, which has only two rotational parameters in $D = 6$. Therefore, we will perform the limit $a_2 \to a_1$ using the parametrization

$$\begin{aligned} a_2 &= a_1 + 2\delta a_2 \varepsilon \,, \\ x_2 &= a_1 + (1 + \xi_2)\, \delta a_2 \varepsilon \,, \end{aligned} \tag{17}$$

where $\varepsilon \ll 1$ is a small parameter and $\delta a_2 > 0$ controls how fast $a_2$ approaches $a_1$. Instead of $x_2 \in (a_1, a_2)$ whose range becomes degenerate, we have introduced a rescaled coordinate $\xi_2 \in (-1, 1)$.

Using a more convenient set of angular coordinates $\phi_\pm = \phi_1 \pm \phi_2$, the resulting metric is

$$\begin{aligned} \boldsymbol{g} \approx -\mathbf{d}t^2 + \frac{2Mr}{\Sigma}\left[\mathbf{d}t - \frac{x_1^2 - a_1^2}{2a_1}\left(\mathbf{d}\phi_+ + \xi_2\, \mathbf{d}\phi_-\right)\right]^2 + \frac{\Sigma}{\Delta_r}\mathbf{d}r^2 - \frac{r^2 + x_1^2}{x_1^2 - a_1^2}\mathbf{d}x_1^2 \\ - \frac{\left(r^2 + a_1^2\right)\left(x_1^2 - a_1^2\right)}{4a_1^2}\left(\frac{\mathbf{d}\xi_2^2}{1 - \xi_2^2} + \mathbf{d}\phi_+^2 + \mathbf{d}\phi_-^2 + 2\xi_2\, \mathbf{d}\phi_+ \mathbf{d}\phi_-\right) \end{aligned} \tag{18}$$

with the metric functions in the form

$$\begin{aligned} \Delta_r &\approx \left(r^2 + a_1^2\right)^2 - 2Mr\,, \\ \Sigma &\approx \left(r^2 + a_1^2\right)\left(r^2 + x_1^2\right)\,. \end{aligned} \tag{19}$$

Most importantly, in addition to the original Killing vectors $\boldsymbol{l}_+$ and $\boldsymbol{l}_-$, we have obtained two new ones after the limit — here denoted by $\boldsymbol{m}$ and $\boldsymbol{n}$. These new vectors are independent of the original Killing vectors and they Lie-preserve the full spacetime metric (18). The complete set of Killing vectors regarding the spatial part of the metric is therefore

$$\begin{aligned} \boldsymbol{l}_+ &= \frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\phi_+}\,, \qquad & \boldsymbol{m} &= \cos\phi_- \sqrt{1-\xi_2^2}\,\frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\xi_2} - \frac{\sin\phi_-}{\sqrt{1-\xi_2^2}}\left(\frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\phi_+} - \xi_2\frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\phi_-}\right)\,, \\ \boldsymbol{l}_- &= \frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\phi_-}\,, \qquad & \boldsymbol{n} &= -\sin\phi_- \sqrt{1-\xi_2^2}\,\frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\xi_2} - \frac{\cos\phi_-}{\sqrt{1-\xi_2^2}}\left(\frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\phi_+} - \xi_2\frac{\boldsymbol{\partial}}{\boldsymbol{\partial}\phi_-}\right)\,. \end{aligned} \tag{20}$$

Their Lie brackets suggest that the symmetry of the metric (18) is indeed further enhanced as three of the Killing vectors above generate the algebra of an $SO(3)$ group

$$[\boldsymbol{l}_-, \boldsymbol{m}] = \boldsymbol{n}\,, \qquad [\boldsymbol{m}, \boldsymbol{n}] = \boldsymbol{l}_-\,, \qquad [\boldsymbol{n}, \boldsymbol{l}_-] = \boldsymbol{m}\,. \tag{21}$$

The vector $\boldsymbol{l}_+$ commutes with all the other vectors. Therefore, the symmetry group in the spatial part of the spacetime decouples from the original $U(1) \times U(1)$ into $SO(3) \times U(1)$ after the limit.

We study static, spherically symmetric spacetimes in quadratic gravity. We show that using a conformal-to-Kundt ansatz leads to a considerable simplification of the vacuum field equations. This simplification allows us to find Schwarzschild-Bach black hole in the form of a power series expansion with coefficients given by a recurrent formula. The Schwarzschild-Bach solution is specified by two parameters, the horizon position and an additional "non-Schwarzschild parameter" $b$ that encodes the value of the Bach tensor on the horizon. For vanishing "Bach" parameter, the Bach tensor vanishes as well and the Schwarzschild metric is recovered. The new form of the metric enables us to investigate the geometrical and physical properties of these black holes, such as tidal effects on test particles and thermodynamical quantities.

*Keywords*: Quadratic gravity; static spherically symmetric solutions; black hole; Bach tensor.

## 1. Introduction

In quadratic gravity, terms quadratic in curvature are added to the usual Einstein-Hilbert action. In the case of four dimensions and a vanishing cosmological constant, the action can be expressed as

$$S = \int \mathrm{d}^4x\,\sqrt{-g}\,\Big(\gamma\,R + \beta R^2 - \alpha\,C_{abcd}\,C^{abcd}\Big), \tag{1}$$

where $\gamma = 1/G$ ($G$ is the Newtonian constant) and $\alpha, \beta$ are additional parameters.

Recently, new static spherically symmetric solutions, representing in particular a non-Schwarzschild black hole, to quadratic gravity have been found in Ref. 1 and further analyzed in Refs. 2, 3, 4, mainly by using numerical methods.

Instead of using the standard spherically symmetric coordinates, we study [5,6] static spherically symmetric solutions in the conformal-to-Kundt form [7] which leads to a considerable simplification of the vacuum field equations allowing us to construct a solution describing the Schwarzschild-Bach black hole in the form of a power series expansion. The coefficients in the expansion are determined by a recurrent formula. We also study physical properties of the Schwarzschild-Bach black hole such as tidal effects on test particles and thermodynamical quantities. The

Schwarzschild-Bach black hole can be also generalized to include a non-vanishing cosmological constant, see Ref. 8.

## 2. The Field Equations

We study the case $R = 0$ (in the case of Einstein–Weyl gravity corresponding to $\beta = 0$, this directly follows from the trace of the field equations). Then the field equations reduce to

$$R_{ab} = 4k\, B_{ab}\,, \tag{2}$$

where $k \equiv \alpha\, G$ and $B_{ab}$ is the Bach tensor

$$B_{ab} \equiv \big(\nabla^c\nabla^d + \tfrac{1}{2}R^{cd}\big)C_{acbd}\,, \tag{3}$$

which is traceless, symmetric and conserved ($g^{ab}B_{ab} = 0$, $B_{ab} = B_{ba}$, $B_{ab}{}^{;b} = 0$).

Instead of using the standard static spherically symmetric metric

$$\mathrm{d}s^2 = -h(\bar{r})\,\mathrm{d}t^2 + \frac{\mathrm{d}\bar{r}^2}{f(\bar{r})} + \bar{r}^2(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)\,, \tag{4}$$

we employ a conformal-to-type D-direct-product-Kundt form [7] of a static spherically symmetric spacetime

$$\mathrm{d}s^2 = \Omega^2(r)\mathrm{d}s^2_{\mathrm{Kundt}} = \Omega^2(r)\big[\,\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2 - 2\,\mathrm{d}u\,\mathrm{d}r + \mathcal{H}(r)\,\mathrm{d}u^2\,\big], \tag{5}$$

where

$$h(\bar{r}) = -\Omega^2\,\mathcal{H}\,, \qquad f(\bar{r}) = -(\Omega'/\Omega)^2\,\mathcal{H}\,, \tag{6}$$

$\Omega'$ denotes the derivative of $\Omega$ with respect to $r$. The metrics (5) and (4) are related via the transformation

$$\bar{r} = \Omega(r)\,, \qquad t = u - \int \mathcal{H}(r)^{-1}\mathrm{d}r\,. \tag{7}$$

We use the time scaling $t \to \sigma^{-1}\,t$ (implying $h \to \sigma^2\,h$) to set $h = 1$ at spatial infinity for asymptotically flat solutions.

The Killing horizon associated with the Killing vector $\partial_t = \partial_u$ is located at $r_h$:

$$\mathcal{H}\big|_{r=r_h} = 0\,, \tag{8}$$

which implies that also $h(\bar{r}_h) = 0 = f(\bar{r}_h)$ (see Eq. (6)).

The main reason behind the considerable simplification of the field equations in the Kundt coordinates is that higher-order corrections to the Einstein theory are in quadratic gravity represented by the Bach tensor (see (2)) which is conformally well behaved $B_{ab} = \Omega^{-2}\,B^{\mathrm{Kundt}}_{ab}$.

It can be shown that in Kundt coordinates, the field equations (2) for the metric functions $\Omega(r)$ and $\mathcal{H}(r)$ reduce to [5,6]

$$\Omega\Omega'' - 2\Omega'^2 = \tfrac{1}{3}k\,\mathcal{B}_1\mathcal{H}^{-1}\,, \tag{9}$$

$$\Omega\Omega'\mathcal{H}' + 3\Omega'^2\mathcal{H} + \Omega^2 = \tfrac{1}{3}k\,\mathcal{B}_2\,, \tag{10}$$

where 2 independent components of the Bach tensor are

$$\mathcal{B}_1 \equiv \mathcal{H}\mathcal{H}'''', \qquad \mathcal{B}_2 \equiv \mathcal{H}'\mathcal{H}''' - \tfrac{1}{2}\mathcal{H}''^2 + 2\,. \tag{11}$$

$\mathcal{B}_1$ always vanishes on the horizon (8).

The Bach and Weyl scalar curvature invariants read

$$B_{ab}\,B^{ab} = \tfrac{1}{72}\,\Omega^{-8}\left[(\mathcal{B}_1)^2 + 2(\mathcal{B}_1+\mathcal{B}_2)^2\right], \tag{12}$$

$$C_{abcd}\,C^{abcd} = \tfrac{1}{3}\,\Omega^{-4}\,(\mathcal{H}''+2)^2\,. \tag{13}$$

Thus, $C_{abcd}\,C^{abcd}=0$ implies $B_{ab}=0$. Moreover, $B_{ab}=0$ if and only if $B_{ab}\,B^{ab}=0$. The invariant (12) implies that there are two geometrically distinct classes of solutions to (9), (10), depending on the Bach tensor, one with $B_{ab}=0$ and another one with $B_{ab}\neq 0$.

In the case of vanishing Bach tensor $\mathcal{B}_1=0=\mathcal{B}_2$, the only solution of Eqs. (9)–(10) is the Schwarzschild metric in accordance with the Birkhoff theorem

$$\Omega(r) = -\frac{1}{r}\,, \qquad \mathcal{H}(r) = -r^2 - 2m\,r^3\,, \tag{14}$$

where a coordinate freedom $r\to\lambda\,r+\nu,\ u\to\lambda^{-1}u$ of the metric (5) was used. Eqs. (7), (6) give $r=-1/\bar{r}$, $f(\bar{r})=1-2m/\bar{r}=h(\bar{r})$, respectively, where $\bar{r}>0$ corresponds to $r<0$ ($r$ increases with $\bar{r}$).

For non-vanishing Bach tensor, Eqs. (9), (10) form an autonomous system (they do not explicitly depend on the variable $r$) and thus its solutions can be found as expansions in the powers of $r$ to any order around any fixed value $r_0$,

$$\Omega(r) = \Delta^n \sum_{i=0}^{\infty} a_i\,\Delta^i\,, \qquad \mathcal{H}(r) = \Delta^p \sum_{i=0}^{\infty} c_i\,\Delta^i\,, \tag{15}$$

where $\Delta\equiv r-r_0,\ n,p\in\mathbb{R}$, and $a_0,c_0\neq 0$. Eqs. (9) and (10) restrict possible dominant powers $n,p$ in (15), see Refs. 5, 6. It turns out that there are only four classes of solutions allowed, namely $[n,p]=[-1,2],\ [0,1],\ [0,0],\ [1,0]$. The class $[-1,2]$ corresponds to the Schwarzschild black hole (14), the class $[1,0]$ is equivalent to the $(s,t)=(2,2)$ class of Refs. 9 and 2 corresponding to a naked singularity, while the Schwarzschild–Bach black hole is contained in the classes $[0,1]$ and $[0,0]$, see Refs. 5, 6.

## 3. Class [0, 1]: Schwa–Bach Black Hole Expressed Around the Horizon $r_h$

Since in the $[0,1]$ class, $r_0$ is the root of $\mathcal{H}$ it corresponds to the horizon $r_h$, see Eq. (8). This class of solutions of quadratic gravity includes non-Schwarzschild black holes with $B_{ab}\neq 0$, see Refs. 5, 6

$$\Omega(r) = -\frac{1}{r} - \frac{b}{r_h}\sum_{i=1}^{\infty}\alpha_i\Big(1-\frac{r}{r_h}\Big)^i, \tag{16}$$

$$\mathcal{H}(r) = (r-r_h)\left[\frac{r^2}{r_h} + 3b\,r_h\sum_{i=1}^{\infty}\gamma_i\Big(\frac{r}{r_h}-1\Big)^i\right], \tag{17}$$

where the initial coefficients are

$$\alpha_0 \equiv 0\,, \quad \alpha_1 = 1\,, \quad \gamma_1 = 1\,, \quad \gamma_2 = \frac{1}{3}\Big(4 - \frac{1}{2kr_h^2} + 3b\Big)\,, \tag{18}$$

and $\alpha_l, \gamma_{l+1}$ for $l \geq 2$ are given by the recurrent relations

$$\alpha_l = \frac{1}{l^2}\Big[\alpha_{l-1}(2l^2 - 2l + 1) - \alpha_{l-2}(l-1)^2 - 3\sum_{i=1}^{l}(-1)^i\,\gamma_i\,(1 + b\,\alpha_{l-i})\big(l(l-i) + \tfrac{1}{6}i(i+1)\big)\Big],$$

$$\gamma_{l+1} = \frac{(-1)^l}{kr_h^2\,(l+2)(l+1)l(l-1)}\sum_{i=0}^{l-1}\big(\alpha_i + \alpha_{l-i}(1 + b\,\alpha_i)\big)(l-i)(l-1-3i)\,. \tag{19}$$

This family of spherically symmetric black holes depends on two parameters:

- The horizon position $r_h$, $r = r_h$ is the root of $\mathcal{H}$ given by (17).
- The Bach parameter $b \neq 0$ for the Schwarzschild–Bach (or Schwa–Bach) black hole with non-zero Bach tensor, while $b = 0$ for the Schwarzschild solution.

On the horizon $r_h$, Eq. (11) gives

$$\mathcal{B}_1(r_h) = 0\,, \quad \mathcal{B}_2(r_h) = -\frac{3}{kr_h^2}\,b\,. \tag{20}$$

The invariants (12), (13) are $B_{ab}\,B^{ab}(r_h) = \frac{r_h^4}{4k^2}\,b^2$ and $C_{abcd}\,C^{abcd}(r_h) = 12\,r_h^4\,(1+b)^2$, respectively.

Fig. 1 shows the rapid convergence in the near-horizon region of the function $h(\bar{r})$ of the metric (4) expressed from $\Omega$ and $\mathcal{H}$ using Eq. (6). The first 20 (red), 40 (orange), 60 (green), 80 (blue), and 100 (violet) terms in the series are compared with the numerical solution of Ref. 1 (black). The horizon is located at $\bar{r}_h = 1$ (i.e., $r_h = -1$), $k = 0.5$ and the value $b = 0.3633018769168$ corresponds to the asymptotically flat case (see Ref. 1). We employed the scaling freedom with $\sigma^2 \approx 2.18$ to obtain $h \to 1$ asymptotically.

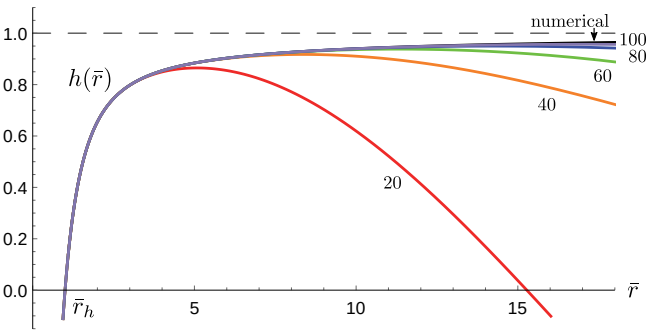

Fig. 1. Rapid convergence of the function function $h(\bar{r})$.

## 4. Class [0, 0]: Schwa–Bach Black Hole Expressed Around Any Point $r_0 \neq r_h$

The solution to Eqs. (9), (10) of the form (15) with $n = 0 = p$ is given by the power series with

$$a_{l+1} = \frac{-1}{l(l+1)\,c_0}\left[\tfrac{1}{3}\,a_{l-1} + \sum_{i=1}^{l+1} c_i\,a_{l+1-i}\left(l(l+1-i) + \tfrac{1}{6}i(i-1)\right)\right],$$

$$c_{l+3} = \frac{3}{k\,(l+3)(l+2)(l+1)l}\sum_{i=0}^{l} a_i\,a_{l+1-i}(l+1-i)(l-3i)\,, \tag{21}$$

for any $l \geq 1$, where $a_0, a_1, c_0, c_1, c_2$ are five free parameters and

$$c_3 = \frac{1}{6kc_1}\left[3a_0(a_0 + a_1c_1) + 9a_1^2c_0 + 2k(c_2^2 - 1)\right],$$

see Refs. 5, 6.

To identify the Schwa–Bach black hole (16), (17), previously expressed around the horizon $r_h$ in the class $[0, 1]$, we have to uniquely determine the five free parameters by evaluating the functions (16), (17) and their derivatives at $r = r_0$. For $B_{ab} = 0$, both classes $[0, 0]$ and $[0, 1]$ reduce to the Schwarzschild black hole. However, the $[0, 0]$ class is a larger family of solutions than the Schwa-Bach black hole since it admits one more parameter.

Moreover, the power series (15) with integer exponents transform in some cases to series with non-integer exponents in the coordinate $\bar{r}$. For example, a new class $(w, t) = (4/3, 0)$ in the notation of Ref. 2 also belongs to our $[0, 0]$ class, see Refs. 5, 6.

## 5. Observable Effects Caused By The Schwa–Bach Black Hole

The Bach tensor, namely two independent parts of the Bach invariant (12), $\mathcal{B}_1, \mathcal{B}_2$, could produce measurable affects on test particles described by the geodetic deviation equation[10]. Apart from the classical Newtonian tidal deformation caused by the Weyl curvature, there are two additional effects due to the Bach tensor, one in the transverse components of the acceleration, the second in the radial component along $\partial_{\bar{r}}$, with amplitudes given by $\mathcal{B}_1, \mathcal{B}_2$ defined in (11). On the horizon, there is only the radial effect caused by $\mathcal{B}_2$ since $\mathcal{B}_1(r_h) = 0$, see (20).

## 6. Thermodynamical Properties: Horizon Area, Temperature, Entropy

The horizon of the Schwarzschild–Bach black hole is generated by the (rescaled) null Killing vector $\ell \equiv \sigma\partial_t = \sigma\partial_u$ and is located at $\mathcal{H} = 0$, i.e., at $r = r_h$, see (8), (17). Its area (using (16)), surface gravity ($\kappa^2 \equiv -\frac{1}{2}\,\ell_{\mu;\nu}\,\ell^{\mu;\nu}$, see Ref. 11), and the black-hole horizon temperature[12] read

$$\mathcal{A} = 4\pi\,\bar{r}_h^2 = 4\pi\,\Omega^2(r_h) = 4\pi\,r_h^{-2}\,, \tag{22}$$

$$\kappa/\sigma = -\tfrac{1}{2}\,\mathcal{H}'(r_h) = -\tfrac{1}{2}\,r_h = \tfrac{1}{2}\,\bar{r}_h^{-1}\,, \tag{23}$$

$$T/\sigma = \tfrac{1}{2\pi}\,\kappa/\sigma = -\tfrac{1}{4\pi}\,r_h = \tfrac{1}{4\pi}\,\bar{r}_h^{-1}\,, \tag{24}$$

respectively. The value of the scaling factor $\sigma$ is fixed by the condition that $h = -\Omega^2\mathcal{H} \to 1$ asymptotically as $\bar{r} = \Omega(r) \to \infty$.

Using the generalized definition of entropy $S = (2\pi/\kappa) \oint \mathbf{Q}$ (see Ref. 13), where the Noether charge 2-form on the horizon is $\mathbf{Q} = -\frac{\Omega^2\,\mathcal{H}'}{16\pi}\left[1+\frac{4}{3}k^2\,\frac{\mathcal{B}_1+\mathcal{B}_2}{\Omega^4}\right]\Big|_{r=r_h} \sin\theta\,\mathrm{d}\theta\wedge\mathrm{d}\phi\,,$ and using Eqs. (20), (22), and (23) the entropy becomes

$$S = \tfrac{1}{4}\mathcal{A}\left(1 - 4k\,r_h^2\,b\right) = \tfrac{1}{4}\mathcal{A}\left(1 - 4k\,\bar{r}_h^{\,-2}\,b\right), \tag{25}$$

which agrees with the results of Ref. 1, with the identification $k = \alpha$, $b = \delta^*$. For the Schwarzschild black hole ($b = 0$) or in Einstein's theory ($k = 0$), we recover the standard expression. For smaller Schwa–Bach black holes (smaller $\bar{r}_h$), the deviations from $S = \frac{1}{4}\mathcal{A}$ are larger, analogously to Ref. 14. $S > 0$ implies $4kb < \bar{r}_h^2$.

Combining Eqs. (22), (24), and (25), gives a relation between the temperature and the entropy

$$T = \tfrac{1}{4}\sigma\left(\pi\,S + 4\pi^2 k\,b\right)^{-1/2}, \tag{26}$$

generalizing $T = \frac{1}{4}(\pi S)^{-1/2}$ for the Schwarzschild black hole.

# Binary population synthesis calculations of Type Ia supernovae

Zheng-Wei Liu[1,2]

[1] *Yunnan Observatories, Key Laboratory for the Structure and Evolution of Celestial Objects, Chinese Academy of Sciences (CAS), Kunming 650216, China*

[*] *E-mail: zwliu@ynao.ac.cn*

The nature of the progenitors of Type Ia supernovae (SNe Ia) remains a mystery. By performing binary population synthesis calculations, theoretical predictions for different SN Ia progenitor models, such as supernova rates, delay times, pre-explosion companion properties and early ultraviolet signatures from ejecta-companion interaction have been presented. The results are then compared with the observations to place constraints on the possible progenitor models of SNe Ia.

*Keywords*: Binaries: close – supernovae: general.

## 1. Introduction

There is consensus that Type Ia supernovae (SNe Ia) arise from thermonuclear explosions of white dwarfs (WDs) in binary systems[1]. However, the nature of their progenitors and the physics of explosion are still unknown[2]. Depending on the nature of the companion star, progenitor scenarios of SNe Ia fall into three general categories: (i) the single-degenerate (SD) scenario[3], in which a carbon-oxygen (CO) WD accretes matter from a non-degenerate companion, potentially a main-sequence (MS), subgiant, red giant (RG), or even helium (He) star, to trigger an explosion when its mass reaches the Chandrasekhar-mass (Ch-mass) limit, (ii) the double-degenerate (DD) scenario[4], in which explosions are caused by the merger of two WDs, (iii) the WD accretes material from an He-burning star or an He WD to lead to a sub-Chandrasekhar-mass (sub-Ch) explosion when the He-shell accumulation reaches a critical value of about $0.02 - 0.2\,M_{\odot}$ [5,6].

Comparing the expected rates and delay times of SNe from binary population synthesis (BPS) calculations with those inferred from the observations can place constraints on progenitor systems of SNe Ia[7]. It is expected that the companion stars in the SD and sub_Ch scenario will be detectable in pre-explosion observations[8]. Also, in the SD scenario, the collision of the SN Ia ejecta with its companion star is expected to produce detectable ultraviolet (UV) emission in the first few days after the SN explosion[9]. To constrain the possible progenitor models of SNe Ia by their pre-explosion and early UV observations, it is required to preform BPS calculations to provide theoretical predictions for the pre-explosion companion properties and early UV signatures in the SD scenario.

## 2. Method and Results

In this work, the Cambridge stellar evolution code STARS[11] is used to trace the detailed binary evolution of a set of systems consisting of a WD and a MS or SG,

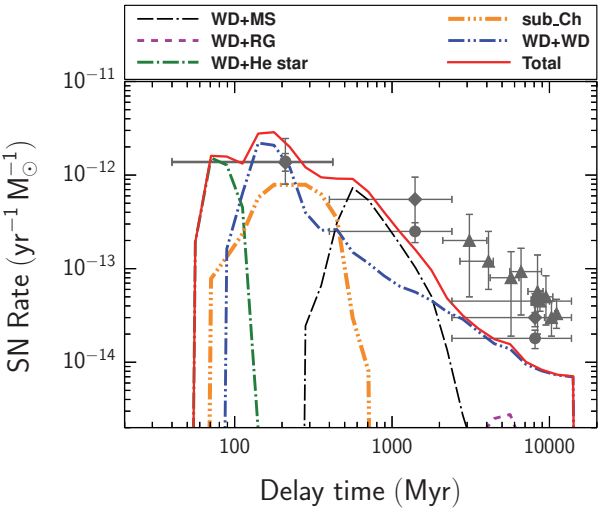

Fig. 1. The delay-time distribution (DTD) of different progenitor scenarios in our calculations. The results are compared to the observed DTD (gray dots[10]).

a RG, or a He star companion. The WDs are treated as point masses. The mass transfer occurs though Roche-lobe overflow (RLOF). In the SD scenario, once the WD accretes the transferred companion material to increase its mass to near the Ch-mass limit ($\sim 1.4\,M_\odot$), an SN Ia explosion is assumed to occur. In the sub_Ch scenario (i.e., for the low mass-transfer-rate He-accreting case), a thick layer of helium is believed to grow on the surface of the WD. As a result, once a He-shell accumulation reaches a critical value ($\sim 0.05\,M_\odot$), the sub-Ch mass thermonuclear explosion is assumed to trigger.

With a series of binary evolution calculations for various close WD binary systems, we determine the initial parameter space leading to SNe Ia in the orbital period–secondary mass (i.e. $\log_{10} P^i$–$M_2^i$ ) plane for various initial CO WD masses ($M_{\rm WD}^i$) in the MS, RG, and He star donor channel. Furthermore, a rapid population synthesis code[13] is used to perform a detailed Monte Carlo simulation. When a binary system evolves to a CO WD + MS (SG, RG, or He star) system, assuming that it will lead to an SN Ia explosion if it is located in the plane of ($\log_{10} P^i$, $M_2^i$) for its $M_{\rm WD}^i$ based on the detailed binary evolution. For the DD scenario in this BPS calculation, SNe Ia are assumed to arise from the merging of two close CO WDs that have a combined mass larger than or equal to the Ch-mass (Webbink 1984). We refer to some previous works for a detailed description about the method and basic assumptions used in this work[7,12,14].

### 2.1. *Rates and delay times*

Figure 1 shows a comparison between the delay-time distribution (DTD[7,14]) of different progenitor scenarios in this calculations and the observed DTD[10]. It is

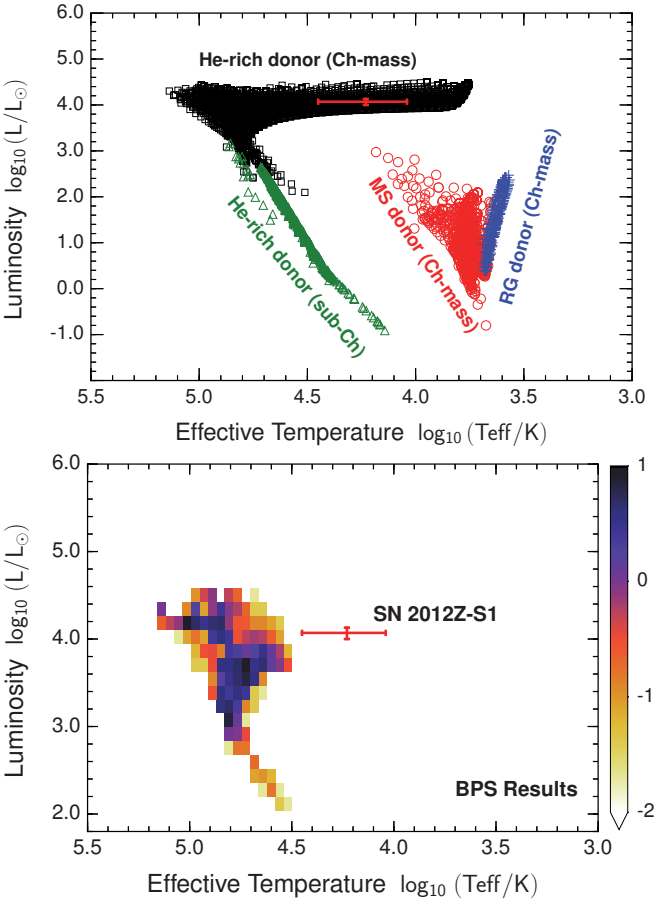

Fig. 2. Top panel: H-R diagram of pre-explosion companions in different SN Ia progenitor scenarios from binary evolution calculations[12]. Bottom panel: the distributions of companions in the the plane of ($\log_{10} T_{\rm eff}$, $\log_{10} L$), which are obtained from BPS calculations assuming a constant star-formation rate of $3.5\,{\rm M}_{\odot}\,{\rm yr}^{-1}$. Here, only the He donor Ch-mass channel is considered. The pre-explosion observation of the SN 2012Z-S1 is also included (the error in red[8]).

found that the DD scenario has a wide distribution of the delay times. The SD scenario seems to be difficult to produce old SNe Ia with the delay times of $>$ 3000 Myr. Also, it is really hard to explain the observed rates and delay times with a single progenitor model, which may indicate that a combination of current models might be an alternative scenario for SNe Ia. Otherwise, a new progenitor paradigm may be needed if SNe Ia are indeed generated from the same origin.

### 2.2. *Pre-explosion companion stars*

The WD can only be observed directly in our own Milky Way and several very nearby galaxies as the WD would be faint. However, the non-degenerate compan-

ions in SD and sub_Ch scenario will be detectable in pre-explosion observations. Therefore, analyzing pre-explosion images at the SN position provides a direct way to constrain SN progenitor systems. With performing detailed binary evolution calculations, the pre-explosion properties of companions in the SD and sub_Ch scenario are shown in Fig. 2. This will be very helpful for constraining progenitor systems of SNe Ia from their pre-explosion observations. Recently, a luminous source (i.e., SN 2012Z-S1) has been discovered from pre-explosion HST images of an SN Ia SN 2012Z, and it is further suggested to be the probable progenitor system of SN 2012Z[8]. In this work, it is found that the detailed binary evolution calculations for the WD+He star Ch-mass channel can contribute significantly to the number of systems in the vicinity of SN 2012Z-S1 (Fig. 2). However, further BPS calculations suggest that the WD+He star channel produces companions as cool as the SN 2012Z-S1 only at very low probability (see Fig. 2).

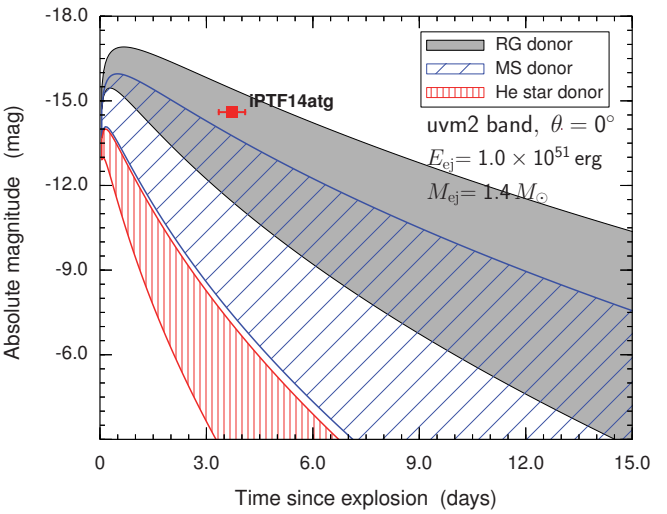

Fig. 3. Distributions of theoretical light curves predicted from the ejecta-companion interaction for different SD progenitor models. Here, only a viewing angle $\theta = 0^\circ$ and $uvm2$ band are considered. The ejecta mass ($M_{\rm ej} = 1.4\,M_\odot$) and explosion energy ($E_{\rm ej} = 10^{51}$ erg) are adopted.

### 2.3. *Early UV emission of ejecta-companion interaction*

In the Kasen's model[9], SN ejecta collides with its companion star, the impacting layers are re-shocked and the kinetic energy partially is dissipated, causing UV flux emission from the shock-heated region. This emission dominates the early-time (few days after SN explosion) light curves within certain viewing angles[9]. By combining our BPS results into the Kasen's analytical model[12], the distributions of early-UV emission from ejecta-companion in the different SD progenitor models are presented in Fig. 3. This theoretical predictions will be helpful for future early-time observations of SNe Ia to constrain their possible progenitors.

A strong UV pulse in the early light curves of an SN Ia iPTF14atg has been detected recently[15]. It has been further suggested that this strong UV pulse supports that some SNe Ia arise from the SD Ch-mass scenario. Here, the predictions from our BPS calculations are compared to the early UV flash of iPTF14atg to put a more stringent on the possible progenitor of this event. It is found that it is unlikely that the detected early UV flash of iPTF14atg arises from the interaction with a MS or He star companion by considering that the actual viewing angle may be larger than $\theta = 0^\circ$ and taking the uncertainties on the explosion parameters into account. However, the results from the RG donor scenario can explain the early UV flash of iPTF14atg (Fig. 3). Therefore, it can be concluded that the progenitor system of iPTF14atg would be most likely a red-giant donor binary system if we assume the observed strong UV pulse of iPTF14atg was indeed produced by the SN ejecta-companion interaction.

## 3. Conclusion and Summary

By performing the detailed binary evolution and population synthesis calculations, some helpful theoretical predictions for different progenitor scenario of SNe Ia have been presented. The results are also compared to current observations to place constraints on the possible SN Ia progentiors. The results and conclusions can be summarized as follows.

i) The DD scenario has a very wide DTD and the SD scenario seems to be difficult to produce old SNe Ia ($> 3000$ Myr). It is hard to explain the observed rates and delay times with a single progenitor model. A combination of different progenitor models seems to provide a better explanation.

ii) Pre-explosion companion properties in the SD and sub_Ch scenario have been presented. This will be helpful for constraining progenitor systems of SNe Ia from their pre-explosion observations. It is found that the He companions in SD scenario can explain the observations of SN 2012Z-S1 at a low probability.

iii) Population synthesis models of early UV emission from ejecta-companion interaction in the SD scenario are presented. The results are useful for comparing with early UV observations of SNe Ia to put constraints on their progenitor models. It is also found that the progenitor system of iPTF14atg would be most likely to have a red-giant donor if we assume its observed UV pulse was indeed produced by the ejecta-companion interaction.

There has recently been an increasing interest in a possible population of type Ia supernovae (SNe Ia) triggered by helium detonation on the surface of a massive white dwarf. In this paper, we first summarize possible observational signatures of the He detonation-triggered SNe Ia, emphasizing the new diagnostics of the He detonation mode potentially seen in the SN light within the first few days since the explosion. We then argue that observational properties of a peculiar SN Ia, MUSSES1604D as discovered by the Hyper Suprime-Cam (HSC) attached with the Subaru telescope, are best explained by the He-detonation scenario. We then discuss possible origins, including the He detonation scenario, of the diversity seen in the photometric properties of SNe Ia in the first few days. While the He detonation could reproduce observational properties of a fraction of SNe Ia showing the excessive emission in the first few days, it is likely that a bulk of them are linked to a different explosion mechanism where the early excess would arise due to an extensive mixing of $^{56}$Ni during the explosion. A combined analysis of the very early phase observations and the maximum-phase observations will be key in mapping the diverse SN Ia zoo into different populations reflecting different progenitors and/or different explosion modes.

*Keywords*: Supernovae; binary stars; nucleosynthesis.

## 1. SNe Ia in the first few days

It has been widely accepted that the type Ia supernova (SN Ia) is a thermonuclear explosion of a massive C+O white dwarf (WD) in a binary system. Details are however yet to be clarified on the nature(s) of the progenitor system(s) and the explosion mode(s) (see Ref. 1 for a review). There are two popular progenitor scenarios; the single degenerate (SD) scenario involves an accreting WD from a non-degenerate companion star,[2,3] while the double degenerate (DD) scenario involves a binary merger of two WDs.[4,5] There is also a variety in the possible mode of the explosion, especially in a way how the explosion is initiated. In the popular delayed-detonation model, the carbon deflagration flame is first triggered near the center of a massive C+O WD close to the Chandrasekhar limiting mass, then the transition to the detonation wave is hypothesized.[6–8]

In the last few years, there has been an increasing interest in a specific mode of the explosion, which involves accretion of helium (He) on the surface of a primary C+O WD.[9–11] If the He accretion is sufficiently rapid, a detonation is initiated within the He layer. The shock wave thus generated would penetrate into the C+O WD, triggering the carbon detonation near the center of the WD. This scenario does not require a Chandrasekhar-mass progenitor; the progenitor WD mass

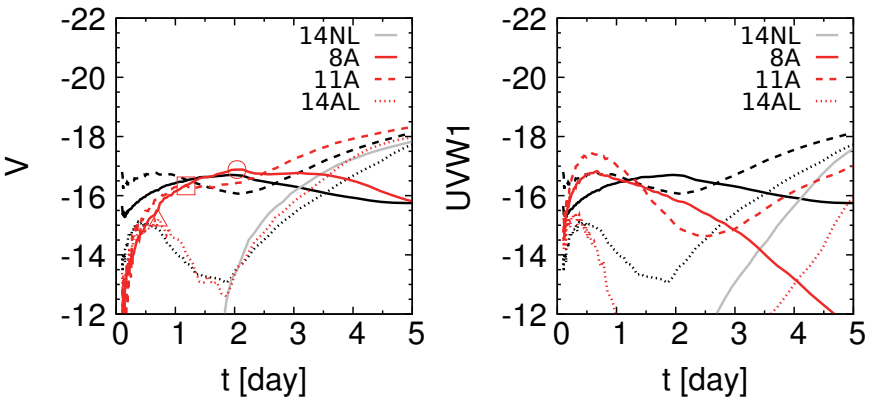

Fig. 1. Examples of the simulated early-phase light curves for the He detonation models, in the $V$-band (left) and in the SWIFT $UVW1$-band (right).[21] Three models with different masses of the primary WD ($0.8, 1.1, 1.4 M_\odot$ for 8A, 11A, 14AL, respectively) are shown by the red curves. The bolometric light curves of the same models are shown by the black curves. The model corresponding to model 14AL but without the He detonation ash (14NL) is shown by the gray curve. Reproduced from the following publication: K. Maeda, et al., The Astrophysical Journal, 861, 78 (2018).[21]

is phenomenologically limited by the capability of synthesizing $^{56}$Ni mass to be consistent with observed SN Ia luminosities.[12,13] To produce $\sim 0.6 M_\odot$ of $^{56}$Ni to account for normal SNe Ia, the WD mass ($M_{\rm WD}$) is $\gtrsim 1 M_\odot$. The primary WD with $M_{\rm WD} \sim 0.8 M_\odot$ will lead to a low luminosity SN, thus at most applicable to sub-luminous sub-classes of SNe Ia. The He-detonation model has been first considered within the SD scenario (the 'double detonation' model), i.e., a C+O WD accreting from a non-degenerate He star, while it has been recently discussed in a context of the DD scenario as well, i.e., a C+O WD merging with another C+O WD with a massive He layer or even with a He WD.[14,15]

Infracting opportunities of the time domain science now allow SNe and transient objects to be studied from the very beginning of their outbursts. The discovery and quick follow-up observations within the first few days since the SN explosions are becoming common in the last few years. For SNe Ia, it has been suggested that an additional blue (UV-strong) and bright emission should be associated with the SD scenario; an interaction of the ejecta with a companion star creates an additional thermal energy, which is then radiated away in a few days, superimposed to the 'red' light diffusing out of the main body of the SN ejecta as powered by the decay chain $^{56}$Ni/Co/Fe.[16] A similar excessive light in the first few days is expected for the interaction between the ejecta and circumstellar media (CSM).[17] As yet another possibility, mixing of $^{56}$Ni towards the outer region of the ejecta may also contribute to the early emission.[18] The first attempt to search for such a signal generally resulted in non-detection; however, as the observational technique and strategy are

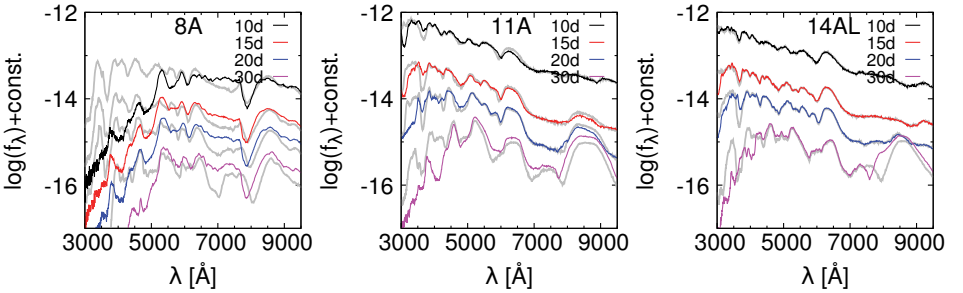

Fig. 2. Synthetic spectra of the He detonation models around maximum light (8A, 11A, 14AL; see the Fig. 1 caption). The spectra of the corresponding models without the He detonation products at the same epochs are also shown by gray lines. Reproduced from the following publication: K. Maeda, et al., The Astrophysical Journal, 861, 78 (2018).[21]

being matured, there is an increasing number of reports for SNe showing the early excess in the first few days (see Ref. 1 for a review).

## 2. He detonation: Expected observational features

Recently, an additional mechanism has been suggested which would create a bright emission in the first few days of SNe Ia; it is the He detonation.[19–21] The He detonation creates either $^{56}$Ni or other radioactive isotopes ($^{52}$Fe which decays into Mn and then Cr, or $^{48}$Cr which decays into V and then Ti). The newly synthesized radioactive isotopes are contained in the thin outermost layer of expanding SN ejecta. Given the small diffusion time there, it creates a bright emission in the first few days, then it is eventually overwhelmed by the main SN emission. The mass of the He layer would be between $0.004M_{\odot}$ (for $M_{\rm WD} \sim 1.4M_{\odot}$) to $\sim 0.13M_{\odot}$ (for $M_{\rm WD} \sim 0.8M_{\odot}$) for the SD scenario, but it is highly uncertain (or can be quite diverse) in the DD scenario. The amount of the surface radioactivity, which determines both the luminosity and duration of the early flash, can be diverse but can create optical signals similar to the predictions from the companion/CSM interaction scenarios. An important difference between the He detonation and the interaction scenarios is the UV-optical color; it is much redder in the He detonation model. Examples of synthetic observables from the He detonation models are shown in Figure 1.[21]

The He detonation would result in highly red spectra around the maximum phases,[13,21,22] as the UV portion of the light experiences substantial line absorptions by the He detonation ash (Figure 2). This feature has indeed been a main argument against the He detonation model to account for a main population of SNe Ia. We however note that this prediction is highly sensitive to the combination of the SN luminosity (which determines ionization) and the mass of the He shell (which determines the mass of the absorbers); either a very thin shell and/or a high luminosity would erase the potential signature of the UV absorptions.[21] This

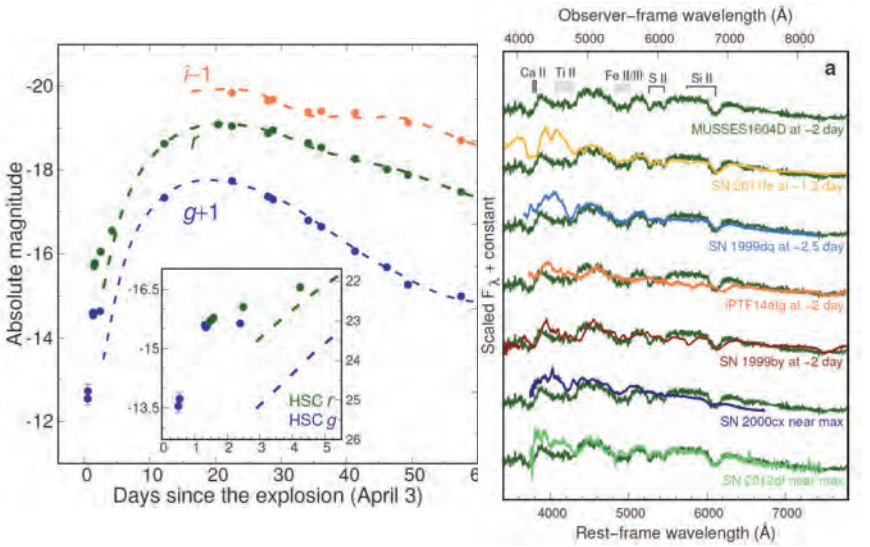

Fig. 3. Multi-band light curves (left) and a spectrum around the maximum light (right) of MUSSES1604D. The right panel shows comparisons to various SNe Ia; the spectrum of MUSSES1604D is shown by the dark green line, while the comparison SNe are shown in different colors. Reproduced from the following publication: J. Jiang, et al., Nature, 550, 80 (2017).[19]

feature adds a predicting power to the He detonation scenario: the properties in the early flash and those in the maximum phases are coupled, and therefore the combined analysis provides a strong diagnostics for the He detonation scenario.

## 3. MUSSES1604D: The first robust candidate of the He detonation

MUSSES1604D is a peculiar SN Ia discovered by a survey using the Hyper Suprime-Cam (HSC) attached with the Subaru telescope.[19] The survey is designed to make the best use of the wide-field capability of the HSC and the deep sensitivity of the 8.2m Subaru telescope, in order to discover relatively high-z SNe Ia in the first day of the explosion.

MUSSE1604D shows an excess of the light in the first few days, as compared to a simple extrapolation from the template SN Ia light curve (Fig. 3). Indeed, except for this early excessive emission, the light curve is largely consistent with normal SNe Ia. Around the maximum phase, it shows clear peculiarities in its spectral features. While it generally resembles normal SNe Ia, additional absorption features are seen in the blue part ($\lesssim 4,500$Å). These absorption features are identified as Ti II and Fe-peaks, which are seen in sub-luminous SNe Ia but not in normal SNe Ia.

A straightforward interpretation is the He detonation-triggered explosion.[19,21] The scenario predicts both the emission in the earliest phase (due to the radioactive power) and the absorptions around the maximum phase (due to the decayed Fe-peak elements and Ti). As a demonstration, radiation transfer simulations are

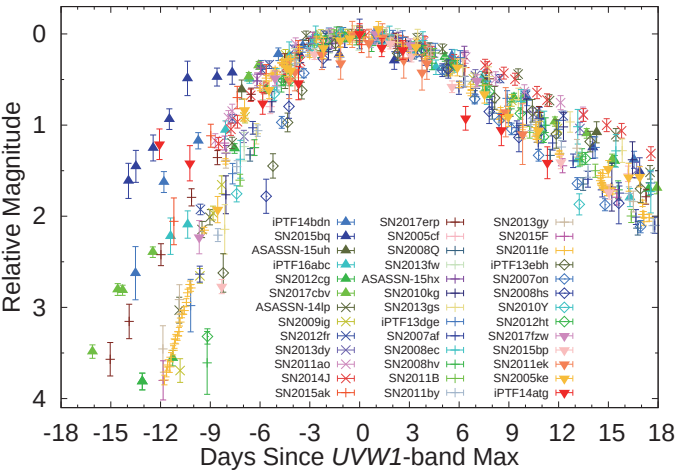

Fig. 4. Light curves of SNe Ia in the SWIFT $UVW1$-band. Reproduced from the following publication: J. Jiang, et al., The Astrophysical Journal, 865, 149 (2018).[23]

performed on a grid of simplified kinematic models which are constructed for a set of parameters; the ejecta mass (which is translated to the mass of the primary WD), the mass of $^{56}$Ni in the main SN ejecta, and the mass of the He shell. The best match is found for $1.28 - 1.38 M_{\odot}$ for the WD mass, $\sim 0.43 M_{\odot}$ for the $^{56}$Ni mass, and $\sim 0.02 - 0.03 M_{\odot}$ for the He shell mass. We note that this combination in the WD mass and the $^{56}$Ni mass deviates from the expectation from the carbon detonation, and this issue is yet to be clarified. The mass of the He shell is largely consistent with the classical double detonation model within the SD scenario.

The rate of MUSSES1604D-like SNe Ia is small; only $\sim 0.5\%$ of SNe Ia show the combination of normal peak luminosity and the peculiar maximum spectra.[19,23] We however note that the properties of the maximum-phase spectra are highly sensitive to the combination of the luminosity and the He shell mass; the MUSSES1604D-like objects may represent a tip of icebergs of the 'He detonation population'.[21] Indeed, the second robust candidate of the He detonation-triggered SN Ia 2018byg has different characteristics than MUSSES1604D, but the variation is understandable within the He detonation model sequence.[24]

## 4. Diversity of SNe Ia in the earliest phases

There are some reports of the detection of the early-phas excess for individual SNe Ia (see Ref. 23 for a review). A systematic study of existing data with early-phase photometric observations well before the maximum light (Fig. 4), which include the objects which were not reported previously, show an interesting trend;[23,25] most, if not all, of SNe Ia showing the early-phase excess are classified as bright SN 1991T/1999aa-like SNe Ia (or the 'shallow Si class'). The exceptions

are iPTF14atg[26] and MUSSES1604D, for which the companion interaction and He detonation, respectively, have been suggested for the mechanism responsible for the early excess.

Furthermore, all the bright SNe Ia with sufficient data in the early phase show the excess. Given that the companion interaction predicts a substantial viewing direction dependence on the strength of the early flash,[16,27] this possibility is immediately rejected to explain the early-phase excess seen in these bright SNe Ia. Further, the duration is long ($\sim$ 10 days) and the color is red, which are inconsistent with the CSM interaction scenario. These properties suggest that the mechanism to create the early excess for the bright SNe Ia is likely the mixing of $^{56}$Ni outward during the explosion.[21,23] Indeed, modeling the spectral sequence for the bright SNe Ia suggests that the $^{56}$NI distribution is extended toward the outer layer,[28] which may support the interpretation. The strength of the signal is diverse; this may indicate that a different degree of the mixing is realized in these SNe Ia.

## 5. Concluding remarks

In this paper, we have summarized our ongoing activity to understand the progenitors and explosion mechanisms of SNe Ia, highlighting one particular mode of the explosion, i.e., the explosion triggered by the He detonation on the surface of a C+O WD. Our conclusions are summarized as follows:

- The He detonation model offers a new mechanism to create the excessive emission from SNe Ia in the first few days, adding to the previously suggested mechanisms (companion interaction, CSM interaction, and $^{56}$Ni mixing).
- The He detonation has a unique prediction; the properties seen in the earliest phase are connected to those in the maximum phases, through the absorption by the He detonation ash.
- Properties of MUSSES1604D, as discovered by the Subaru/HSC high-cadence survey likely within the day of the explosion, are best explained by the He detonation scenario.
- Except for two SNe Ia (iPTF14atg and MUSSES1604D), SNe with the early excess show strong preference to a bright SN 1991T/1999aa-like subclass. The most likely mechanism to create the early excessive emission for these bright SNe is the mixing of $^{56}$Ni towards the outer layers during the explosion.
- A combined analysis of the very early phase observations and the maximum-phase observations will be key in mapping the diverse SN Ia zoo into different populations reflecting different progenitors and/or different explosion modes.

# Spin flip-flops from secular dynamics of compact binaries

Keresztes, Zoltán, Tápai, Márton and Gergely, László Á.

*Institute of Physics, University of Szeged, Dóm tér 9, Szeged, H-6720, Hungary*

Compact binary systems are investigated on timescales where the gravitational radiation backreaction is negligible but which is much longer than the orbital period. On this conservative timescale we use averaged equations over one orbital period removing the short time-scale modulations but keeping the secular variations. The effects of the eccentricity on the spin flip-flop is studied for equal mass binary systems. We find that eccentricity does not affect the flip-flop magnitude but it has a significant influence on its period.

## 1. Introduction

The first direct detection of gravitational waves was announced in 2016 by the LIGO Scientific Collaboration and Virgo Collaboration, one century after Einsten proposed their existence. Ten additional events have emerged since the first detection. All observed gravitational waves originated from compact binary systems,[1–8] and in two cases the spin of the merging black holes was identified with high significance.[2,8,9] Therefore the accurate description of the orbital and spin dynamics of compact binary systems is important. Effects due to the spin evolution can also occur before the merger. The precession of the dominant spin (of the larger mass supermassive black hole of the binary) was identified for the first time through its jet characteristics from VLBI radio data spanning over 18 years.[10]

The evolution of the compact binary system consists of three consecutive phases: i) inspiral, ii) merger and iii) ringdown. In the first regime the dynamics can be described by the post-Newtonian (PN) formalism. On the conservative timescale where the gravitational radiation backreaction is negligible the spin effects appear throught the spin–orbit (SO), the spin–spin (SS) and the quadrupole[a]–monopole (QM) couplings, giving contributions to the relative acceleration of the binary components and leading to spin precessional equations.[11,12] The conservative timescale contains two additional subscales. The shorter is given by the orbital period, while the longer by the precessional period of the orbital plane and spins. On the orbital timescale the spin effects on the orbit were analyzed setting up a generalized Kepler equation.[13–16] On the precessional timescale the effects occurring on the shortest timescale can be swept away by averaging methods. Then a simplified system of equations is obtained, governing the longtime spin evolution. The averaged dynamics for circular orbits with SO and SS coupling terms[17] and for generic bounded orbits with SO couplings[18,19] were derived. With the inclusion of the SO, SS and QM couplings Racine identified a new constant of motion for black holes which have specific quadrupole parameter and solved analytically the averaged spin equations

[a]If the quadrupole moment is spin induced.

for circular orbits.[20] By an additional averaging over the precession timescale the evolution of the magnitude of total angular momentum during the inspiral was investigated.[21,22] These efforts were exploited for building waveforms.[23]

Several interesting spin related behaviours were identified in compact binary dynamics. When the orbital angular momentum and the total spin are anti-aligned and nearly cancel each other the orbital plane changes significantly during a relatively short-lived transitional precession period[17]. In binaries having components with significantly different masses, the direction of dominant spin relative to the total angular momentum can change significantly during the inspiral.[24] This spin-flip may explain the formation of X-shape radio galaxies.[25] When the spin vector of the larger black hole $\mathbf{S_1}$ (dominant spin) approximately lies in the plane of motion, while the smaller spin $\mathbf{S_2}$ is closely aligned with the orbital angular momentum $\mathbf{L}_N$, the smaller spin slowly evolves to be anti-aligned with $\mathbf{L}_N$, then periodically changes back and forth on a timescale shorter than the gravitational radiation reaction timescale.[26] This effect, dubbed spin flip-flop was investigated in a wider parameter range for binaries moving on circular orbits.[27–29] Recently a parameter range has been identified where the flip-flop happens on relatively short timescales, and dubbed as wide precession.[30] Then over the period during which the magnitude of the total spin changes from its minimum to its maximum and back to the minimum value, one of two spins evolves from complete alignment with $\mathbf{L}_N$ to complete anti-alignment.

Here we investigate the effects of the eccentricity on the magnitude and the period of spin flip-flop on conservative timescale. For this purpose we use averaged equations over one orbital period keeping only the secular effects.

## 2. Secular spin evolution of compact binaries moving on eccentric orbits

The orbital and spin dynamics of the compact binary systems up to 2PN orders with SO, SS and QM couplings is given by equations (36)–(42)[31] in terms of dimensionless osculating orbital elements and spin angles. This system of equations describes the motion of an object with reduced mass $\mu$ around another component with total mass $m$. There are two variables which characterize the shape of the reduced mass' orbit:

$$\mathfrak{l}_r = \frac{cL_N}{Gm\mu} \ , \tag{1}$$

and the orbital eccentricity

$$e_r = \frac{A_N}{Gm\mu} \ , \tag{2}$$

with speed of light $c$, gravitational constant $G$, magnitudes $L_N$ and $A_N$ of the orbital angular momentum $\mathbf{L}_N$ and of the Laplace-Runge-Lenz vector $\mathbf{A}_N$. There are three Euler angles in the system of equations: the inclination $\alpha = \arccos\left(\hat{\mathbf{J}} \cdot \hat{\mathbf{L}}_N\right)$,

the longitude of the ascending node $\phi_n = \arccos\left(\hat{\mathbf{x}} \cdot \hat{\mathbf{l}}\right)$ and the argument of the periastron $\psi_p = \arccos\left(\hat{\mathbf{l}} \cdot \hat{\mathbf{A}}_N\right)$. Here $\mathbf{J}$ is the total angular momentum, conserved in the 2PN dynamics, $\hat{\mathbf{l}} = \hat{\mathbf{L}}_\mathbf{N} \times \hat{\mathbf{J}}$, $\hat{\mathbf{x}}$ denotes a fixed direction perpendicular to $\hat{\mathbf{J}}$ and the hat denotes unit vectors. The magnitudes of the spin vectors are constant and they are characterized by the dimensionless quantities:

$$\chi_i = S_i \frac{c}{G} m_i^{-2} \ . \tag{3}$$

The polar angles of the spin vectors are

$$\kappa_i = \arccos\left(\hat{\mathbf{S}}_i \cdot \hat{\mathbf{L}}_\mathbf{N}\right) \ , \tag{4}$$

and their azimuthal angles

$$\zeta_i = \arccos\left(\hat{\mathbf{S}}_i^{\perp} \cdot \hat{\mathbf{A}}_N\right) \ , \tag{5}$$

with $\mathbf{S}_i^{\perp} = \mathbf{S}_i - \hat{\mathbf{L}}_\mathbf{N}\left(\mathbf{S}_i \cdot \hat{\mathbf{L}}_\mathbf{N}\right)$.

We investigate the secular effects which occur over many orbital periods. The average of any function $f$ over one orbital period is

$$T\bar{f} = \int_0^T f\left(t\right) dt = \int_0^{2\pi} f\left(\chi_p\right) \frac{1}{\dot{\chi}_p} d\chi_p \ , \tag{6}$$

where $\chi_p$ is the true anomaly, the angle between $\hat{\mathbf{A}}_N$ and the position of the reduced mass. The distance $r$ between the binary components changes periodically, thus

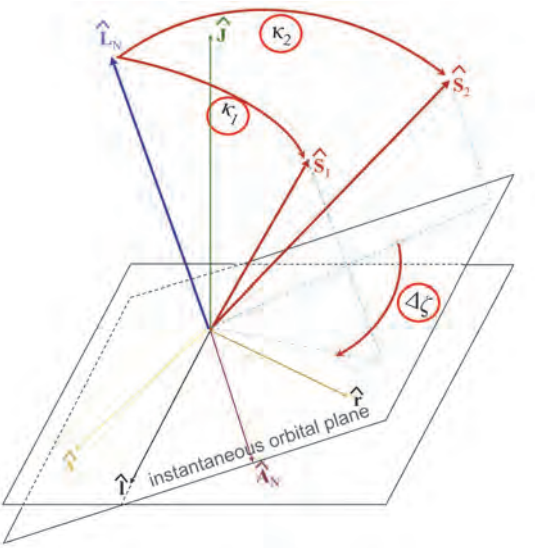

Fig. 1. The spin angles $\kappa_i$ and $\Delta\zeta = \zeta_1 - \zeta_2$ are shown.

there are turning points, where $\dot{r} = 0$. The parameter $\chi_p$ is chosen such that $\dot{r}(\chi_p = k\pi) = 0$, where $k$ is an integer number. The orbital period $T$ is the time spent between $\chi_p = 0$ and $\chi_p = 2\pi$. Applying Eq. (6) for the time derivatives $f = \left\{\dot{\iota}_r, \dot{e}_r, \dot{\alpha}, \dot{\phi}_n, \dot{\psi}_p, \dot{\kappa}_i, \dot{\zeta}_i\right\}$ leads to the secular dynamics. These equations are given with 1PN corrections and SO coupling.[32] The averaged equations valid up to 2PN orders will be presented.[33] We note that the shape variables are constants of motion $\dot{\bar{\iota}}_r = \dot{\bar{e}}_r = 0$ on the secular time-scale (where the gravitational radiation backreaction is negligible). In addition, the equations for the variables $\kappa_i$ and $\Delta\zeta = \zeta_1 - \zeta_2$ (shown on Fig. 1) are decoupled from the set of equations governing the evolutions of $\alpha, \phi_n, \psi_p$ and $\zeta_1 + \zeta_2$.

On Fig. 2 the color map highlights the values of the difference between the extremal values of $\kappa_2$ occuring during the evolution, denoted $\Delta\kappa_2$, for an equal mass binary system in the parameter space span by $\kappa_1(0)$ and $\kappa_2(0)$. The orbital eccentricity and the initial value of $\Delta\zeta$ were chosen as $\bar{e}_r = 0.1$ and $\Delta\zeta(0) = \pi/2$. On the left panel $\chi_1 \ll \chi_2$. Large flip-flops with $\Delta\kappa_2 \approx \pi$ occur at $\kappa_1(0) \approx \pi/2$, originally identified for circular orbits.[26] For $\chi_1 = \chi_2 = 0.95$ the right panel shows that large flip-flops appear in completely different regions than for $\chi_1 \ll \chi_2$.

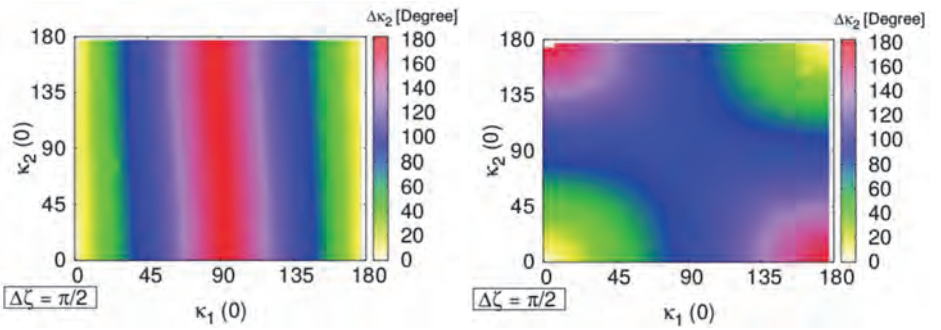

Fig. 2. The color map represents $\Delta\kappa_2$ (the difference between the extremal values of $\kappa_2$ occuring during the evolution) as a function of $\kappa_1(0)$ and $\kappa_2(0)$. On the left panel $\chi_1 = 0.95$ and $\chi_2 = 0.05$ corresponding to $\chi_2 \ll \chi_1$ while on the right panel $\chi_1 = \chi_2 = 0.95$ (in this case $\Delta\kappa_2 = \Delta\kappa_1$). The additional fixed parameters are $\Delta\zeta(0) = \pi/2$, $m_1 = m_2$, $m = 20M_\odot$, $\bar{e}_r = 0.1$ and $\bar{\varepsilon} = 0.0001$.

The period of the flip-flop during which $\kappa_2$ changes from its minimum to its maximum and back to its minimum is shown on Fig. 3 as a function of eccentricity. The flip-flop period (a dimensionless number) is given in units of $Gm/c^3$. On the left panel $\chi_1 \ll \chi_2$ while on the right panel $\chi_1 = \chi_2 = 0.95$, and $\Delta\zeta(0) = \pi/2$ on both panels. At the orange, white and black contour lines $\Delta\kappa_2$ has the values $\pi/3$, $\pi/2$ and $2\pi/3$, respectively. Since these lines are horizontal, $\Delta\kappa_2$ does not depend on the eccentricity. We have confirmed this property in a wide parameter range for binaries with equal mass.

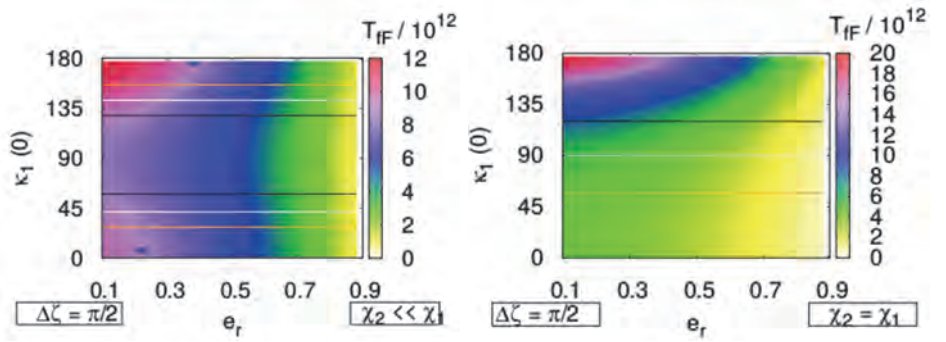

Fig. 3. The color map shows the flip-flop periods in dimensionless units as a function of $\bar{e}_r$. At the horizontal orange, white and black contour lines $\Delta\kappa_2$ has the values $\pi/3$, $\pi/2$ and $2\pi/3$, respectively. On the left panel $\chi_1 = 0.95$ and $\chi_2 = 0.05$ corresponding to $\chi_2 << \chi_1$ while on the right panel $\chi_1 = \chi_2 = 0.95$ (in this case $\Delta\kappa_2 = \Delta\kappa_1$). Common parameters for both panels are $\kappa_2\,(0) = \pi/10$, $\Delta\zeta\,(0) = \pi/2$, $m_1 = m_2$, $m = 10^5 M_\odot$ and $\bar{\varepsilon} = 0.0001$.

## 3. Conclusions

Spin flip-flop effects were considered for equal mass binaries moving on eccentric orbits. When one of the binary components is slowly spinning with respect to the other, the largest variation in the polar angle of the smaller spin occurs when the dominant spin is near perpendicular to the orbital angular momentum. However the magnitude of the flip-flop strongly depends on the ratio of the spin parameters. For binaries with same identical parameters the flip-flop magnitude is largest in the near regions of the two corner points ($\kappa_1\,(0) = 0$, $\kappa_2\,(0) = \pi$) and ($\kappa_1\,(0) = \pi$, $\kappa_2\,(0) = 0$) (see Fig. 2).

We have found that the magnitude of the flip-flop is unchanged for different orbital eccentricities. However the eccentricity significantly influences the period of the flip-flop. As the eccentricity increases, the flip-flop period decreases. Comparing the low ($\bar{e}_r \approx 0.1$) and high ($\bar{e}_r \approx 0.9$) eccentric orbits, the period decreases by one order of magnitude in certain cases, for fixed $\kappa_1\,(0)$.

# A public framework for Feynman calculations and post-Newtonian gravity

Michele Levi

*Institut de Physique Théorique, CEA & CNRS, Université Paris-Saclay*
*91191 Gif-sur-Yvette, France*
*michele.levi@ipht.fr*

We report here on a line of work that has played a key role in formally establishing and going beyond the state of the art in the effective field theory (EFT) approach and in post-Newtonian (PN) gravity. We also outline here how this comprehensive framework in fact forms the outset of a prospective rich research program, building on the public Feynman and PN technology developed.

*Keywords*: Effective field theories; Post-Newtonian theory; Gravitational waves; High precision calculations.

## 1. Introduction

In recent years significant progress was made in a line of research, based on an Effective Field Theory (EFT) approach for the treatment of gravitational waves (GWs), emitted from coalescing binaries, which was put forward by Goldberger et al.[1–3]. Such binaries contain compact components, which still orbit in non-relativistic (NR) velocities in their long inspiral phase, and are therefore analytically studied via the post-Newtonian (PN) approximation in gravity[4]. Here we report in particular on a series of works, which focused on the treatment of the challenging and realistic case, where the constituents of the binary are rotating[5–13], and on making the general EFT framework widely accessible and available to the community, including a public automated computation tool[14–16]. This line of work has played a key role in formally establishing and going beyond the state of the art in the EFT approach and in PN gravity, where we also outline here how this comprehensive framework in fact forms the outset of a prospective rich research program, building on the public Feynman and PN technology developed. For a general overview presentation of the main unique advances in the field of EFTs of PN gravity, and the various prospects of using field theory to study gravity theories at all scales, see Ref. 17.

## 2. Effective Field Theories of Post-Newtonian Gravity

Multi-scale problems are prevalent in physics, and as it turns out the compact binary inspiral is also of this kind. Such problems are amenable to a systematic treatment using the framework of EFTs, originally developed in the context of quantum field theories (QFTs) and particle physics. The compact binary inspiral involves indeed a hierarchy of scales, controlled by the NR orbital velocity, $v$, which constitutes the small parameter of the effective theories at each of the intermediate scales in the problem. There are three widely separated characteristic scales in the binary inspiral problem: The scale of the single compact object, $r_s$, the scale of the orbital

separation of the binary, $r$, and the scale of radiation, emitted from the binary in GWs, with a wavelength $\lambda$. These scales satisfy $r_s \sim Gm \sim rv^2 \sim \lambda v^3$, where $m$ is the typical mass of the single compact object, $v \ll 1$, and in the PN approximation $n\text{PN} \equiv v^{2n}$ order corrections to Newtonian gravity are found. Therefore one needs to proceed to construct a tower of EFTs in stages, where in each stage an effective theory is devised to remove the corresponding intermediate characteristic scale.

The setup of EFTs is then universal, and it follows one of the two complementary procedures to construct an EFT, which are referred to as "bottom-up" and "top-down". Both of these approaches are also used in the binary inspiral problem. At the first stage, where the scale of the single object is to be eliminated, the full theory of gravity is considered as General Relativity (GR), and is given, e.g., in terms of the following Einstein-Hilbert action:

$$S[g_{\mu\nu}] = -\frac{1}{16\pi G}\int d^4x\sqrt{g}\,R[g_{\mu\nu}], \tag{1}$$

with $g_{\mu\nu}$ for the gravitational field. Then, in the bottom-up approach we construct the effective action by identifying the relevant degrees of freedom (DOFs) and the symmetries at the desirable scale. In this case, this means that the remaining bulk action, after decomposing the gravitational field into $g_{\mu\nu} \equiv g^s_{\mu\nu} + \bar{g}_{\mu\nu}$, where $g^s_{\mu\nu}$ represents the strong field modes to be removed in the effective action, is augmented with a worldline action, which contains new worldline DOFs of a point particle. The effective action is then of the following form:

$$\begin{aligned} S_{\text{eff}}[\bar{g}_{\mu\nu}(x), y^\mu(\sigma), e^\mu_A(\sigma)] &= S[\bar{g}_{\mu\nu}] + S_{\text{pp}}[\bar{g}_{\mu\nu}(y), y^\mu(\sigma), e^\mu_A(\sigma)] \\ &= -\frac{1}{16\pi G}\int d^4x\sqrt{\bar{g}}\,R[\,\bar{g}_{\mu\nu}] + \sum_{i=1}^{\infty} C_i(r_s)\int d\sigma\,\mathcal{O}_i(\sigma), \end{aligned} \tag{2}$$

where the worldline DOFs depend on the worldline parameter $\sigma$, $\mathcal{O}_i$ are the operators evaluated on the worldline, and $C_i$ denote the "Wilson coefficients", which encapsulate the UV physics suppressed, and depend only on the scale $r_s$.

At the second stage, the field component is further decomposed into components with definite scaling in the velocity, i.e. $\bar{g}_{\mu\nu} \equiv \eta_{\mu\nu} + H_{\mu\nu} + \widetilde{h}_{\mu\nu}$, where $H_{\mu\nu}$ denotes the orbital field modes, which we want to eliminate at this stage, and $\widetilde{h}_{\mu\nu}$ denotes the radiation modes. We then proceed with the top-down approach to integrate out the orbital scale by starting from the following two-particle action, obtained from the previous stage:

$$S_{\text{eff}}[\bar{g}_{\mu\nu}, y^\mu_1, y^\mu_2, e^{\ \mu}_{1\,A}, e^{\ \mu}_{2\,A}] = S[\bar{g}_{\mu\nu}] + \sum_{a=1}^{2} S_{pp}[\bar{g}_{\mu\nu}(y_a), (y_a)^\mu, (e_a)^{\ \mu}_{A}](\sigma_a). \tag{3}$$

We integrate out the orbital field modes explicitly, using a standard diagrammatic expansion with the following definition for the new effective action:

$$e^{iS_{\text{eff}}[\widetilde{h}_{\mu\nu},(y_c)^\mu,(e_c)^{\ \mu}_{A}]} \equiv \int \mathcal{D}H_{\mu\nu}\, e^{iS_{\text{eff}}[\bar{g}_{\mu\nu},y^\mu_1,y^\mu_2,e^{\ \mu}_{1\,A},e^{\ \mu}_{2\,A}]}, \tag{4}$$

where now there are new worldline DOFs, with the subscript 'c', of a composite particle, that is the binary system.

Finally, when the conservative sector is concerned, no radiation modes are present, and one should arrive at an effective action, which no longer contains field modes, or another scale to remove.

## 3. Spinning Particles in Gravity

Gravitating spinning objects have been considered as particles in an action approach both in special and general relativity already more than 40 years ago, see e.g. Refs. 18, 19, yet they were first tackled in the context of the EFT approach for PN computations of the binary inspiral in Ref. 20. Spin in Relativity necessarily implies having a non-vanishing finite size[a], i.e. a deviation from the point particle view, which is also adopted in the EFT approach, and this poses a challenge for the construction of an EFT for a gravitating spinning particle. Moreover, once we leave Newtonian physics, a unique notion of a "center of mass" is lost, and hence there is an ambiguity as to the choice of the variables describing the rotation of the object.

Nevertheless, as we noted above the way to proceed is to construct an EFT for a gravitating spinning particle, following a bottom-up procedure, i.e. by identifying the relevant DOFS, and coupling them in all possible ways allowed by the proper symmetries at this scale. After this first EFT is obtained, we can proceed to explicitly compute, using the top-down procedure starting from the two-particle EFT, the PN binding interactions of the binary system, i.e. the second EFT of a composite particle with spins. The formulation of these EFTs was indeed introduced in Ref. 9 (see also Ref. 16 for a comprehensive pedagogic presentation), and allowed in particular to constrain spin-induced finite size effects to all orders in spin, and to arrive at equations of motion (EOMs) and Hamiltonians in a straightforward manner.

### 3.1. *A gravitating spinning particle*

Let us then go over the relevant DOFs and symmetries for the EFT at the first stage[9]. First, it is assumed that the isolated object has no intrinsic permanent multipole moments beyond the spin dipole.

Then, for a spinning object, there are two types of worldline DOFs, added to the gravitational field DOFs. The crucial points to highlight for these three types of DOFs, specific to the spinning case, are: 1. The tetrad field, $\eta^{ab}\tilde{e}_a{}^\mu(x)\tilde{e}_b{}^\nu(x) = g^{\mu\nu}(x)$, represents the gravitational field DOFs, rather than simply the metric, $g_{\mu\nu}(x)$, in order to couple the field to the rotational particle DOFs; 2. The spinning particle position in the worldline coordinates, $y^\mu(\sigma)$, does not necessarily represent the rotating object's "center"; 3. The worldline tetrad, $\eta^{AB}e_A{}^\mu(\sigma)e_B{}^\nu(\sigma) = g^{\mu\nu}$,

[a]Otherwise, the rotational velocity of the object would surpass the speed of light.

is considered for the worldline rotational DOFs, and enables to define the worldline angular velocity, $\Omega^{\mu\nu}(\sigma) \equiv e_A^\mu \frac{De^{A\nu}}{D\sigma}$, so that its conjugate, the worldline spin, $S_{\mu\nu}(\sigma)$, is considered as a further rotational DOF in the action.

Similarly, when considering the spinning case, further symmetries should be taken into account in addition to general covariance and worldline reparametrization invariance, which arise already in the point mass case. First, there are parity invariance, and Lorentz invariance of the tetrad field. For the worldline tetrad, there is the $SO(3)$ invariance of the spatial triad, and on the other hand, an invariance under the choice of completion of the spatial triad to a tetrad through a timelike vector, to which we refer as "spin gauge invariance". The latter is a gauge of the rotational variables, namely of the tetrad, as well as of the spin.

The point particle action in Eq. 2 for a rotating object can then be written in the following form[9,18,19]:

$$S_{\rm pp} = \int d\sigma \left[ -m\sqrt{u^2} - \frac{1}{2} S_{\mu\nu}\Omega^{\mu\nu} + L_{\rm NMC}\left[u^\mu, S_{\mu\nu}, \bar{g}_{\mu\nu}\left(y^\mu\right)\right] \right], \tag{5}$$

where $u^\mu \equiv dy^\mu/d\sigma$, $S_{\mu\nu} \equiv -2\frac{\partial L}{\partial \Omega^{\mu\nu}}$, and $L_{\rm NMC}$ denotes the non-minimal coupling part, which only contains mass/spin-induced higher order terms. Here, the minimal coupling part is fixed from considering solely general covariance and reparametrization invariance, and it is implicitly assumed that the covariant gauge[21] is used for the rotational variables. Yet, the minimal coupling rotational term should be generalized, in the same vein of Stueckelberg action, to manifestly display the gauge freedom related with the choice of rotational variables[9]. The non-minimal coupling part of the action should also be constrained, using parity invariance and other symmetries and properties of the problem[9].

The minimal coupling rotational term is then transformed as follows[9]:

$$\frac{1}{2} S_{\mu\nu}\Omega^{\mu\nu} = \frac{1}{2}\hat{S}_{\mu\nu}\hat{\Omega}^{\mu\nu} + \frac{\hat{S}^{\mu\nu}p_\nu}{p^2}\frac{Dp_\mu}{D\sigma}, \tag{6}$$

where the hatted variables on the right hand side are the generic rotational variables, $p_\mu$ is the linear momentum, and an extra term with an acceleration emerges in the action. This extra term is not preceded by any Wilson coefficient, as it originates from minimal coupling, yet it contributes to finite size effects, and just accounts for the fact that a gravitating spinning object must have some finite size. Moreover, the leading order (LO) spin-induced non-minimal worldline couplings are recovered to all orders in the spin, and can be written in the following concise form[9]:

$$\begin{aligned} L_{\rm NMC} = &\sum_{n=1}^{\infty} \frac{(-1)^n}{(2n)!}\frac{C_{ES^{2n}}}{m^{2n-1}} D_{\mu_{2n}}\cdots D_{\mu_3}\frac{E_{\mu_1\mu_2}}{\sqrt{u^2}} S^{\mu_1}S^{\mu_2}\cdots S^{\mu_{2n-1}}S^{\mu_{2n}} \\ &+ \sum_{n=1}^{\infty} \frac{(-1)^n}{(2n+1)!}\frac{C_{BS^{2n+1}}}{m^{2n}} D_{\mu_{2n+1}}\cdots D_{\mu_3}\frac{B_{\mu_1\mu_2}}{\sqrt{u^2}} S^{\mu_1}S^{\mu_2}\cdots S^{\mu_{2n-1}}S^{\mu_{2n}}S^{\mu_{2n+1}}, \end{aligned} \tag{7}$$

where new Wilson coefficients precede each of the spin-induced non-minimal coupling terms. These terms are composed from the electric or magnetic curvature components, $E_{\mu\nu}$ or $B_{\mu\nu}$, respectively, and their covariant derivatives, and the spin vector, $S^\mu$, dual to the antisymmetric spin tensor, $S_{\mu\nu}$. Of this infinite set of operators, the first three, namely the quadrupole, octupole, and hexadecapole couplings, contribute up to the 4PN order for rapidly rotating objects[9,10,12].

### 3.2. *A gravitating composite particle with spins*

The obtainment of the EFT at the second stage is in principle more straightforward, as the one-particle EFT is already at our disposal to begin with, and so the computation from the perturbative expansion of the functional integral over the two-particle EFT is expected to be automatic. Yet, when spins are concerned, the situation is less than obvious. First, the field DOFs and the particle DOFs are entangled in the coupling of spin to gravity, e.g., in Eqs. 5, 6. For this to be remedied, it is necessary to also fix the gauge of the rotational variables of the particle at the level of the action of the spinning particles, as was first advocated in Ref. 5. Indeed, in an action approach one can proceed to directly insert the gauge of the rotational variables at any stage. Only once the field DOFs at the orbital scale are cleanly separated, one can proceed to integrate them out, using standard perturbative techniques.

Hence, first we transform to new rotational variables: the worldline Lorentz matrices, contained in the locally flat angular velocity, $\hat{\Omega}^{ab}_{\rm LocFla} = \hat{\Lambda}^{Aa}\frac{d\hat{\Lambda}_A{}^b}{d\sigma}$, and the spin projected to the local frame, $\hat{S}_{ab} = \tilde{e}^\mu_a \tilde{e}^\nu_b \hat{S}_{\mu\nu}$. The minimal coupling term in Eq. 6 can then be rewritten in the following form[6,9]:

$$\frac{1}{2}\hat{S}_{\mu\nu}\hat{\Omega}^{\mu\nu} = \frac{1}{2}\hat{S}_{ab}\hat{\Omega}^{ab}_{\rm LocFla} + \frac{1}{2}\hat{S}_{ab}\omega_\mu{}^{ab}u^\mu, \tag{8}$$

using the Ricci rotation coefficients, $\omega_\mu{}^{ab} \equiv \tilde{e}^b{}_\nu D_\mu \tilde{e}^{a\nu}$, defined from the tetrad field. The gauge of the rotational variables is then fixed to what we formulate as the "canonical" gauge. Other than that, we should also fix the gauge of the field DOFs, where we recall that the Kaluza-Klein (KK) decomposition is beneficially applied to the NR space+time metric[22,23]. Then, the gauge of the tetrad field is fixed to the Schwinger's time gauge, which corresponds to the KK decomposition. Eventually, all unphysical DOFs are eliminated from the action, and one can proceed to compute the EFT using standard QFT multi-loop techniques, such as integration by parts (IBP), and known loop master integrals.

Finally, it was shown how to derive directly from the resulting effective actions the corresponding EOMs and the Hamiltonians.

## 4. Applications and State of the Art

The formulation of the tower of EFTs with spins for the conservative sector, presented in the previous section, built on Refs. 5, 6, 7, 8, which handled the sector

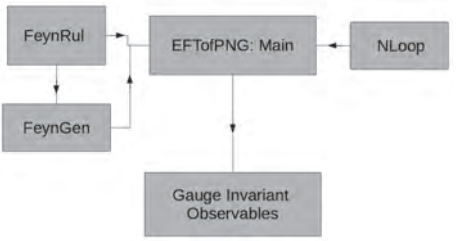

Fig. 1. An outline of the public "EFTofPNG" package version 1.0, which is both a high precision Feynman computation tool and a PN theory code[14]. The design is modular, where the flow among the independent units is shown.

linear in the individual spins, up to the two-loop level, and clarified some crucial points, which led up to the complete framework introduced in Ref. 9. In the latter, all the conservative sector with spins was derived up to the 3PN order for rapidly rotating objects, including the NLO spin-squared sector, which contains spin-induced quadrupole effects, and was shown to agree with the corresponding results derived within the canonical Hamiltonian approach, see e.g., Ref. 24. Moreover, higher order results were derived at the 3.5PN order, for the LO cubic-in-spin sector, which contains up to the spin-induced octupole[10], and for the NNLO spin-orbit sector[11]. Further new higher order results for the quartic-in-spin sector, with up to the spin-induced hexadecapole[10], and for the NNLO spin-squared sector[12], were completed at the 4PN order. All in all, this line of work completed the conservative sector with spins to the 4PN order accuracy, on par with the level of accuracy attained in the non-spinning case[4,16].

### 4.1. *A public Feynman and post-Newtonian code*

The entire framework presented here was also put into a fully open automated computation tool, "EFTofPNG", that is approachable and encouraging engagement within the community[14]. The comprehensive and self-contained "EFTofPNG" code can be found in the public repository in `https://github.com/miche-levi/pncbc-eftofpng`, where the current version handles the point mass sector, and all the spin sectors up to the state of the art. The design of the code is modular, see Fig. 1, so that various units of the code could be efficiently used and developed independently for different purposes in various generic contexts in physics. In particular, since the Mathematica code builds on the "xTensor" package for efficient computer tensor algebra, the treatment of Wick contractions is made significantly more efficient, compared to other common Feynman codes, by considering $n$-point functions as tensors of rank $n$. On the other hand, this is the first code made public in PN theory, and is also geared towards the needs of the GW community.

At this time when the influx of GW data is expected to multiply, it is essential to publicly share the up to date analytic output of PN theory, required for

the improvement of theoretical gravitational waveform templates[25–27]. We strongly advocate public development of the code to improve its efficiency, and to extend it, innovating towards higher orders of PN accuracy, and incorporating extensions of the theory to cover more sectors, especially non-conservative ones. We maintain that community development will also help push a number of eventually necessary research directions. Considering the independent units of the code, as seen in Fig. 1, let us list then just some of the diverse collective prospects for development: The "FeynRul" unit can be expanded to implement various alternative theories of gravity rather than just the theory of GR; The "FeynGen" unit can be modified to efficiently generate Wick contractions and Feynman graphs for any generic perturbative scheme; The "NLoop" unit, which handles and manipulates loop master integrals and IBP relations, useful in any context of amplitudes computations, can be extended analytically to higher loop orders, and to improve in computational efficiency; Finally, the "Gauge Invariant Observables" unit, which is aimed to deliver the final output of PN theory, in terms of useful gauge invariant quantities, is to be progressively developed along with the advances in PN theory, such that these would be directly available to the GW community for the waveform modeling.

## Acknowledgments

I am grateful to John Joseph Carrasco for his pleasant and significant support. I would like to thank Luc Blanchet, who chaired the session, and invited me to present the EFTs of PN theory with spins. I would like to especially acknowledge my collaborator on this line of research, Jan Steinhoff, who also created with me the "EFTofPNG" code. It is with great pleasure that I extend my gratitude to Donato Bini for the warm hospitality throughout the MG15 meeting. My work is supported by the European Research Council under the European Union's Horizon 2020 Framework Programme FP8/2014-2020, "preQFT" grant no. 639729, "Strategic Predictions for Quantum Field Theories" project.

# Search for high-energy neutrinos from binary neutron star mergers

Nora Linn Strotjohann* for the IceCube Collaboration

*DESY Zeuthen,*
*15738 Zeuthen, Germany*
**E-mail: nora.linn.strotjohann@desy.de*

To search for transient astrophysical neutrino sources, IceCube's optical and X-ray follow-up program is triggered by two or more neutrino candidates arriving from a similar direction within 100 s. However, the rate of such neutrino multiplets was found to be consistent with the expected background of chance coincidences, such that the data does not provide indications for the existence of short-lived transient neutrino sources. Upper limits on the neutrino flux of transient source populations are presented in Aartsen et al. (2019)[1] and we show here how these limits apply to the predicted neutrino emission from binary neutron star mergers.

*Keywords*: Neutrino astronomy; binary neutron star mergers; short GRBs.

## 1. Introduction

The first (and so far only) detected binary neutron star merger is the object GW 170817[2] with the electromagnetic counterpart GRB 170817A.[3] The detected gamma-ray and multiwavelength emission indicates that a relativistic jet was launched during the merger.[4] It has been suggest that cosmic rays could be accelerated within this jet and an associated flux of high-energy neutrinos has been predicted.[5,6] A search for neutrino emission from the position of GRB 170817A was carried out by the ANTARES, IceCube and Pierre Auger observatories, but no signal was detected.[7]

Here, we present limits on the neutrino emission of short-lived transients,[1] which also apply to binary neutron star mergers and are independent of the limits derived for GRB 170817A. The results are based on data from the IceCube neutrino observatory, an ice-Cherenkov detector located at the geographic South pole.[8] An array of 5 160 optical sensors instruments a volume of $\sim 1\,\mathrm{km}^3$ and allows to detect neutrino interactions in the energy range between $\sim 100\,\mathrm{GeV}$ and a few PeV.[1]

IceCube's optical and X-ray follow-up program (OFU program)[1,9–11] is taylored to search for neutrino emission in connection with gamma-ray bursts (GRBs) or core-collapse supernovae (CCSNe) with choked jets. An alert is defined as two or more tracklike events which are detected within 100 s with a maximal angular separation of 3.5°. The OFU program currently only uses neutrino candidates from the northern sky to avoid the large background of downgoing atmospheric muons. The aim of the program is to identify astrophysical neutrino sources through optical and X-ray follow-up observations, which can be triggered within $\sim 1\,\mathrm{min}$.[12,13] Examples of follow-up campaigns are presented in Aarten et al. (2015)[10], Aartsen et al. (2017)[11], and Evans et al. (2015)[13], but the observations so far did not identify a likely neutrino source and the number of neutrino multiplets is consistent with the expected number of chance coincidences of atmospheric neutrinos or muons.[1]

## 2. Generic Limits on Short-Lived Neutrino Transients

Upper limits on the neutrino flux of short-lived transients have been published in Aartsen et al. (2019)[1] and are summarized in this section. The analysis is based on 1648.1 days of IceCube data (collected between September 2011 and May 2016). Only one alert consisting of three neutrino candidates was detected during this time.[11] This is consistent with the estimated background of 0.34 chance coincidences and the resulting 90% upper limit on the expected number of astrophysical neutrino multiplets (alerts consisting of more than two neutrino candidates) is $< 4.0$.

To calculate a limit on the median neutrino luminosity of short-lived transients, an extragalactic source population is simulated and those scenarios which yield more than 4 astrophysical neutrino multiplets are disfavored at 90% confidence level. The source properties are chosen to be similar to long GRBs or CCSNe and several assumptions are tested to quantify their impact on the resulting limit. The assumed population properties are:

(1) **redshift distribution**: star formation rate for CCSN-like sources[14] and the distribution observed by *Swift* for GRB-like sources.[15]
(2) **neutrino luminosity function**: small fluctuations (one astronomical magnitude) for CCSN-like sources, observed gamma-ray luminosity function for GRB-like sources.[15]
(3) **neutrino spectrum**: an $E^{-2.13}$ or $E^{-2.5}$ spectrum between 100 GeV and 10 PeV as measured for the astrophysical neutrino flux at $\sim 100$ TeV.[16,17]
(4) **transient duration**: duration of long GRBs observed by the *Swift* BAT.[1]

The rate density of transients and the population's neutrino flux are free parameters in the calculation. The resulting upper limits are shown as orange and gray bands in Fig. 1 and correspond to the 90% c.l. upper limits on the energy emitted in neutrinos by the median source in the population. The limit for the GRB-like population is stronger mainly due to the steeply falling luminosity function of long GRBs.[15] The lower edge of the band shows the limit for an $E^{-2.13}$ spectrum, while the upper edge is for an $E^{-2.5}$ spectrum. The dashed diagonal lines show the source energy for which the population would produce the entire astrophysical neutrino flux assuming an $E^{-2.5}$ spectrum. The corresponding lines for an $E^{-2.13}$ spectrum are lower by a factor of 13, but are not shown here for clarity.

Rare sources, such as GRBs with a rate of $\sim 4 \times 10^{-10}\,\mathrm{Mpc}^{-3}\,\mathrm{yr}^{-1}$,[18] can only produce a small fraction of the astrophysical neutrino flux without producing more than 4 neutrino multiplets. This confirms the non-detections from the stacked IceCube searches for neutrinos from GRBs.[19,20] If, on the other hand, many faint sources contribute to the flux, no neutrino multiplets are expected as even the brightest sources only yield one or two detected events. The limits are purely based on neutrino data and hence also apply to short-lived transients that commonly remain undetected, such as binary neutron star mergers or low-luminosity GRBs. They are therefore more general than stacked searches.

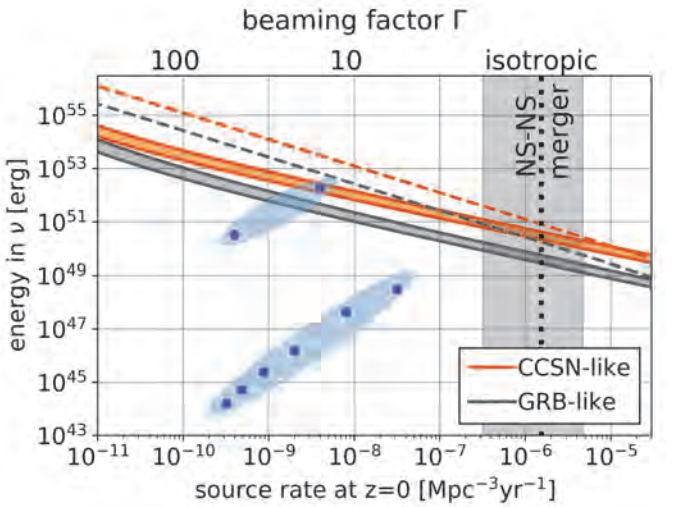

Fig. 1. Upper limits (orange and gray bands) on the median energy emitted by a transient in neutrinos (between 100 GeV and 10 PeV; for three neutrino flavors; compare Ref. 1). The dashed lines correspond to the source energy for which the population would produce the entire astrophysical neutrino flux for an $E^{-2.5}$ spectrum. The blue dots show the predicted high-energy neutrino emission from binary neutron star mergers, where the upper dots are for the Kimura extended emission (EE) model[5] and the lower ones for the Biehl prompt flux model.[6]

## 3. Limits on the Neutrino Flux of Binary Neutron Star Mergers

While the results presented in Aartsen et al. (2019)[1] (and summarized in the previous section) were calculated for a generic population of neutrino sources, the limits are now compared to specific models for the high-energy neutrino emission from binary neutron star mergers. Such models have for example been published by Kimura et al. (2017)[5] and Biehl et al. (2018)[6]. There are considerable uncertainties on the model parameters, such as the beaming factor or the baryonic loading, which result in large differences between the precited neutrino emission shown in Fig. 2. We test several models, listed in Table 1, that predict neutrino emission within 100 s and yield a considerably higher neutrino flux between 100 GeV and 10 PeV.

To quantify the sensitivity of the OFU program to the predicted neutrino fluxes, the spectral shapes are multiplied with the effective area of the OFU event selection. This yields the expected number of neutrino events from a merger in the northern sky at a distance of 40 Mpc which is given in the fourth column of Table 1. The fifth column lists within which distance three or more detected neutrinos are expected from a merger. It is neglected here that an object with fewer expected events might nevertheless produce a neutrino triplet due to Poisson fluctuations.[21]

Contrary to the assumptions for the limit calculation (summarized in Sect. 2), the spectra shown in Fig. 2 do not follow a power law. To allow a comparison an effective source energy is calculated. It corresponds to the energy of a source with an $E^{-2.13}$ spectrum between 100 GeV and 10 PeV for which the same number

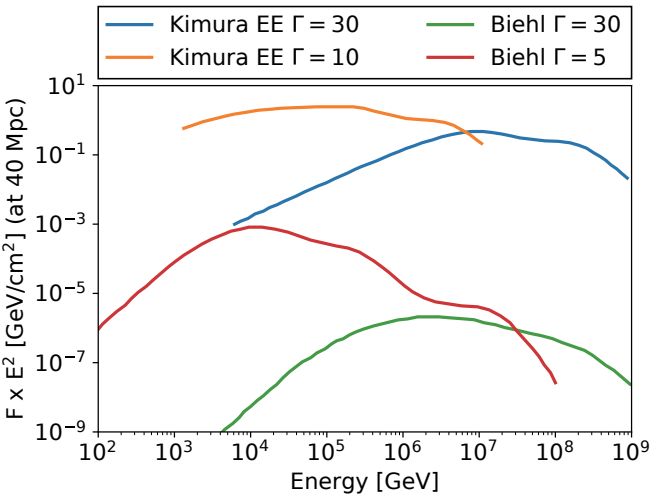

Fig. 2. Predicted neutrino spectra of binary neutron star mergers model according to the Kimura extended emission model[5] and the Biehl prompt emission model[6].

Table 1. Predicted high-energy neutrino emission from binary neutron star mergers. The beaming factor $\Gamma$ determines the rate of detectable transients. The expected number of $\nu_\mu$ events (fourth column) is for the OFU event selection for sources in the northern sky. The next column lists the distance within which three or more events are expected a merger in the northern sky. The two last columns show the energy emitted in neutrinos (for the sum of all three neutrino flavors) between 100 GeV and 10 PeV and the effective source neutrino energy, the energy of a source with an $E^{-2.13}$ spectrum with the same expected number of OFU events.

| Model | $\Gamma$ | rate [$\mathrm{Mpc^{-3}\,yr^{-1}}$] | $\nu_\mu$ events at 40 Mpc | max. dist. [Mpc] | energy in $\nu$ [erg] | eff. energy in $\nu$ [erg] |
|---|---|---|---|---|---|---|
| Kimura EE opt. | 10 | $4 \times 10^{-9}$ | 90 | $< 220$ | $1.2 \times 10^{52}$ | $1.9 \times 10^{52}$ |
| Kimura EE mod. | 30 | $4 \times 10^{-10}$ | 1.5 | $< 30$ | $8 \times 10^{50}$ | $3 \times 10^{50}$ |
| Biehl optimistic | 5 | $3 \times 10^{-8}$ | 0.02 | $< 10$ | $1.6 \times 10^{48}$ | $3 \times 10^{48}$ |
| Biehl moderate | 30 | $1 \times 10^{-9}$ | $1 \times 10^{-5}$ | $< 0.1$ | $4 \times 10^{45}$ | $2 \times 10^{45}$ |

of events is expected. The effective source energy is given in the last column of Table 1. The actual source energy is calculated by integrating the spectra in Fig. 2 and is listed in the second last column of the table. The difference is less than a factor of three for all considered neutrino spectra.

The flux upper limits moreover depend on the rate density of transients at $z = 0$. As shown in Fig. 1, the limits get stronger for larger rates, because it becomes more likely that a source happens within the distance where it is detectable (listed in the fifth column of Table 1). The rate of binary neutron star mergers was measured based on the detected event and the gray, vertical band in Fig. 1 shows the rate within its $1\sigma$ uncertainty. The considered models, however, predict collimated neutrino emission which reduces the rate of observable events by a factor of $1/(2\Gamma)$. The collimation factors and resulting rates are listed in the second and third column

of Table 1. Extended gamma-ray emission is moreover only expected for every second short GRB[5] (and was not detected for GRB 170817A) which reduces the rate accordingly. Potential neutrino emission from misaligned mergers[5,6] is not considered for simplicity. The redshift distribution only has a minor influence on the upper limits. When using the observed evolution of short GRBs[22] the limits become 13% stronger compared to the star formation rate used for the CCSN-like population (see appendix of Aartsen et al. (2019)[1]).

The predicted rates and the source energies for binary neutron star mergers are shown as blue dots in Fig. 1. The upper dots are for the Kimura EE model[5] and the lower ones for the Biehl prompt emission model[6]. The Kimura prompt emission model is not shown: It assumes a beaming factor of 1000 and has an effective neutrino energy of $5 \times 10^{43}$ erg.[5] Figure 1 shows that the optimistic EE model is within reach of the OFU program. If the luminosity fluctuations between individual mergers are as large as the fluctuations observed for long GRBs in gamma rays, the lower edge of the gray band represents the relevant upper limit and the model would be disfavored at 90% confidence limit. The models for prompt neutrino emission, however, predict fluxes and rates that are many orders of magnitude below the IceCube sensitivity.

## 4. Discussion

The observed gamma-ray emission of GRB 170817A indicates the presence of a relativistic jet which might be able to accelerate cosmic rays and yield a neutrino flux. No neutrino emission was detected from GRB 170817A which is expected since the jet was likely misaligned by 30°.[4] Moreover, no extended gamma-ray emission was observed from the central engine.[3] An additional difficulty was that the source was located above the horizon for both the ANTARES and the IceCube detectors which reduces the sensitivity.[7]

Independent upper limits on the neutrino emission of 100 s-long transients are provided by IceCube's OFU program. The sensitivity of the OFU program to a merger located at 40 Mpc was evaluated for several models and the results are listed in Table 1. For the most optimistic model the OFU program would likely be triggered if the merger happens within $\sim$ 220 Mpc in the northern sky. To estimate how likely a nearby merger occurs during the $\sim$ 5 years of analyzed data, we calculate the rate of mergers which have a jet pointed at Earth. The most optimistic model predicts a relatively large rate of bright sources, such that one or several neutrino multiplets would have been detected by the OFU program.

Most prompt models, however, predict that the flux from the population of binary neutron star mergers only makes up a small fraction of the astrophysical neutrino flux. In this case, IceCube might not be sensitive enough to detect the neutrino emission from a merger. With only one detected binary neutron star merger, the uncertainties on the physical properties of these objects are still large. Models might become more precise, once more observational information is available.

Figure 2 shows that the predicted neutrino flux of several models peaks at PeV energies. Since April 2016, IceCube announces events with energies $\gtrsim 100\,\mathrm{TeV}$ to the public.[12] Follow-up observations of these alerts could hence provide an alternative way to find binary neutron star mergers. The source of a single event is, however, on average located at a large distance (the median distance is 3 Gpc assuming no source evolution)[21]. The horizon distance of the Ligo-Virgo detector was $\sim 200\,\mathrm{Mpc}$ in run O2 and might increase to 300 Mpc in run O3.[2,23] The optical peak magnitude of GRB 170817A was $-15.5$ in the $R$-band.[3] This would allow a detection within 140 Mpc (300 Mpc) by a telescope with a limiting magnitude of 20 (22). If a single PeV neutrino is detected from a binary neutron star merger, the source is likely in most cases not detectable by gravitational wave detectors or electromagnetic follow-up telescopes.

# Hyperbolic scattering in a two-body system

Donato Bini* and Andrea Geralico**

*Istituto per le Applicazioni del Calcolo "M. Picone," CNR I-00185 Rome, Italy*
**E-mail: donato.bini@gmail.com*
***E-mail: andrea.geralico@gmail.com*

We review some known results obtained in the context of hyperbolic scattering in a two-body system, stressing the state of the art, the main actual challenges and the related difficulties.

## 1. Introduction

The gravitational interaction between two (massive, spinning or with a 2−polar structure, . . . , with $n$−polar structure) bodies is a fundamental problem which has been largely investigated in many different contexts, all aiming at a complete description of the underlying gravitational phenomena but limited by the range of validity of the considered modeling used in the description of the interaction itself. The problem should be discussed in exact general relativity (GR), allowing for all the necessary information concerning the (most important) strong field regime and the effects of the nonlinearity of the gravitational interaction as follows from the Einstein's equations. Unfortunately, no such exact solutions are available up to now in a genuine GR context and one is forced to cope with some approximate treatment, ranging from weak-field and slow-motion (Post-Newtonian (PN) approximation[1]), weak-field (Post-Minkowskian (PM) approximation[2,3]), extreme-mass-ratios (i.e., the condition in which the mass of one of the two bodies is much larger of the other, discussed with perturbation theories and gravitational self-force (GSF)[4]), numerical relativity (NR)[5]. In between, there are various effective field theory formalism, like the effective-one body[6,7], which have shown over the years the capability to simply absorb information from any such context and re-use properly and efficiently.

Given an initial state configuration of the two bodies, the attractive nature of gravitation imply that they necessarily approach each other and two possible scenarios are available: capture (the more massive of the two attracts and then swallows the other) or escape (the two bodies can be close enough but they have enough energy to resist the attraction). The first situation is characterized by elliptic-like motions, the second by hyperbolic-like or parabolic-like motions. Clearly, the description becomes more and more difficult as soon as the strong field regime is reached and any approximation scheme becomes of poor utility, if not even useless.

Anyway, both cases are of particular importance in view of the possibility to detect gravitational wave signals from Earth-based interferometers operating now (Ligo[8] and Virgo[9]) and also (more likely) by future, forthcoming satellite missions involving space-based interferometers.

Since elliptic-like motions have been largely studied, we will review here the scattering situation, focusing on the known results for the scattering angle, and witnessing an increasing interest on this topic in the recent literature.

## 2. Scattering of a test particle by a black hole

Let us consider first the simplest case of a test particle scattered by a black hole, e.g., a Kerr black hole with line element written in standard Boyer-Lindquist coordinates $(t, r, \theta, \phi)$ given by

$$ds^2 = -\left(1 - \frac{2Mr}{\Sigma}\right) dt^2 - \frac{4aMr}{\Sigma} \sin^2\theta dt d\phi + \frac{\Sigma}{\Delta} dr^2 + \Sigma d\theta^2 + \frac{A}{\Sigma} \sin^2\theta d\phi^2 \,. \quad (1)$$

Here $\Delta = r^2 - 2Mr + a^2$, $\Sigma = r^2 + a^2\cos^2\theta$ and $A = (r^2 + a^2)^2 - \Delta a^2 \sin^2\theta$, $M$ and $a$ denoting the total mass and the specific angular momentum, respectively, so that the quantity $\hat{a} = a/M$ is dimensionless. The inner and outer horizons are located at $r_\pm = M \pm \sqrt{M^2 - a^2}$.

The geodesic equations on the equatorial plane lead to the following equation for the orbit

$$\left(\frac{du}{d\phi}\right)^2 = \frac{\hat{a}^4}{2} \frac{(u - u_+)^2 (u - u_-)^2}{(u_4 - u)^2} (u - u_1)(u - u_2)(u - u_3) \,, \quad (2)$$

where $u = M/r$ and $u_1 < u_2 < u_3$ are the ordered roots of the equation

$$u^3 - (\hat{x}^2 + 2\hat{a}\hat{E}\hat{x} + \hat{a}^2) \frac{u^2}{2\hat{x}^2} + \frac{u}{\hat{x}^2} + \frac{\hat{E}^2 - 1}{2\hat{x}^2} = 0 \,, \quad (3)$$

the constants $\hat{E}$ and $\hat{L}$ denoting the conserved energy and azimuthal angular momentum per unit mass of the particle, respectively, with $x = M\hat{x} = \hat{L} - a\hat{E}$, while

$$u_\pm = \frac{M}{r_\pm} \,, \quad u_4 = \frac{\hat{L}}{2M\hat{x}} = \frac{1}{2}\left(1 + \frac{\hat{a}\hat{E}}{\hat{x}}\right) . \quad (4)$$

For hyperbolic orbits we have $u_1 < 0 < u \leq u_2 < u_3$, with $u_2$ corresponding to the closest approach distance.

The ultrarelativistic limit ($\hat{E} \gg 1$) of Eq. (2) has been studied in Ref. 10 for fixed values of the impact parameter $b = M\hat{b} = \hat{L}/\sqrt{\hat{E}^2 - 1}$. The deflection angle $\delta(\hat{a}, \alpha) = 2\phi(0) - \pi$ associated with the whole scattering process has been computed there. For large values of the impact parameter, i.e., for small values of $\alpha = \hat{b}^{-1}$, the first few terms of its expansion are given by

$$\begin{aligned} \delta(\hat{a}, \alpha) = {} & 4\alpha + \left(\frac{15}{4}\pi - 4\hat{a}\right)\alpha^2 + \left(\frac{128}{3} - 10\pi\hat{a} + 4\hat{a}^2\right)\alpha^3 \\ & + \left(\frac{3465}{64}\pi - 192\hat{a} + \frac{285}{16}\pi\hat{a}^2 - 4\hat{a}^3\right)\alpha^4 \\ & + \left(\frac{3584}{5} - \frac{693}{2}\pi\hat{a} + 512\hat{a}^2 - 27\pi\hat{a}^3 + 4\hat{a}^4\right)\alpha^5 + O(\alpha^6) \,. \end{aligned} \quad (5)$$

Ref. 10 has also compared this result for a test particle without structure to the high-energy scattering of an extended body with spin-induced quadrupolar structure (characterized by the dimensionless spin parameter $\hat{s}$ and the polarizability constant $C_Q$) by a Kerr black hole as well as of a pointlike particle in the field of a (slowly) rotating (slightly) deformed source endowed with a mass quadrupole moment (characterized by the dimensionless intrinsic angular momentum $\hat{a}$ and the quadrupole parameter $q$), as described by the (approximate) Hartle-Thorne solution[11]. In all these situations the scattering angle can be formally written as

$$\delta = \delta_{\rm geo} + \delta_{\rm struct}\,, \tag{6}$$

where $\delta_{\rm geo}(q,\hat{a},\alpha)$ contains information on the background source only, whereas

$$\delta_{\rm struct}(\hat{s},C_Q;\hat{a},\alpha) = \delta_{\rm spin}(\hat{s};\hat{a},\alpha) + \delta_{\rm spin^2}(\hat{s}^2,C_Q;\hat{a},\alpha)\,, \tag{7}$$

also depends on the constitutive parameters of the scattered extended body. The first few terms of the corresponding expansion are given by

$$\begin{aligned}
\delta_{\rm spin}(\hat{s};\hat{a},\alpha) &= \hat{s}\left[-4\alpha^2 + \left(8\hat{a} - \frac{15}{2}\pi\right)\alpha^3 \right.\\
&\left. +(-128 + 30\pi\hat{a} - 12\hat{a}^2)\alpha^4 + O(\alpha^5)\right],\\
\delta_{\rm spin^2}(\hat{s}^2,C_Q;\hat{a},\alpha) &= \hat{s}^2\left\{4C_Q\alpha^3 + \left[\frac{45}{4}\pi - 12\hat{a}\right.\right.\\
&\left.\left. + \left(\frac{135}{16}\pi - 12\hat{a}\right)(C_Q-1)\right]\alpha^4 + O(\alpha^5)\right\}.
\end{aligned} \tag{8}$$

Therefore, if the spin is known, measuring $\delta_{\rm struct}$ can be used for instance to constrain the equation of state of the extended body undergoing the scattering process.

## 3. Two-body scattering in a Post-Newtonian framework

The present knowledge of the PN orbital Hamiltonian for a two-body system is at the 4th PN order, with several interesting new features with respect to the previous 3PN level which include the presence of a non-local term. Up to the 4PN level the scattering angle is given by the sum of a local part $\chi_{\rm loc}$ and a tail part $\chi_{\rm tail}$, the latter starting at the 4PN level, i.e.,

$$\begin{aligned}
\chi_{\rm loc}(E,L) &= \sum_{n=0}^{4}\frac{1}{c^{2n}}\chi^{(\rm nPN)}(E,L) + O\left(\frac{1}{c^{10}}\right),\\
\chi_{\rm tail}(E,L) &= \frac{1}{c^8}\chi^{(\rm 4PN)}_{\rm tail}(E,L) + O\left(\frac{1}{c^{10}}\right).
\end{aligned} \tag{9}$$

To show some explicit expression (see Ref. 12 for additional details) it is convenient to introduce the notation

$$\alpha \equiv \frac{1}{\sqrt{2\bar{E}j^2}}\,, \qquad B(\alpha) \equiv \arctan\alpha + \frac{\pi}{2}\,, \tag{10}$$

where $j$ is the dimensionless angular momentum $L$ and $\bar{E}$ is a Newtonian-like energy variable (see Eq. (32) in Ref. 12). A part from the Newtonian contribution

$$\frac{1}{2}\chi^{(\mathrm{N})}(\bar{E},j) = \arctan\alpha = B(\alpha) - \frac{\pi}{2}\,, \tag{11}$$

the form of the various PN terms $\chi^{(\mathrm{nPN})}$ (including the local part of the 4PN term) is of the type

$$\frac{1}{2}\chi^{(\mathrm{nPN})}(\bar{E},j) = \frac{1}{j^{2n}}\left[C^{B}_{(\mathrm{nPN})}B(\alpha) + C^{0}_{(\mathrm{nPN})}\right] \tag{12}$$

with the coefficients $C^{B}_{(\mathrm{nPN})}$ and $C^{0}_{(\mathrm{nPN})}$ rational functions of $\alpha$. For example

$$\begin{aligned}
\frac{1}{2}\chi^{(1\mathrm{PN})}(\bar{E},j) &= \frac{1}{j^{2}}\left[3B(\alpha) + \frac{(3\alpha^2+2)}{\alpha(1+\alpha^2)}\right] \\
\frac{1}{2}\chi^{(2\mathrm{PN})}(\bar{E},j) &= \frac{1}{j^{4}}\left[C^{B}_{(2\mathrm{PN})}B(\alpha) + C^{0}_{(2\mathrm{PN})}\right]\,,
\end{aligned} \tag{13}$$

with

$$\begin{aligned}
C^{B}_{(2\mathrm{PN})} &= -\frac{3[2(5\alpha^2+1)\nu - 5(1+7\alpha^2)]}{4\alpha^2}\,, \\
C^{0}_{(2\mathrm{PN})} &= -\frac{[2(15\alpha^4+28\alpha^2+13)\nu - 105\alpha^4 - 190\alpha^2 - 81]}{4\alpha(1+\alpha^2)^2}\,.
\end{aligned} \tag{14}$$

In $\chi^{(4\mathrm{PN})}_{\mathrm{loc}}(\bar{E},L)$, however, it enters the following (Hadamard-regularized) integral

$$I_\chi \equiv -\frac{16j\nu}{15}\,\mathrm{Pf}\int_0^{u_{(\max)}} \frac{u^4\ln(u)(-74\bar{E}+37j^2u^2-62u)}{(2\bar{E}-j^2u^2+2u)^{3/2}}du\,, \tag{15}$$

whose value can be anyway given in an approximated form, $u_{(\max)}$ being the (Newtonian) minimum approach dimensionless inverse distance.

## 4. Two-body scattering in a Post-Minkowskian framework

The scattering angle is known since much time at 2PM[3,13,14]

$$\chi = \frac{2(2\gamma^2-1)}{j(\gamma^2-1)^{1/2}} + \frac{3}{4}\pi\frac{(5\gamma^2-1)}{j^2h}\,, \tag{16}$$

where $\gamma$ denotes the rescaled effective energy of the system $\gamma = \frac{E-Mc^2}{\mu c^2}$ and

$$h = \sqrt{1+2\nu(\gamma-1)}\,. \tag{17}$$

The connection between the ultrarelativistic limit of this result and the ultra high-energy quantum scattering results of Amati, Ciafaloni and Veneziano[15,16] has been recently exploited in Ref. 17. It has been shown there that the scattering process between the two (nonrotating) bodies is equivalently described in terms of the scattering of a massless particle in a modified Schwarzschild metric of the form

$$ds^2 = -f_t dt^2 + f_r^{-1}dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2)\,, \tag{18}$$

with

$$f_t(u) = (1-2u)\left(1 + \frac{15}{2}u^2 - 18u^3 + \frac{1845}{16}u^4 + \dots\right),$$
$$f_r(u) = (1-2u)\,. \tag{19}$$

The scattering angle then turns out to be

$$\delta(\alpha) = 4\alpha + \frac{56}{3}\alpha^3 + O(\alpha^5)\,, \tag{20}$$

with vanishing both the coefficients at $O(\alpha^2)$ and $O(\alpha^4)$.

Very recently, after the MG meeting, in the literature has appeared the 3PM scattering angle, derived straightforwardly from re-summation of scattering amplitudes and quantum field theory approaches[18,19]. The high-energy limit of the latter result does not seem to reproduce previous results by Amati, Ciafaloni and Veneziano, even if both approaches use rather involved techniques, making difficult independent checks. The ongoing discussion will hopefully clarify this issue soon.

## 5. Difficulties for a GSF approach

The main difficulty in a GSF approach is related to the spectrum of radiation emitted. In fact, differently from the case of a particle orbiting a black hole moving along a circular trajectory for which the spectrum is peaked around the circular motion frequency, in the case of a hyperbolic orbits the spectrum is infinite (all frequencies are excited) and this complicates matters.

# Extended bodies in perturbed black hole spacetimes: the gravitational self-force approach

Andrea Geralico* and Donato Bini†

*Istituto per le Applicazioni del Calcolo "M. Picone," CNR, Rome, I-00185, Italy*

**E-mail: andrea.geralico@gmail.com*

*†E-mail: donato.bini@gmail.com*

We review the necessary framework to study self-force effects induced by an extended body endowed with internal structure up to the quadrupole moving in a Schwarzschild black hole spacetime. The motion is described according to the Mathisson-Papapetrou-Dixon model. The metric perturbations are computed by using the Regge-Wheeler gauge. We apply this formalism to the case of Detweiler's redshift invariant for spinning particles along circular equatorial orbits.

*Keywords*: Black hole perturbations; extended bodies; gravitational self-force.

## 1. Introduction

After the detection of the first gravitational wave signal emitted by a binary black hole system,[1] further improving our analytical modelling of the general relativistic two-body gravitational interaction has become mandatory. Many methods have been actively pursued over the years, including post-Newtonian (PN) theory,[2] gravitational self-force (GSF) theory[3] and the Effective-One-Body (EOB) formalism.[4–6] The synergy between all these approaches is currently successfully used to construct semi-analytical templates which are able to describe the complete waveform emitted by coalescing binary black holes.

GSF theory applies when the mass ratio of the two bodies is very small, so that the whole dynamics can be treated as a perturbation induced by the smaller body with mass $m_1$ on the background gravitational field of the bigger one with mass $m_2$. The goal is to compute gauge-invariant quantities, like redshift and spin precession invariants, which can be eventually converted into useful information for other approaches, e.g., the EOB model. Many analytical results have been obtained in the last few years for a particle moving along circular as well as slightly eccentric equatorial orbits around both non-rotating (Schwarzschild) and rotating (Kerr) black holes (see, e.g., Ref. 7 for a recent review). To first order in the mass ratio, the small body is considered as following a geodesic orbit in a suitably regularized perturbed spacetime. However, if the small body has a non-negligible internal structure (e.g., spin, quadrupole moment and higher multipoles) the orbit will be no longer geodesic, but accelerated due to the coupling between curvature and multipolar structure of the body as described by the Mathisson-Papapetrou-Dixon (MPD) model.[8–10] The first GSF computations have been recently performed in the case of redshift invariant and tidal invariants for spinning particles orbiting a Schwarzschild black hole, to linear order in spin.[11,12]

## 2. Motion of extended bodies in a given background spacetime

The MPD equations governing the motion of an extended body endowed with a quadrupole moment in a given gravitational background read

$$\begin{aligned}\frac{DP^\mu}{d\tau} &= -\frac{1}{2}R^\mu{}_{\nu\alpha\beta}U^\nu S^{\alpha\beta} - \frac{1}{6}J^{\alpha\beta\gamma\delta}\nabla^\mu R_{\alpha\beta\gamma\delta}\\ \frac{DS^{\mu\nu}}{d\tau} &= 2P^{[\mu}U^{\nu]} + \frac{4}{3}J^{\alpha\beta\gamma[\mu}R^{\nu]}{}_{\gamma\alpha\beta}\,,\end{aligned} \tag{1}$$

where $P = mu$, with $u \cdot u = -1$ and $||P||^2 = -m^2$, is the (timelike) generalized 4-momentum of the body with effective mass $m$ (which does not coincide with the bare mass $\mu$, but depends on its structure) and $U^\alpha = dx^\alpha/d\tau$ is the (timelike) unit tangent vector to the particle's world line, $\mathcal{C}$, used to make the multipole reduction. The two four vectors $U$ and $u$ are in general not aligned, and $P$ (i.e., $u$) has support only along $\mathcal{C}$. The (antisymmetric) spin tensor $S^{\mu\nu}$ (with support only along $\mathcal{C}$, like $P$) is assumed to satisfy the supplementary conditions

$$S^{\mu\nu}u_\nu = 0\,. \tag{2}$$

As standard, the spin vector (orthogonal to $u$) associated with the spin tensor is given by

$$S(u)^\alpha = \frac{1}{2}\eta(u)^{\alpha\beta\gamma}S_{\beta\gamma}\,, \qquad \eta(u)_{\alpha\beta\gamma} = u^\mu\eta_{\mu\alpha\beta\gamma}\,. \tag{3}$$

Its magnitude $s$ is such that

$$s^2 = S(u)\cdot S(u) = \frac{1}{2}S_{\mu\nu}S^{\mu\nu} = -\frac{1}{2}\mathrm{Tr}[S^2]\,, \qquad [S^2]^\alpha{}_\beta = S^{\alpha\mu}S_{\mu\beta}\,. \tag{4}$$

Finally, $J^{\alpha\beta\gamma\delta}$ is the quadrupole tensor of the particle, again with support only along $\mathcal{C}$. For instance, in the case of a spin-induced quadrupole tensor we have[13]

$$J^{\alpha\beta\gamma\delta} = 4u^{[\alpha}\tilde{\chi}(u)^{\beta][\gamma}u^{\delta]}\,, \qquad \tilde{\chi}(u) = \frac{3}{4}\frac{C_Q}{m}[S^2]^{\mathrm{STF}}\,, \tag{5}$$

where

$$[S^2]^{\mathrm{STF}\,\alpha\beta} = [S^2]^{\alpha\beta} - \frac{1}{3}P(u)^{\alpha\beta}\mathrm{Tr}[S^2] = [S(u)\otimes S(u)]^{\mathrm{TF}}\,, \tag{6}$$

$P(u) = g + u\otimes u$ projecting orthogonally to $u$, represents the symmetric-tracefree part (STF) of the spin tensor (or, equivalently, of the spin vector). The constant parameter $C_Q$ is equal to unity in the case of a black hole, whereas for neutron stars it depends on the equation of state.

When the background spacetime has Killing vectors, there are conserved quantities along the motion. For example, in the case of stationary axisymmetric spacetimes with coordinates adapted to the spacetime symmetries, $\xi = \partial_t$ is the timelike Killing vector and $\eta = \partial_\phi$ is the azimuthal Killing vector. The corresponding conserved quantities are the energy $E$ and the angular momentum $J$ of the particle,

namely

$$E = -\xi_\alpha P^\alpha + \frac{1}{2} S^{\alpha\beta} \nabla_\beta \xi_\alpha \,,$$
$$J = \eta_\alpha P^\alpha - \frac{1}{2} S^{\alpha\beta} \nabla_\beta \eta_\alpha \,. \tag{7}$$

Finally, the energy momentum tensor of a quadrupolar particle is given by

$$T^{\alpha\beta} = \int d\tau \frac{1}{\sqrt{-g}} \mathcal{T}^{\alpha\beta} \,, \tag{8}$$

where

$$\mathcal{T}^{\alpha\beta} = \left( U^{(\alpha} P^{\beta)} + \frac{1}{3} R_{\gamma\delta\epsilon}{}^{(\alpha} J^{\beta)\epsilon\delta\gamma} \right) \delta^4 - \nabla_\gamma \left( S^{\gamma(\alpha} U^{\beta)} \delta^4 \right)$$
$$- \frac{2}{3} \nabla_\delta \nabla_\gamma \left( J^{\delta(\alpha\beta)\gamma} \delta^4 \right) \,, \tag{9}$$

$\delta^4$ denoting the 4-dimensional delta function centered on the particle's worldline, i.e., $\delta^4 \equiv \delta^4(x^\alpha - x^\alpha(\tau))$.

## 3. GSF program

Let $g^{\rm R}_{\alpha\beta} = \bar{g}_{\alpha\beta} + q h^{\rm R}_{\alpha\beta}$ with $q = m_1/m_2 \ll 1$ be the regularized perturbed metric, where

$$\bar{g}_{\alpha\beta} dx^\alpha dx^\beta = -f dt^2 + f^{-1} dr^2 + r^2 (d\theta^2 + \sin^2\theta d\phi^2) \,, \tag{10}$$

with $f = 1 - 2m_2/r$, is the background Schwarzschild spacetime written in standard coordinates $(t, r, \theta, \phi)$, and $h^{\rm R}_{\alpha\beta}$ is the regularized metric perturbation due to the extended body. The main steps to analytically compute first-order metric perturbations in a Schwarzschild spacetime by using the Regge-Wheeler-Zerilli (RWZ) approach[14,15] are recalled below.

Decompose first both the perturbed metric $h_{\mu\nu}$ and the energy momentum tensor $T_{\mu\nu}$ associated with the perturbing body in tensor harmonics in the RW gauge. Einstein's field equations then lead to two different sets of equations for even-parity and odd parity quantities. Odd-parity waves satisfy the simple RW equation with odd-parity source terms; even-parity waves satisfy, instead, the more complicated Zerilli equation with even-parity source terms. However, the Zerilli equation can be mapped onto a RW equation with different source terms, so that one eventually has to solve a single RW equation, with appropriate (odd-parity or even-parity) source terms, i.e.,

$$\mathcal{L}^{(r)}_{\rm (RW)}[R^{\rm (even/odd)}_{lm\omega}] = S^{\rm (even/odd)}_{lm\omega}(r) \,. \tag{11}$$

Here $\mathcal{L}^{(r)}_{\rm (RW)}$ denotes the RW operator

$$\mathcal{L}^{(r)}_{\rm (RW)} = f(r)^2 \frac{d^2}{dr^2} + \frac{2m_2}{r^2} f(r) \frac{d}{dr} + [\omega^2 - V_{\rm (RW)}(r)]$$
$$= \frac{d^2}{dr_*^2} + [\omega^2 - V_{\rm (RW)}(r)] \,, \tag{12}$$

with $d/dr_* = f(r)d/dr$, and the RW potential

$$V_{(\mathrm{RW})}(r) = \frac{f(r)}{r^2}\left[l(l+1) - \frac{6m_2}{r}\right]. \tag{13}$$

The source terms are singular at the location $r = r_0(t)$ of the particle, namely

$$S^{(\mathrm{even/odd})}_{lm\omega}(r) = \sum_k s^{(\mathrm{even/odd})}_k(t)\delta^{(k)}(r - r_0(t))\,, \tag{14}$$

with $\delta^{(k)}(r - r_0(t))$ denoting the $kth$-order derivative of the Dirac delta function.

Next one needs the solutions to the homogeneous RW equation for $l \geq 2$, which are obtained by using different methods: PN approximation (generic $l$, weak-field and slow motion), Wentzel-Kramers-Brillouin (WKB) approximation (large $l$), Mano, Suzuki and Takasugi (MST) technique[16] (specified values of $l$). The solutions to the inhomogeneous RW equation are then computed through the Green's function method for both even and odd-parity source terms, i.e.,

$$R^{(\mathrm{even/odd})}_{lm\omega}(r) = \int dr' \,\frac{G(r,r')}{f(r')} S^{(\mathrm{even/odd})}_{lm\omega}(r')\,, \tag{15}$$

where the (retarded) Green's function

$$G(r,r') = \frac{1}{W}\Big[X^{\mathrm{in}}_{l\omega}(r)X^{\mathrm{up}}_{l\omega}(r')H(r'-r) + X^{\mathrm{in}}_{l\omega}(r')X^{\mathrm{up}}_{l\omega}(r)H(r-r')\Big]\,, \tag{16}$$

is expressed in terms of the two independent homogeneous solutions $X^{\mathrm{in}}_{l\omega}$ and $X^{\mathrm{up}}_{l\omega}$ of the RW operator. Here $W_{l\omega}$ denotes the (constant) Wronskian

$$W_{l\omega} = f(r)\left[X^{\mathrm{in}}_{l\omega}(r)\frac{dX^{\mathrm{up}}_{l\omega}(r)}{dr} - \frac{dX^{\mathrm{in}}_{l\omega}(r)}{dr}X^{\mathrm{up}}_{l\omega}(r)\right] = \mathrm{const.} \tag{17}$$

and $H(x)$ is the Heaviside step function.

Once the radial function is known for both parities, the perturbed metric components are then computed by Fourier anti-transforming. At this point one can construct the gauge-invariant quantity one is interested in, which still depends on the azimuthal number $m$ and the orbital angular momentum number $l$, and evaluate it at the source location, where the perturbed metric is singular. After multiplying by the angular part, the sum over $m \in [-l, l]$ is done by using spherical harmonic identities, whereas the sum over $l \in [0, \infty)$ requires a suitable regularization procedure to converge. The contribution of the non-radiative multipoles $l = 0, 1$ has to be evaluated separately. In fact, these are purely gauge modes which carry into the hole the energy $E$ and the angular momentum $J$ of the particle (which are both $O(q)$), leading to a linearized Kerr solution with total mass $m_2 + E$ and angular momentum $J$.

## 4. Detweiler's redshift invariant for spinning particles along circular orbits

Let us consider the simplest case of a spinning particle moving along a circular orbit on the equatorial plane with spin vector orthogonal to it. By neglecting higher multipoles the MPD equations imply that $P$ and $U$ are aligned to first order

in spin, the spin vector is parallel transported and both the particle's mass and the spin magnitude are constants of motion. It is convenient to introduce the spin parameter $\hat{s} \equiv s/(m_1 m_2)$ such that $|\hat{s}| \ll 1$.

Detweiler's redshift invariant is defined as the linear-in-mass-ratio change in the time component of the particle's 4-velocity. The latter is given by $U = u^t k$, where $k = \partial_t + \Omega \partial_\phi$ is assumed to be a Killing vector field of the perturbed metric. The normalization condition $U \cdot U = -1$ gives

$$-(u^t)^{-2} = k \cdot k = -f + \Omega^2 r^2 + h_{kk} \,, \tag{18}$$

where

$$h_{kk} = h_{\alpha\beta} k^\alpha k^\beta = h^{(0)}_{kk} + \hat{s} h^{\hat{s}}_{kk} \,. \tag{19}$$

The MPD equations of motion then imply the following solution for the angular velocity $\Omega$

$$m_2 \Omega = u^{3/2} \left[ 1 - \frac{3}{2} \hat{s} u^{3/2} + q(\tilde{\Omega}_1 + \hat{s} \tilde{\Omega}_{1\hat{s}}) \right] , \tag{20}$$

where

$$\tilde{\Omega}_1 = -\frac{m_2}{4u^2} \partial_r h^{(0)}_{kk} \,, \tag{21}$$

as well as the spin correction

$$\tilde{\Omega}_{1\hat{s}} = \tilde{\Omega}^{(h)}_{1\hat{s}} + \tilde{\Omega}^{(\partial h)}_{1\hat{s}} + \tilde{\Omega}^{(\partial^2 h)}_{1\hat{s}} \,, \tag{22}$$

both depend on the metric components $h_{\alpha\beta} = h^{(0)}_{\alpha\beta} + \hat{s} h^{(1)}_{\alpha\beta}$ and their derivatives evaluated at $r = m_2/u$ (see Eq. (2.15) in Ref. 12).

It is useful to introduce the dimensionless frequency parameter $y = (m_2 \Omega)^{2/3}$, which once substituted into Eq. (18) in place of both $\Omega$ and $u$ leads to the following definition of the Detweiler's inverse redshift invariant $z_1(y) = [u^t(y)]^{-1}$

$$\begin{aligned} z_1(y) &= \sqrt{1-3y} - \frac{q}{2\sqrt{1-3y}} \left[ h^{(0)}_{kk}(y) + \hat{s} \left( h^{\hat{s}}_{kk}(y) + m_2 y^{1/2} [\partial_r h^{(0)}_{kk}](y) \right) \right] \\ &\equiv z_1^{(0)}(y) + q \left[ z_1^{(1)\hat{s}^0}(y) + \hat{s} z_1^{(1)\hat{s}^1}(y) \right] . \end{aligned} \tag{23}$$

Therefore, in order to determine the spin dependent term $z_1^{(1)\hat{s}^1}(y)$ one needs two compute $h^{\hat{s}}_{kk}(y)$ and $[\partial_r h^{(0)}_{kk}](y)$ separately, following the procedure outlined in the previous section (all necessary details can be found in Ref. 11). The final result is

$$\begin{aligned} z_1^{(1)\hat{s}^1}(y) = {} & y^{7/2} - 3y^{9/2} - \frac{15}{2} y^{11/2} \\ & + \left( -\frac{6277}{30} + \frac{20471}{1024}\pi^2 - 16\gamma - \frac{496}{15}\ln(2) - 8\ln(y) \right) y^{13/2} \\ & + \left( \frac{653629}{2048}\pi^2 - \frac{87055}{28} - \frac{729}{14}\ln(3) + \frac{3772}{105}\ln(2) - \frac{52}{5}\gamma - \frac{26}{5}\ln(y) \right) y^{15/2} \\ & + O(y^8) \,, \end{aligned} \tag{24}$$

where only the first few terms have been shown, for simplicity.

This is the first GSF analytical computation of a gauge-invariant quantity which takes into account the internal structure of the perturbing body, simply given by its spin in this case. Tidal invariants in the same context has been studied in Ref. 12. These works can be further generalized by adding higher multipoles to the structure of the body (e.g., quadrupole moment), or by considering different orbits (e.g., eccentric), or even a rotating background field (Kerr black hole). In these more general cases the redshift variable should be properly modified in order to be a gauge-invariant quantity. This is still an open problem which requires further investigation.

# Field theory for gravity at all scales

Michele Levi

*Institut de Physique Théorique, CEA & CNRS, Université Paris-Saclay*
*91191 Gif-sur-Yvette, France*
*michele.levi@ipht.fr*

We review here the main advances made by using effective field theories (EFTs) in classical gravity, with notable focus on those unique to the EFTs of post-Newtonian (PN) gravity. We then proceed to overview the various prospects of using field theory to study the real-world gravitational wave (GW) data, as well as to ameliorate our fundamental understanding of gravity at all scales, by going from the EFTs of PN gravity to modern advances in scattering amplitudes, including computational techniques and intriguing duality relations between gauge and gravity theories.

*Keywords*: Effective field theories; Theories of gravity, Duality of gauge and gravity theories; Scattering amplitudes; High precision calculations; Gravitational waves.

## 1. Introduction

In recent years there has been a growing recognition in the all-encompassing relevance of the field theoretic framework beyond the quantum realm of particle physics, in which much of it has been conceived. Most notably, for long, in the absence of a viable quantum theory of gravity, the overlap between field theory and classical gravity has been largely deemed nonexistent. In particular, the conceptual framework of effective field theories (EFTs), which is intimately tied with the notion of renormalization, was widely regarded as uniquely ingrained in the domain of quantum field theories (QFTs). In order to dispel the latter fallacy, however, suffice it to acknowledge that 'renormalization' can in fact be taken as synonymous with 'resolution of physical scales'. Once this realization is made, it becomes clear that the framework of EFTs is evidently a universal one, and that it can be applied on any wide range of physical scales. Moreover, the EFT framework is a solid and powerful one, providing an inherent setup strategy and a robust toolbox, geared towards yielding high precision predictions to a desirable accuracy.

Indeed, just over a decade ago, an EFT approach to handle gravitational waves (GWs), emitted from inspiralling compact binaries, which are analytically treated with post-Newtonian (PN) gravity [1], was put forward by Goldberger et al. [2–4]. This novel approach has resulted, in turn, further applications of EFTs in classical gravity. Notably, significant progress was demonstrated in the application of EFTs to higher dimensional gravity in the context of large extra dimensions [5–9]. Further, also in the context of GWs, an investigation of an EFT treatment for the extreme mass ratio inspiral (EMRI) case of compact binaries, was initiated in Ref. 10. Moreover, within a decade the initial EFT approach to PN gravity has been able – in important sectors of the theory – to catch up and go beyond the spectacular state of the art [11], already accomplished within the traditional framework of General Relativity (GR).

In what follows we highlight the main meaningful unique advances made in the EFT approach to PN gravity, yet more importantly, we point to the main prospects on a broader scope of using field theory to study gravity, stretching from delivering highly demanding accurate predictions for real-world GW data, to confronting our fundamental grasp of QFTs and gravity theories at all scales.

## 2. From Gravitational Waves to Gravity at all Scales

Significant progress was made via the EFT approach to PN gravity, which is concerned with the analytical prediction of the inspiral portion of the GW signal. While this progress is evident and encouraging, it crucially serves to illustrate the great potential, still awaiting, in the use of field theory to study gravity, with many implications at various levels. First, there are clear anticipated developments still within the EFTs of PN gravity and the theoretical modeling of the GW signal. Further, even if still only in the context of GWs, modern advances in scattering amplitudes hold the promise to possibly enable an analytical treatment of the GW signal in its entirety, that is also in the strong field regime, beyond the inspiral phase. This may significantly improve upon the current phenomenological GW modeling, which relies heavily on the effective-one-body (EOB) formulation[12], by allowing for a smooth analytical model of the whole signal. Yet, more broadly, these advances from scattering amplitudes also importantly allow us to study gauge and gravity theories at a fundamental level, across the classical and quantum regimes.

Let us first review the main unique advancements accomplished within the EFTs of PN gravity so far. The most notable and extensive progress was realized in the treatment of the spinning sector, with several new higher order PN corrections. Next-to-leading order (NLO) effects in the conservative sector were first tackled in Refs. 13, 14, 15, following Refs. 16, 14, and further resolved and extended to the current state of the art, at the fourth PN (4PN) order for rapidly rotating compact objects, in Refs. 17, 18, 19, 20, 21, 22, 23, following Refs. 17, 24, 20, 18. Further, partial results at NLO in the radiative sector were presented in Ref. 25. Moreover, following Ref. 26, which also led to a new finite size correction of radiation reaction in classical electrodynamics[27], and Refs. 28, 29, a leading order effect of radiation reaction with spins was obtained in Ref. 30. All in all, beyond the specific new PN results obtained with spins, there has been an improvement in the understanding of classical spins in gravity.

Another remarkable finding in the field was the uncovering of classical renormalization group (RG) flows of the Wilson coefficients, which characterize the effective theories, both at the one-particle level[31], and at the level of the composite system, for the multipole moments of the binary[4,32]. These give rise to higher order PN logarithm corrections, which constitute unique predictions of the EFT framework. In addition, the 2PN order correction for a generic $n$-body problem was considered in Ref. 33, where automated computations were first advocated. Finally, the 'EFTofPNG' code for high precision Feynman calculations in PN gravity was

created[34], comprising the first comprehensive code in PN theory made public. The code consists of independent modules for easy adaptation and future development, where some prospects of building on this state of the art PN technology for various research purposes, were outlined in Ref. 35.

Within the methodology of the EFTs of PN gravity, there are several important directions, where development is required. The first is the solution of higher order PN equations of motion (EOMs) for accurate orbital dynamics. One interesting related way to find such closed form solutions, is the dynamical RG method, suggested in Ref. 36. Further, the treatment of non-conservative sectors with the EFTs of PN gravity has been rather limited, and so these various sectors should be tackled with a proper EFT formulation, and implementation for new PN results. Another objective to follow is the possible improvement or extension of the EFT formulation for spinning objects. For example, an alternative EFT formulation, which is ideally suited for the treatment of slowly rotating objects, based on a coset construction, was presented in Ref. 37. Further investigation is required in order to see whether these independent EFT formulations may possibly be integrated, and entail an even better understanding of classical spins in gravity. Next, we note the analysis of the mass- and spin-induced Wilson coefficients, and of the binary multipole coefficients, which also mostly remains to be approached via formal EFT matching. Finally, the continual public development of the 'EFTofPNG' code, or similar open codes, is required in order to keep up to date with the actual progress in PN theory. In that regard, it is important to note that classical theories of gravity, which modify GR in the IR, motivated by the cosmological constant problem and the dark matter puzzle[38–41], can be incorporated in a rather straightforward manner into the 'EFTofPNG' code, in order to study their analytical predictions for the GW signal from the compact binary inspiral, see, e.g., Refs. 42, 43, 44.

### 2.1. *Advances and prospects for gravity in field theory*

Ultimately, we would like to invoke the correspondence – at any level – between gauge and gravity theories, in order to push beyond the state of the art in high precision computation for concrete analytical predictions of the real-world GW signal, as well as to directly ameliorate our fundamental understanding of the foundations of these theories, in particular of gravity. These objectives can be considerably facilitated by turning to modern field theory advances in the domain of scattering amplitudes, see, e.g., Ref. 45. In fact, the field of EFTs in PN gravity, on which we have focused hitherto, and of scattering amplitudes, which are both directly concerned with baldly tackling demanding high precision computation driven by experiment, share more profound parallels beyond the obvious robust technical tools they entail, see, e.g., in Ref. 46. Both of these fields push to the exposure of the universal commonalities across classical and quantum field theories, and drive us to confront our fundamental grasp of the underlying foundations of these theories. One crucial difference to note, though, between these fields, is that where in

scattering amplitudes the computational outcome is directly related with the physical observables, the objects which are commonly computed in classical gravity are coordinate/gauge dependent quantities.

Let us then note, more specifically, some prospective avenues to deploy this broad correspondence of gauge theories and gravity. First, there is the standard working knowledge, which can be exchanged between the theories, e.g. multi-loop techniques in QFT, such as integration by parts (IBP), and high loop master integrals, along with other Feynman calculus and technology[34,35,46]. This was nicely demonstrated, e.g., in Refs. 47, 48, where an analytic evaluation of a four-loop master integral was provided for the first time from the classical gravity context. Furthermore, modern scattering amplitudes advances, such as the BCFW on-shell recursion relations[49], and generalized unitarity methods, which imply that tree level data encodes all multiplicity at the integrand level, were put forward to extract classical higher order loop results for gravitational scattering[50–53]. Such a scattering treatment may also enable to analytically tackle the strong field regime of the GW signal, and hence smoothly model analytically the entire signal, as we noted above.

Yet, of particular interest are the novel intriguing color-kinematics or BCJ duality relations, and the related double copy correspondence[54,55], see, e.g., review in Ref. 56, which were discovered in the context of high loop computations of amplitudes in supersymmetry and supergravity theories. Such relations were already known from string theory to hold at tree level, but formulated in terms of the novel generic double copy correspondence, these relations have been successfully used to study UV divergences of supergravity theories. This recent new perspective on gravity, viewing gravitons as double copies of gluons, suggests that even the simplest gauge theories and GR are in fact frameworks, which are intimately connected. Though this correspondence was uncovered in the perturbative context, it was also found, remarkably, that particular classical *exact* solutions in GR, are in fact double copies of exact "single copy" counterparts in corresponding gauge theories. Such classical solutions include all vacuum stationary solutions, most notably, Kerr black holes, as well as their higher dimensional generalizations, see Ref. 57 and references therein. Yet, the underlying origin of these perturbative relations, as well as their essential connection to the particular classical exact correspondence revealed, are yet to be uncovered.

In conjunction with the recent novel methods from scattering amplitudes, it is expected that this double copy correspondence can be used to advance the analytical calculations for the theoretical prediction of the GW signal, which may also help to shed more light on the nature and origin of this correspondence. Related with that end, an important time dependent case was studied in terms of the exact double copy of the Kerr-Schild form, of an arbitrarily accelerating point source[57]. In this case the radiation current is double copied to the radiation stress-energy tensor in Fourier space, and both are related to the corresponding scattering amplitudes, which can be obtained from the amputated currents. Hence, the work in Ref. 57

made a first explicit connection between the classical double copy in an exact form, to that in the perturbative scattering amplitudes context. At this point it should also be stressed, that from the scattering amplitudes context, it is already known that gluon amplitudes can double copy to arbitrary combinations of amplitudes for gravitons, and the additional unobserved dilaton and B fields, depending on the choice of the polarization states in the gauge theory amplitudes. This was indeed an ambiguous issue in Ref. 58, which built on Ref. 57, and that subsequently Ref. 59 set out to address, with Ref. 60 following up successfully at NLO.

Finally, we note the topic of soft graviton theorems for scattering amplitudes, which were recently demonstrated to be equivalent to gravitational memory effects, as part of a triple equivalence of the IR structure of gauge and gravity theories among soft theorems, asymptotic symmetry, and memory effects[61]. The latter may have observable signatures on the GW signal.

## Acknowledgments

I am grateful to John Joseph Carrasco for his meaningful encouragement. I would like to thank Donato Bini for the warm hospitality throughout the MG15 meeting, and in particular on the session, where this review was presented. It is also a delightful pleasure to acknowledge Roy Kerr who graced us with his inspiring presence. My work is supported by the European Research Council under the European Union's Horizon 2020 Framework Programme FP8/2014-2020 "preQFT" grant no. 639729, "Strategic Predictions for Quantum Field Theories" project.

We determine the binding energy, the total gravitational wave energy flux, and the gravitational wave modes for a binary of rapidly spinning black holes, working in linearized gravity and at leading orders in the orbital velocity, but to all orders in the black holes' spins. Though the spins are treated nonperturbatively, surprisingly, the binding energy and the flux are given by simple analytical expressions which are finite (respectively third- and fifth-order) polynomials in the spins. Our final results are restricted to the important case of quasi-circular orbits with the black holes' spins aligned with the orbital angular momentum.

*Keywords*: Binary black holes; Gravitational waves; Nonperturbative method; High precision calculations; Spinning point particles; Post-Newtonian approximation.

## 1. Introduction

The general relativistic two-body problem, in particular the description of compact binaries, as one of the most important sources of gravitational waves (GW) detectable from Earth, poses a large challenge for analytical as well as numerical calculations. Accurate waveform models are an essential ingredient for the detection of GW signals. The detections of such signals[1] have demonstrated the success of the approaches, but the need for more accurate and more general descriptions of binary dynamics in general relativity (GR) persists and will grow with future more sensitive GW detectors. Several (perturbative) analytic approaches to the two-body problem in GR have been developed. Among others, the post-Newtonian (PN) expansion[2]. It is an analytic approach for arbitrary mass ratio compact binaries in the weak-field, slow-motion (characterized by $\epsilon_{\rm PN} \sim v^2/c^2 \sim Gm/rc^2$) and small spin regime (determined by the expansion parameter $\epsilon_{\rm spin} \sim Gm\chi/rc^2$)[a]. Analytic results from the PN approximation, together with numerical descriptions of the late inspiral, plunge, and merger, can be combined synergetically in effective-one-body (EOB) models[3,4].

Previously, PN results for binary black holes (BBHs), in particular for the black holes' (BH) spins, were obtained order by order in the perturbative series, since for BBHs: $\epsilon_{\rm PN} \sim \epsilon_{\rm spin}$. This way, the conservative dynamics of spinning BBHs was computed up to 4PN order[5]; for the leading orders at various orders in spin see Refs. 6–13. For spin-dependent leading orders in the radiative sector, see Refs. 14–17.

[a] With $cS/Gm^2 = \chi \in [0, 1)$, the dimensionless spin parameter.

However, by treating both expansion parameters separately, we are able to derive compact analytic expressions for gauge-invariant quantities (GW energy flux, GW modes, conserved energy etc.) for a BBH at the leading PN orders to all orders in the BHs' spins – treating the spins nonperturbatively.

## 2. Effective action

In a harmonic-gauge framework, with a linearized metric perturbation $h_{\mu\nu} = g_{\mu\nu} - \eta_{\mu\nu} \sim \mathcal{O}(G)$, following the derivations in Refs. 19 and 20, we implement an effective action of a two point-particle system with a spin-induced multipole structure (for each particle) and respective multipole couplings to the gravitational field. In $G = c = 1$ units, this effective description is split into particle- and spin-kinetic terms $S_{\rm kin}[\mathbf{T}_A]$, interaction terms $S_{\rm int}[\mathbf{h}, \mathbf{T}_A]$ of the $A$th black hole and a term, $S_G[\mathbf{h}]$, containing the gravitational field's dynamics at linear order in $h_{\mu\nu}$, so that

$$S^{\rm BBH}_{\rm eff}[\mathbf{h}, \mathbf{T}_1, \mathbf{T}_2] = S_G[\mathbf{h}] + \{S_{\rm kin}[\mathbf{T}_1] + S_{\rm int}[\mathbf{h}, \mathbf{T}_1] + (1 \leftrightarrow 2)\}.$$

The Wilson coefficients in Ref. 18 were set to unity through a matching procedure to Kerr spacetime, as outlined in Ref. 20. This way, all spin-induced multipoles of the black holes are coupling to the linear metric perturbation $h_{\mu\nu}$ by (still containing nonlinear velocity contributions) [18,19]

$$S_{\rm int}[\mathbf{h}, \mathbf{T}_A] = \int dt \left\{ \sum_{\ell=0}^{\infty} \frac{m U^\mu_A U^\nu_A}{2\gamma_A\, \ell!} {\rm Re}\left[ i^\ell a^L_A \partial_L h_{\mu\nu} + i^{\ell-1} a^\rho_A \epsilon_{\nu\rho}{}^{\alpha\beta} a^{L-1}_A \partial_\alpha \partial_{L-1} h_{\beta\mu} \right] \right\},$$

where $a^\mu_A$ is the spin 4-vector, $U^\mu_A$ the velocity 4-vector (parameterized by coordinate time $t$) and $\gamma_A$ the Lorentz factor of the $A$th BH respectively. $\mathbf{h}$ encompasses the gravitational degrees of freedom and $\mathbf{T}$ encodes the multipolar degrees of freedom of the individual black holes. Note, we used the multi-index notation $L := \mu_1 \dots \mu_\ell$. This interaction term arises from considering all possible combinations of the vacuum Riemann tensor, multipole moments and particle's velocities at linear order in the metric perturbation, under the restriction of reparameterization invariance [18].

## 3. Conservative dynamics

From the above action principle, the linearized field equations in the near zone of the binary can be deduced (to linear order the velocities) and solved to all orders in spin. A Fokker-type action with Lagrangian (including all spin-spin couplings in this linearized framework with up to linear velocity contributions)

$$\begin{aligned} \mathcal{L} = &\left[ - m_1 + \frac{m_1}{2} v_1^2 + \frac{1}{2} \boldsymbol{S}_1 (\boldsymbol{v}_1 \times \dot{\boldsymbol{v}}_1) + \boldsymbol{S}_1 \cdot \boldsymbol{\Omega}_1 + (1 \leftrightarrow 2) \right] \\ &+ m_1 m_2 \sum_{\ell=0}^{\infty} \frac{(-1)^\ell}{(2\ell)!} \left[ a_0^{2L} + \frac{2 v^i a_0^j \epsilon_{ij}{}^k a_0^{2L}}{(2\ell+1)} \frac{\partial}{\partial r^k} \right] \frac{\partial r^{-1}}{\partial r^{2L}} \end{aligned} \tag{1}$$

in the center-of-mass frame, is obtained. We introduced the BHs' masses $m_A$, 3-velocities $\boldsymbol{v}_A(t)$, spin 3-vectors $\boldsymbol{a}_A = \boldsymbol{S}_A/m_A$ and combination $\boldsymbol{a}_0 = \boldsymbol{a}_1 + \boldsymbol{a}_2$, as

well as the BHs' separation vector $\boldsymbol{r}$ with $r = |\boldsymbol{r}|$ and the angular velocity vector $\boldsymbol{\Omega}_A$. The equations of motion for the BBH, in a quasi-circular limit and for spin vectors aligned with the orbital angular momentum of the system, can be resummed and solved for the angular frequency $\omega$ of the orbits in compact fashion. To linear order in the metric perturbation $h_{\mu\nu}$ and velocities $\boldsymbol{v}$ (i.e., at leading PN order), but to all orders in the spins $\boldsymbol{a}_A$, the angular frequency is given by $\ddot{\boldsymbol{r}} = -\omega^2 \boldsymbol{r}$, with $\omega^2 = M/r[r - v(2a_0 + \sigma^*)](r^2 - a_0^2)^{-3/2}$. Here we defined $M = m_1 + m_2$ and $\sigma^* = |\boldsymbol{\sigma}^*| = |m_2\boldsymbol{a}_1 + m_1\boldsymbol{a}_2|/M$.

Gauge-invariant quantities (e.g., Noether charges or the GW modes) are conveniently expanded in the commonly used expansion parameter $x = (M\omega)^{2/3}$, such that $\epsilon_{\rm PN} \sim x$ and $\epsilon_{\rm spin} \sim x\chi$. In the following $\chi$ serves as book keeping parameter for the order in spin considered (e.g., $a_A \sim \mathcal{O}(\chi)$, $a_A^2 \sim \mathcal{O}(\chi^2)$, ...). At each order in $\chi$, we consider the lowest order in $x$, i.e., the leading PN order at each order in spin. Notice that this is different from the traditional PN order counting in $1/c^2$ (since we treated $\epsilon_{\rm spin}$ and $\epsilon_{\rm PN}$ as independent).

The conserved energy and total angular momentum of the two-body system can be obtained as the associated Noether charges of (1). Recasting the angular frequency $\omega$ in $x$ yields, together with the respective Noether charges as functions of $r$, the binding energy $E(x)$ and total angular momentum $J(x) = L(x) + m_1 a_1 + m_2 a_2$ perpendicular to the orbital plane of the BBH at the leading PN orders at all orders in spin

$$E(x) = -\frac{\mu x}{2}\Big\{1 + \frac{x^{3/2}}{3M}(7a_0 + \delta a_-) - \frac{x^2 a_0^2}{M^2} - \frac{x^{7/2} a_0^2}{M^3}(a_0 - \delta a_-)\Big\}, \text{ and}$$
$$L(x) = \mu x^{-1/2}\Big\{M - \frac{5}{12}x^{3/2}(7a_0 + \delta a_-) + \frac{x^2 a_0^2}{M} + \frac{3x^{7/2}}{4M^2}a_0^2(a_0 - \delta a_-)\Big\}.$$

Where the symmetric mass ratio $\nu = \mu/M$, the antisymmetric mass ratio $\delta = (m_1 - m_2)/M$, and $a_-$ being the projection of $\boldsymbol{a}_- = \boldsymbol{a}_1 - \boldsymbol{a}_2$ orthogonal to the orbital plane.

Remarkably, the spin-expansions of the binding energy $E$ and orbital angular momentum $L$ terminate after cubic-in-spin contributions. Note that this polynomial structure in spin hinges on the use of $x$ (or $\omega$) as the variable in the conserved quantities.

## 4. Radiative sector

The far zone dynamics, i.e., the gravitational effects at future null infinity, are related with the near zone dynamics through a matching of the PN solution obtained above and the far zone post-Minkowskian expansion[2]. The matching procedure yields a relation between the source multipole moments and the emitted GW modes and total GW energy flux at future null infinity. The GW polarization waveform $h_+ - ih_\times = \sum_{\ell,m} {}_{-2}Y_{\ell m} h_{\ell m}$ is projected onto a basis of spin weighted spherical harmonics ${}_{-s}Y_{\ell m}$. The GW modes $h_{\ell m}$ are explicitly given in eq. (84) of

Ref. 20. The spin expansion of the even-$m$ modes terminates at a finite order. The odd-$m$ modes have contributions at all orders in spin, though they, are resumed in a compact form, i.e., terms like $\sqrt{M^2+x^2a_0^2}$ appear. Expanding these term, $\sqrt{M^2+x^2a_0^2} = M + x^2a_0^2/(2M) - x^4a_0^4/(8M^3) + \mathcal{O}(x^6\chi^6)$, yields the contributions at the leading PN order at each order in spin.

In an adiabatic approximation, at the leading PN orders at each order in the BHs' spin, we find the total GW energy flux

$$\mathcal{F} = \frac{\mu^2 x^5}{M^2}\Bigg[\frac{32}{5} - \frac{8x^{3/2}}{5M}\Big\{8a_0 + 3\delta a_-\Big\} + \frac{2x^2}{5M^2}\Big\{32a_0^2 + a_-^2\Big\} - \frac{4x^{7/2}}{15M^3}\Big\{16a_0^3 + 2a_0a_-^2 + 52\delta a_0^2a_- + \delta a_-^3\Big\} + \frac{2x^4a_0^2}{5M^4}\Big\{16a_0^2 + a_-^2\Big\} + \frac{2a_0^2x^{11/2}}{15M^5}\Big\{64a_0^3 + a_0a_-^2 - 68\delta a_0^2a_- - 3\delta a_-^3\Big\}\Bigg].$$

Again, the infinite sets of spin-induced multipolar interactions of the two BHs remarkably cancel out at higher than quintic-in-spin contributions. Hence, the total energy flux conveys full information about the spin effects at leading PN order in the first five terms of the spin expansion.

## 5. Conclusion

We determined the binding energy, the gravitational wave modes and total energy flux emitted by a spinning nonprecessing binary black hole in quasi-circular motion at leading post-Newtonian orders at all orders in spin. Our results include contributions of arbitrarily large PN order, counting in $1/c^2$. In particular, we obtained for the first time the quartic-in-spin contributions to the 4PN waveform and total energy flux, along with all higher-order-in-spin contributions at the corresponding leading PN orders. Remarkably, the binding energy, the total energy flux, as well as the even-in-$m$ gravitational wave modes only contain a finite number of nonzero contributions in their spin expansions at leading post-Newtonian order.

Conversely, the modes where all powers in spin appear are nevertheless rather compact, which can be used to improve the resummation of modes, e.g., in the synergetic EOB waveform model[21]. Though our results are only valid for aligned spins, they can still be used to approximate waveforms from precessing binaries[22].

# Quantitative analysis of the inflationary model: reheating process

Massimo Carinci[1a] and Giovanni Montani[1b]

[1] *Department of Physics, La Sapienza, Rome, Italy*
[a] *massimo.carinci@uniroma1.it;* [b] *giovanni.montani@enea.it*

There are various models that were proposed as scalar fields for inflation, some of these with an 'attractor solutions' to which the system evolves. For each of these models, we have a different evolution of the energy density for relativistic matter and dark matter, which were created during the reheating period, at the end of inflation in the early Universe, as a result of the 'inflaton' decay. Furthermore, the temperature at which the reheating takes place also depends on the type of scalar field. In this work, we consider the polynomial scalar field (chaotic inflation) of the sixth degree, and we study it with numerical methods varying the 'free parameters' a, b, c, obtaining the attractor behavior in particular conditions. Finally, we calculate the reheating temperature, establishing, for this case, that we are in the regime of *good reheating*.

## 1. Scalar Field Dynamics

During inflation, the Universe is dominated by a scalar field '$\varphi$', the **inflaton**, which causes the accelerated expansion. The field behavior is given by the potential $V(\phi)$. The field 'rolls' along the potential (the so-called **slow-roll inflation**, see Figure 1 on the right) and stops in the minimum, after that inflation ends.

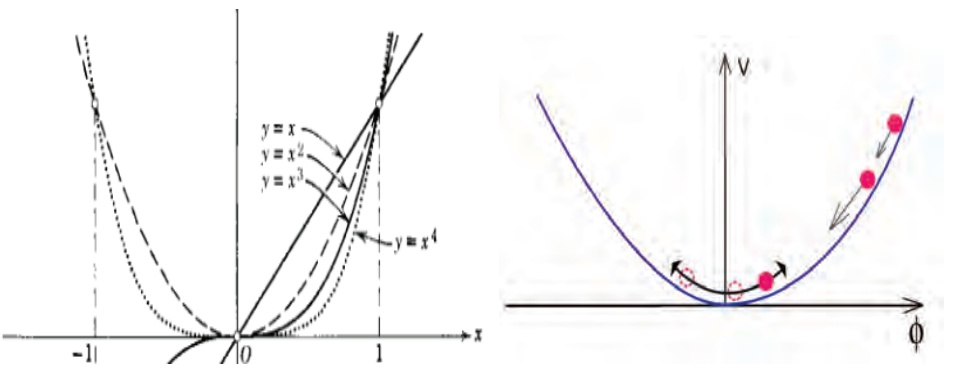

Fig. 1. On the left, form of the chaotic potential varying the exponent of the power scalar field $\alpha$. On the right, the quadratic potential: the circles show the inflaton field at various stages of its evolution. When the circle reaches the minimum, the inflation ends. So the circle starts to oscillate around the minimum and the reheating phase begins.

The simplest potentials which describe the inflation are (see Figure 1 on the left):

$$V = a \times \phi^{\alpha} \quad a = \text{const}, \quad \alpha = 2, 4, 6$$

This kind of potential, proposed by Linde, is said '*chaotic inflation*'. It is symmetric and has a minimum for $\phi = 0$, where $V = 0$.

Fixed $\alpha$, the coefficient a can be calculated with the following formula[3]:

$$\frac{g}{M_{Pl}^{4-n}} = \frac{3}{8\pi}\left(\frac{n}{4}\right)^2 \cdot \left(\frac{4\pi}{nN_e}\right)^{(n+2)/2} \cdot \Delta_{\mathcal{R}}^2.$$

where $M_{pl}$ is the Planck mass, $\Delta_{\Re}$ is the amplitude of the scalar perturbation, whose value is $5 \times 10^{-5}$ and $\mathrm{N}_e$ is the e-folding number. So, assuming $\mathrm{N}_e = 60$, we obtain:

| | |
|---|---|
| ✓ $a \leq 10^{-13}$ | *if* $\alpha = 4$; |
| ✓ $a \leq 10^{-15} M_{pl}^{-2}$ | *if* $\alpha = 6$. |

## 2. Attractor Solution

In the phase space, these potentials have attractor solution to which its solutions must converge over time (see Figure 2 on the left, for the quadratic potential). If we consider a potential with all the three terms:

$$\boxed{\mathrm{V} = \mathrm{a} \times \varphi^2 + \mathrm{b} \times \varphi^4 + \mathrm{c} \times \varphi^6} \tag{1}$$

When $\mathrm{a} > \mathrm{b}, \mathrm{c}$ we have no changes (Figure 2 on the right, in red). But if b and/or c is of the same order of a, we have a pick (in blue). In fact, in this case the potential is less inclined (Figure 1, left), and the solution, at first, converges more slowly.

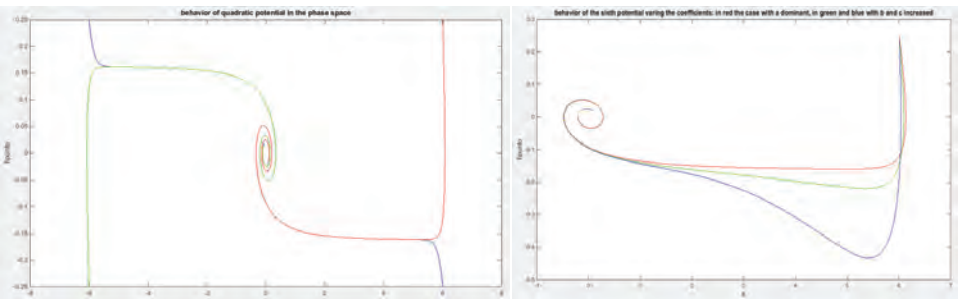

Fig. 2. Phase portrait in the $(\varphi, \dot{\varphi})$-plane of the dynamics of a scalar field for a quadratic potential (left) and for a sixth grade potential (right). For the last case, we plot the solutions for different values of the coefficients. It's clearly visible the pick, putting appropriate coefficients. This illustrates the mechanism of attraction toward the slow-roll solution.

## 3. Reheating Phase

During inflation, all the energy density is concentrated in the scalar field. This energy density can be used to be transformed in other form, for example radiation. This process of conversion is called **reheating**, while the temperature at which the process takes place is called **reheating temperature**. Let's see what happen during this process. Just before of the end of inflation the Universe is cold and

hibernated in a state of low entropy: in fact, $T(t) \sim a^{-1}(t)$, where $T(t)$ is the temperature as a function of the time. The scalar field starts to move quickly along the Hubble time-scale, and starts to oscillate around the minimum of the potential (see Figure 1 on the right). During this process, the inflaton can decay, producing light energetic particles. So, the interaction of the inflaton provides a *probability decay* $\Gamma$. This phase end when all the energy is in thermal equilibrium with the radiation.

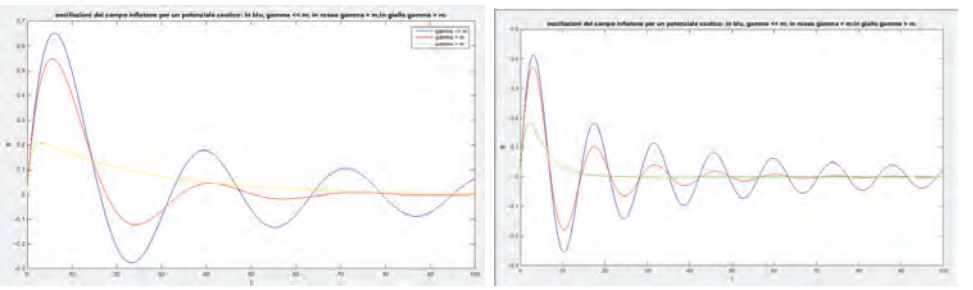

Fig. 3. Oscillations of the field f after inflation for quadratic potential (left) and for sixth grade potential (right) varying $\Gamma$. For the last case, we have a more oscillations because of the potential form.

The Figure 3 on the left shows the behavior of $\phi$ during reheating for quadratic potential. At the end of inflation $\Gamma$ is small, but later it increases, damping the oscillations. When $\Gamma \sim$ H, the reheating end. If $\Gamma <$ 3H, the reheating can't start, and we have a slow-roll phase. If we consider the sixth grade potential (eq. 1), we have the same behavior, but with a greater number of oscillations and a smaller amplitude (see Figure 3 on the right). This happens because of the potential form: it's less curved and wider in the minimum (Figure 1 on the left), so that the scalar field, having a less space, oscillates with greater frequency.

Now, we investigate the matter creation process during the reheating period. For this purpose, we consider the Universe as an open thermodynamics system, restricting our analysis to the case of a flat FRW metric. During the reheating, the constituents of the Universe are the inflationary scalar field, the ordinary matter, and the dark matter, assumed to be perfect fluid. So, the total energy density $\rho$ is:

$$\rho = \rho_\phi + \rho_{\mathrm{DM}} + \rho_{\mathrm{m}}$$

Let's see what are the equations which describe the reheating process. First of all, we have got to consider the dynamics of the scalar field and the matter. From the respective components of the *energy-momentum tensor* in a flat space-time, and applying them the energy conservation law, we have:

$$\dot{\phi}\ddot{\phi} = 3H\dot{\phi}^2 + V'(\phi)\dot{\phi} + \dot{\rho}_m + 3H(\rho_m + p_m) = 0.$$

In order to describe the transition process between the scalar field and the matter component, we introduce the friction term $\Gamma$, so we can decompose the previous equation in two equations:

$$\ddot{\phi} = 3H\dot{\phi} + V'(\phi) + \Gamma\dot{\phi} = 0 \quad \dot{\rho}_m + 3H(\rho_m + p_m) - \Gamma\dot{\phi}^2 = 0. \tag{2}$$

For the dark matter, we can consider a similar equation. Moreover, we need to consider the *balance equation of the particle flux vector* in the FRW geometry:

$$\Psi_m = \dot{n}_m + 3Hn_m$$

We assume that the function $\Psi$ is proportional to the energy density of the inflationary scalar field $\rho_\varphi$, and introducing the friction term $\Gamma$, we get:

$$\dot{n}_{\mathrm{m}} + 3Hn_{\mathrm{m}} = \frac{\Gamma_{\mathrm{m}}}{m_{\mathrm{m}}}\rho_\phi \tag{3}$$

We also consider the *Einstein gravitational field equations* in a flat FRW Universe, which, with inflationary scalar field, ordinary matter and dark matter fluids, becomes:

$$3H^2 = \frac{1}{m_{Pl}^2}(\rho_\phi + \rho_{\mathrm{DM}} + \rho_{\mathrm{m}}) \tag{4}$$

The particle creation is essentially determined by the energy density $\rho_\varphi$ and pressure $p_\varphi$ of the scalar field $\varphi$.

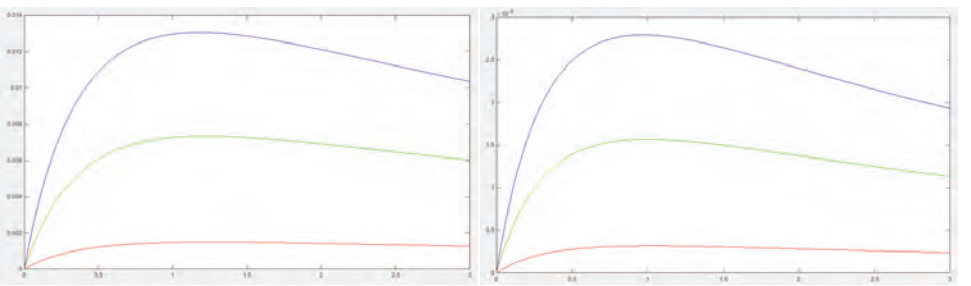

Fig. 4. Time variation of the dark matter energy density (left) and of the radiation (right) during the reheating period in the presence of a quadratic potential, varying the rate decay $\Gamma$.

The equations (2), (3) and (4) form a system of differential equations, which can be solved numerically. The Figure 4 shows the behavior of dark matter (on the left) and ordinary matter (on the right) for different values of $\Gamma$, while the scalar field decreases to zero. In fact, matter is created at the expense of the field. As we can see, it's possible to distinguish two phases: in the first, the matter energy density increases from zero to a maximum value; in the second, the matter energy density begins to decrease because of the expansion of the Universe, which becomes the dominant force. On the other hand, the energy density of the scalar field decreases

during the reheating phase, and tend to zero in the large time limit. During this phase, the Universe continues to accelerate because of the negative creation pressure, which induces an additional acceleration.

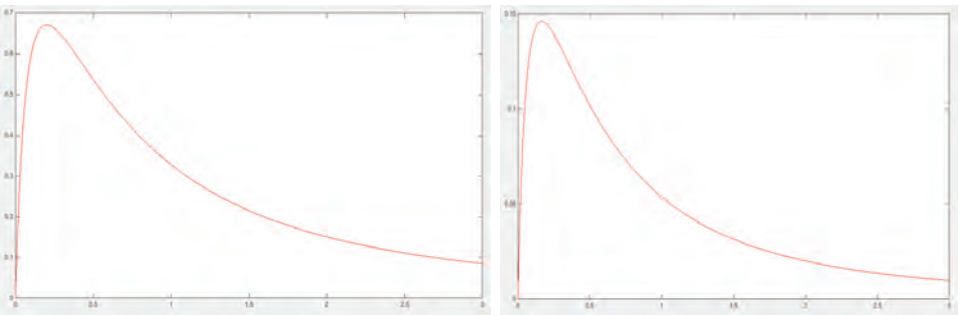

Fig. 5. The same as Figure 4, but with a sixth grade potential, with fixed Γ.

On the other hand, considering the sixth grade potential (see Figure 5, left and right), we observe a pick at the beginning of reheating and, after that, the density rapidly decreases. Also in this case, we can attribute this behavior to the potential form: there is a large particles production when reheating starts, but after the scalar field decays.

Finally, we must calculate the reheating temperature. At the end of inflation, $T_{reh}$ must have an upper limit because of the Hubble parameter, which decreases in time:

$$\frac{T_{max}}{M_{pl}} < \left(\frac{90}{8\pi^3 g_*}\right)^{1/4} \left(\frac{H_e}{M_{pl}}\right)^{1/2}$$

where $g$ is the number of the degrees of freedom (its value is ∼100). In fact, at the end of inflation, the slow-roll parameter $\varepsilon \sim 1$, from which we can estimate $H_e$ for different potentials $V(\varphi_e)$. Then, we obtain*:

| | |
|---|---|
| ✓ $T_{reh} \leq 2 \times 10^{15}$ GeV | *if* $\alpha = 2$, |
| ✓ $T_{reh} \leq 10^{15}$ GeV | *if* $\alpha = 4$, |
| ✓ $T_{reh} \leq 8 \times 10^{14}$ GeV | *if* $\alpha = 6$ |

So, the model of potential that warms the Universe better, when the reheating phase begins, is the quadratic potential. For comparison, the maximum temperature, independent from the kind of potential considered, is: $T_{max} \leq 10^{16}$ GeV.

*In this proceeding, we not consider the self-coupling of the inflaton. In the case of weakly-coupled inflaton, the Temperature is lower: $T_{reh} \leq 10^{12}$ GeV.

## 4. Conclusion

Summarizing, during the reheating phase the production of particles takes place, due to the decay of the inflationary scalar field. We got a plot describing the evolution of the matter in the time for the sixth grade potential using the Einstein equations and the components of the energy-momentum tensor, and we compared it with the case of the quadratic potential. So, we can say that a different function of the scalar field have some consequences on the inflation theory. The next goal is to understand what is the best potential for inflation. I mean, is the quadratic potential a good approximation to understood inflation (and the other terms of higher order are only little corrections)? Or do we need to add other terms yet? In fact, we can see the sixth grade potential as a *Taylor expansion of the hyperbolic cosine*.

# Black holes with synchronised hair: connecting Kerr black holes with Bose Einstein condensates

Carlos A. R. Herdeiro*

*Centro de Astrofísica e Gravitação - CENTRA,*
*Departamento de Física, Instituto Superior Técnico - IST, Universidade de Lisboa - UL,*
*Avenida Rovisco Pais 1, 1049-001 Lisboa, Portugal*
** E-mail: carlosherdeiro@tecnico.ulisboa.pt*

I provide a brief summary of the work done on asymptotically flat black holes with synchronised hair. These black holes form families of solutions that interpolates between vacuum Kerr black holes and Bose-Einstein condensates of massive bosonic fields.

*Keywords*: Black holes, fundamental fields.

## 1. Testing the Kerr hypothesis

The *Kerr hypothesis* is the conjecture that astrophysical black holes, when near equilibrium, are approximately described by the Kerr metric.[1] This hypothesis is motivated by the electro-vacuum uniqueness theorems,[2] but it is a conjecture when considering arbitrary sorts of matter or fundamental fields.[3]

Testing, theoretically, the Kerr hypothesis amounts to keep some healthy skepticism about this idea, which, albeit not in tension with any observation at present,[4] is far from proved in any rigorous theoretical or observational sense. In particular one may ask: 1) are all astrophysical black holes in equilibrium *exactly* represented by the Kerr metric? or 2) Are *all* these black hole of the same type? or, allowing for an even more dramatic possibility, 3) Are all these astrophysical black hole *candidates* really black holes?

## 2. Good models

The Kerr solution is not just the unique theoretical vacuum black hole model; it is a *good* model. One may postulate some broad theoretical criteria for a good theoretical model of a compact object: 1) It should appear in a well motivated and consistent physical model (at least as an effective field theory); 2) It should have a dynamical formation mechanism; 3) It should be *sufficiently* stable. Here the key word is "sufficiently". Indeed absolute stability is not mandatory for physical relevance, that always hinges on a competition of timescales for any putative instability as compared to other relevant astrophysical processes. As an extreme example, an astrophysical object that has a slowly growing instability, with an e-folding time comparable to the Hubble time, is, for all astrophysical processes, effectively stable.[5] For Kerr, 1) is General Relativity (GR), 2) is gravitational collapse and 3) has been established at the level of mode stability.[6]

To match observations, moreover, the good model must give rise to the right phenomenology, including all electromagnetic observables (X-ray spectrum, shadows, QPOs, star orbits, *etc*), for which, however, current data is not particularly

constraining and the need for astrophysical modelling often yields degeneracies that prevent significant constraints. In this respect the gravitational wave channel, being more pristine, is also more promising. But at the moment we can only expect data for events with a limited range of black hole masses (say, between 1-100 solar masses). LISA will, of course, improve this prospect.

As mentioned above, there is no clear tension between the Kerr model and current observations. Still, given the precision and spread of observations will increase in the next decades, it is certainly worth asking if there are other theoretically sound models that have different "good" black holes, and how different is their phenomenology.

## 3. No-hair theorems

There are two meanings for "black hole no-hair theorems" in the literature. Firstly, the uniqueness theorems[2] are often called no-hair theorems. This falls under the rationale that the uniqueness theorems show electro-vacuum, physical, single black hole spacetimes have essentially no structure/no multipolar freedom/no hair. Despite the fact that Kerr black holes have a non-trivial multipolar structure,[7] this structure is completely determined by the mass and angular momentum, the two only macroscopic degrees of freedom they are allowed to have. Secondly, in models *beyond* electrovacumm (*i.e.* with more general matter content and/or modified gravitational field equations) one can establish (typically partial) results on the inexistence of new black hole solutions with other degrees of freedom rather than those associated to Gauss laws, and hence gauge symmetries, such as total mass, angular momentum (and electric-type charges). Many such no-hair theorems, in models with scalar fields for instance, have been established.[8] The scalar field case is particularly appealing as a test ground, since scalar fields are technically simple and are well motivated in models beyond the standard model of particle physics (string theory, supersymmetry, multi-Higgs, Kaluza-Klein, *etc*). But many examples of "hairy" black holes have also been found, even in models where no-hair theorems exist, by circumventing one or more of the assumptions. Typically these models violate either explicitly or effectively energy conditions. A different type of mechanism that has been found to allow for black hole hair is the *synchronisation mechanism*.

## 4. The synchronisation mechanism

In 2014, a new type of asymptotically flat, black hole spacetimes with a new macroscopic degree of freedom was constructed.[9] The model was Einstein's gravity minimally coupled to a massive complex scalar field. The scalar field has an associated global charge, a Noether charge, but since the scalar field is not gauged, this charge does not have an associated Gauss law. Thus, it provides the black hole with *hair*. Physically, if the scalar field falls into the black hole, this charge vanishes (unlike,

say, electric charge, due to the Gauss law). Thus, the scalar field needs to be in a non-linear equilibrium with the black hole, for this Noether charge to be non-trivial.

This example of hairy black holes occurs in GR, not modified gravity. The matter obeys all relevant energy conditions. The black holes are asymptotically flat, regular on and outside an event horizon, they continuously connect to the Kerr solution, to which they reduce in the limit where the scalar field vanishes. They also connect continuously to relativistic Bose-Einstein condensates called boson stars,[10] to which they reduce in the limite where the horizon size is reduced to zero. They have an independent scalar charge which is primary hair.[8] They can form dynamically and be sufficiently long lived (see below). Although these solutions have been constructed numerically, an existence proof has been provided.[11] Moreover, more than an example, these solutions provide a mechanisms for endowing black holes with hair. Generalisations with self interacting scalar hair,[12] with Proca hair,[13] Kerr-Newman black holes with synchronised hair,[14] higher dimensional Myers-Perry black holes with this sort of synchronised hair,[15,16] also in AdS,[17] excited states[18] and generalisations with higher azimuthal winding numbers[19] are just some of the examples considered so far.

## 5. The synchronisation mechanism: physics rationale

The physical understanding for the existence of Kerr black holes in equilibrium with a stationary scalar field configuration can be obtained by a linear analysis. One considers the massive Klein-Gordon equation in the background of a Kerr black hole. Separation of variables can be achieved in Boyer-Lindquist coordinates $(t, r, \theta, \phi)$[20], by taking a scalar field ansatz of the sort

$$\Phi = f(r, \theta) e^{-i(\omega t + m\phi)} \ , \tag{1}$$

where $\omega$ is the frequency of the mode and $m$ its azimuthal winding number, and one ends up with solving a radial equation which can be cast in a Schrödinger-like form. Unlike the Hydrogen atom problem of elementary quantum mechanics, however, the generic problem in the Kerr black hole does not admit bound states solutions with a real frequency $\omega$. This is because the boundary condition at the event horizon (a purely ingoing wave) makes the Hamiltonian non-hermitian. In this generic case, only *quasi*-bound states are possible, with a complex frequency, wherein the imaginary part, $\mathcal{I}(\omega)$ is determining the decay (for $\mathcal{I}(\omega) < 0$) or growth rate (for $\mathcal{I}(\omega) > 0$) of the mode. But for the special case in which the black hole's horizon angular velocity $\Omega_H$ is synchronous with the phase angular velocity of the mode $\omega/m$, that is

$$\omega = m\Omega_H, \tag{2}$$

which is the *synchronisation condition*, $\mathcal{I}(\omega) = 0$ and true bound states, in the sense of quantum mechanics, exist. These are stationary clouds around Kerr black holes. It was S. Hod who first considered these clouds by specialising to the extremal

Kerr background,[21] in which case the radial equation becomes *precisely* the same confluent hypergeometric equation that arises in the case of the Hydrogen atom (without spin) in the Coulomb potential. This yields a beautiful and perfect analogy between atomic orbitals and stationary scalar clouds around Kerr black holes. For the non-extremal case the qualitative analogy remains.[9,22–25]

For $\omega > m\Omega_H$, $\mathcal{I}(\omega) < 0$; this is the decaying regime (the only one which is present in the Schwarzschild case). For $\omega < m\Omega_H$, $\mathcal{I}(\omega) > 0$; this is the growing or *superradiant regime*, in which the mode extracts rotational energy from the Kerr black hole.[26] Thus the stationary clouds exist as zero modes of the superradiant instability of Kerr black holes. Kerr black holes with scalar hair can be seen as the non-linear continuation of these scalar clouds, when they are made heavy and backreact.

How to construct such heavy scalar clouds in a rotating black hole background? It turns out that self-gravitating scalar field configurations of a scalar of the type (1) were already known in the literature: *boson stars*. So, these hairy black holes can be seen as a rotating boson star in non-linear equilibrium with a central black hole horizon.[27]

Let us remark on how the existence of these black holes with synchronised hair is compatible with well known no-scalar hair theorems. Symmetry non-inheritance between the matter field and the geometry allows them to circumvent the powerful Bekenstein's theorem[28] and rotation allows them to circumvent the Peña-Sudarksy theorem[29] that applies to spherical symmetry non-inheriting solutions.

## 6. Black holes with synchronised hair: phenomenological features

Since Kerr black holes with synchronised hair interpolate between the vacuum Kerr solution and boson stars, their phenomenology will be Kerr-like in the vicinity of the Kerr limit, and Kerr-unlike in the vicinity of the boson star limit. This is what has been observed, for instance, at the level of their shadows,[30,31] K$\alpha$-line in the $X$-ray spectrum,[32] star orbits and their possible relation to observable quasi-periodic-oscillations[33], or the morphology of accretion disks around them.[34] Consequently, current observations that are compatible with the Kerr model, can only rule out regions in the parameter space wherein deviations are large, but not regions in the parameter space where deviations are small, sufficiently close to the Kerr limit.

## 7. Black holes with synchronised hair: dynamical issues

It has been known since the 1970s[35–37] that in the presence of ultra-light massive bosonic fields, astrophysical Kerr black holes would be unstable against superradiance. The end point of this instability has been a lingering question. Recent numerical evidence suggests that the instability saturates when the synchronisation

condition is met,[38] and that the resulting solutions are Kerr black holes with synchronised hair.[39,40] As pointed out before these developments, these configurations could not be the end point of the instability, since they are themselves prone to superradiant instabilities.[41] Recent progress managed to compute the time scale of the superradiant instability of a sample of hairy black hole solutions, all of them very close to the Kerr limit.[42] These results motivated a bound for the timescale of the leading superradiant instability of Kerr black holes with synchronised hair.[5] For regions of the parameter space this timescale can be larger than the Hubble scale. Moreover, the instability becomes weaker as the hairiness of the black holes increase, when a proper analysis is performed.[5] The upshot is that these solutions could form dynamically from the superradiant instability of Kerr and be sufficiently long lived, at least as superradiance goes.

## 8. Open issues and further remarks

The three theoretical broad criteria given above for a good model of compact object are met by Kerr black holes with syncronised hair: 1) They appear in a well motivated and consistent physical model, which is GR minimally coupled to innocuous, albeit exotic, matter; 2) They have a dynamical formation mechanism (superradiance); 3) They can be sufficiently stable, with an instability timescale for the only known instability – superradiance – above the Hubble time.

Of course, it remains to understand what the ultralight scalar (or vector) field could be from the view point of fundamental particle physics. Here, the issue of fuzzy dark matter may provide an interesting connection.[43,44] Or if there are other more catastrophic instabilities. In any case, these models illustrate that there exist fairly reasonable theoretical possibilities (albeit with admittedly exotic physics) of alternative models to the Kerr paradigm. Their study is a high risk, high gain endeavour: producing detailed phenomenology will constrain the model and the corresponding exotic physics or, in the best case scenario, provide a smoking gun to this new physics. But above all, testing the Kerr hypothesis by looking for alternative models represents scientific open mindedness.

## Acknowledgments

I extremely grateful to all my co-authors in the works reported herein, first and foremost Eugen Radu. # Adiabatic perturbations are not always conserved: the case of global adiabaticity

Antonio Enea Romano

In the context of single-field inflation, the conservation of the curvature perturbation on comoving slices, $\mathcal{R}_c$, on super-horizon scales is one of the assumptions necessary to derive the consistency condition between the squeezed limit of the bispectrum and the spectrum of the primordial curvature perturbation. However, the conservation of $\mathcal{R}_c$ holds only after the perturbation has reached the adiabatic limit where the constant mode of $\mathcal{R}_c$ dominates over the other (usually decaying) mode. In this case, the non-adiabatic pressure perturbation defined in the thermodynamic sense, $\delta P_{nad} \equiv \delta P - c_w^2 \delta\rho$ where $c_w^2 = \dot{P}/\dot{\rho}$, usually becomes also negligible on superhorizon scales. Therefore one might think that the adiabatic limit is the same as thermodynamic adiabaticity. This is in fact not true. In other words, thermodynamic adiabaticity is not a sufficient condition for the conservation of $\mathcal{R}_c$ on super-horizon scales. In this paper, we consider models that satisfy $\delta P_{nad} = 0$ on all scales, which we call global adiabaticity (GA), which is guaranteed if $c_w^2 = c_s^2$, where $c_s$ is the phase velocity of the propagation of the perturbation. A known example is the case of ultra-slow-roll(USR) inflation in which $c_w^2 = c_s^2 = 1$. In order to generalize USR we develop a method to find the Lagrangian of GA K-inflation models from the behavior of background quantities as functions of the scale factor. Applying this method we show that there indeed exists a wide class of GA models with $c_w^2 = c_s^2$, which allows $\mathcal{R}_c$ to grow on superhorizon scales, and hence violates the non-Gaussianity consistency condition.

## 1. Introduction

A period of accelerated expansion during the early stages of the evolution of the Universe, called inflation,[1–3] is able to account for several otherwise difficult to explain features of the observed Universe such as the high level of isotropy of the CMB[4] radiation and the small value of the curvature. Some of the simplest inflationary models are based on a single slowly-rolling scalar field, and they are in good agreement with observations. It is commonly assumed in slow-roll models that adiabaticity in the thermodynamic sense, $\delta P_{nad} \equiv \delta P - c_w^2 \delta\rho = 0$ where $c_w^2 = \dot{P}/\dot{\rho}$, implies the conservation of the curvature perturbation on uniform density slices $\zeta$, and hence the conservation of the curvature perturbation on comoving slices $\mathcal{R}_c$, on super-horizon scales.

In[5] it was shown that there can be important exceptions, i.e. in some cases thermodynamic adiabaticity does not necessarily imply the super-horizon conservation of $\mathcal{R}_c$ and $\zeta$, and that they can differ from each other. This can happen even for models in which $c_w^2 = c_s^2$. Here $c_s$ is the speed of propagation of the curvature perturbation. It turns out that it may be defined as $c_s^2 \equiv (\delta P/\delta\rho)_c$, where the suffix "c" means a quantity evaluated on comoving slices defined by $\delta T_0^i = 0$ (or equivalently slices on which the scalar field is homogeneous). An example is ultra-slow-roll

(USR) inflation , in which the flat potential $V(\phi) = V_0$ yields exact adiabaticity $\delta P_{nad} = 0$ on all scales. USR inflation could in principle last for 60 e-folds, but then it would be difficult to make it consistent with observation. Alternatively, one can study models in which a USR phase is followed by a conventional slow-roll phase , at which stage $\mathcal{R}_c$ becomes conserved. In USR inflation, both $\mathcal{R}_c$ and $\zeta$ exhibit super-horizon growth but their behavior is very different from each other. As it has been stressed in , the non-freezing of $\mathcal{R}_c$ has important phenomenological consequences. Since the freezing of $\mathcal{R}_c$ on superhorizon scales is a necessary ingredient for Maldacena's consistency relation to hold, models that do not conserve $\mathcal{R}_c$ can actually violate that consistency condition. We note as well that another consequence of superhorizon growth of $\mathcal{R}_c$ is that it should be evaluated at the end of inflation, instead of just after horizon crossing .

In this paper focusing on K-inflation, i.e., Einstein-scalar models with a general kinetic term, we explore in a general way other single field models which have $c_w^2 = c_s^2$, hence satisfy $\delta P_{nad} = 0$ on all scales which we call globally adiabatic (GA), but which may not conserve $\mathcal{R}_c$. We find a generalization of the USR model.

The method we adopt is based on establishing a general condition for the non-conservation of $\mathcal{R}_c$ in terms of the dependence of the background quantities, in particular the slow-roll parameter $\epsilon \equiv -\dot{H}/H^2$ and the sound velocity $c_s$, on the scale factor $a$.

We first derive the necessary condition for the comoving curvature perturbation $\mathcal{R}_c$ to grow on superhorizon scales. Next we determine $\rho(a)$ and $P(a)$ by solving the continuity equation. Then using the equivalence between barotropic fluids and $K$-inflationary models which satisfy the condition $c_w^2 = c_s^2$ , we determine the corresponding Lagrangian for the equivalent scalar field model. Using this method we obtain a new class of GA scalar field models which do not conserve $\mathcal{R}_c$.

Throughout the paper we denote the proper-time derivative by a dot ($\dot{} = d/dt$), the conformal-time derivative by a prime ($\prime = d/d\eta = a\, d/dt$) and the Hubble expansion rates in proper and conformal times by $H = \dot{a}/a$ and $\mathcal{H} = a'/a$, respectively. We also use the terminology "adiabaticity" for thermodynamic adiabaticity $\delta P_{nad} = 0$ throughout the paper.

## 2. Conservation of $\mathcal{R}_c$ and global adiabaticity

We set the perturbed metric as

$$ds^2 = a^2\Big[-(1+2A)d\eta^2 + 2\partial_j B dx^j d\eta + \big\{\delta_{ij}(1+2\mathcal{R}) + 2\partial_i\partial_j E\big\}dx^i dx^j\big\}\Big]\,. \tag{1}$$

In[5] it was shown that independently of the gravity theory and for generic matter the energy-momentum conservation equations imply

$$\delta P_{nad} = \left[\left(\frac{c_w}{c_s}\right)^2 - 1\right](\rho + P)A_c\,. \tag{2}$$

In the case of general relativity, the additional relation $A_c = \dot{\mathcal{R}}_c/H$ gives an important relation for the time derivative of $\mathcal{R}_c$

$$\delta P_{nad} = \left[\left(\frac{c_w}{c_s}\right)^2 - 1\right](\rho + P)\frac{\dot{\mathcal{R}}_c}{H}. \tag{3}$$

The non-adiabatic pressure perturbation is given according to its thermodynamics definition

$$\delta P_{nad} \equiv \delta P - c_w^2 \delta\rho. \tag{4}$$

This definition of $\delta P_{nad}$ is important because it is gauge invariant and $\delta P_{nad} = \delta P_{ud}$, where $\delta P_{ud}$ is the pressure perturbation on uniform density ($\delta\rho = 0$) slices. It appears in the equation for the curvature perturbation on uniform density slices $\zeta \equiv \mathcal{R}_{ud}$ obtained from the energy conservation law,

$$\zeta' = -\frac{\mathcal{H}\delta P_{nad}}{(\rho + P)} + \frac{1}{3}\overset{(3)}{\Delta}(v - E')_{ud} \tag{5}$$

where $v$ is the 3-velocity potential ($v = \delta\phi/\phi'$ for a scalar field). In general, the curvature perturbations on uniform density and comoving slices are related as

$$\zeta = \mathcal{R}_c + \frac{\delta P_{nad}}{3(\rho + P)(c_s^2 - c_w^2)}\,. \tag{6}$$

A common interpretation of these equations is that when when $\delta P_{nad} \approx 0$ with $c_w^2 \neq c_s^2$, $\zeta$ and $\mathcal{R}_c$ are approximately equal because of eq. (6), and they are both approximately conserved on super-horizon scales because of eq. (3). This is in agreement with the well-known coincidence of $\zeta$ and $\mathcal{R}_c$ on super-horizon scales for slow roll-models in general relativity, since in this case $c_s \neq c_w$ and $\delta P_{nad} \approx 0$ on superhorizon scales.

The equation (3) is the key relation to understand how $\mathcal{R}_c$ depends on the non-adiabatic pressure $\delta P_{nad}$. First of all let us note that this equation is valid on any scale. The advantage of it with respect to eq. (5) is that it does not involve gradient terms, so it allows us to directly relate $\delta P_{\rm nad}$ to $\dot{\mathcal{R}}_c$ if $c_w^2 \neq c_s^2$, while in eq. (5) $\dot{\zeta}$ depends on spatial gradients, which in the case of USR are not negligible on super-horizon scales[5]. This explains why in USR in which $c_w^2 = c_s^2 = 1$, both $\mathcal{R}_c$ and $\zeta$ are not conserved despite $\delta P_{nad} = 0$.

It should be noted here that for slow-roll attractor models $c_w^2 \neq c_s^2$ in general, and $\mathcal{R}_c$ is time-varying on sub-horizon scales. This implies that the non-adiabatic pressure perturbation $\delta P_{nad}$ on sub-horizon scales is not zero. In other words, the attractor models are adiabatic only on super-horizon scales, and we call these models super-horizon adiabatic (SHA).

From eq. (3) we can immediately deduce that in general relativity there are two possible scenarios for the non-conservation of $\mathcal{R}_c$,

$$\begin{aligned} &(1) \quad c_s^2 = c_w^2\,, \quad \delta P_{nad} = 0\,, \\ &(2) \quad c_s^2 \neq c_w^2\,, \quad \delta P_{nad} \neq 0\,. \end{aligned} \tag{7}$$

Here we focus on the first case. It is trivial to see that because of the gauge invariance of $\delta P_{nad}$ the condition $c_w^2 = c_s^2$ automatically implies $\delta P_{nad} = 0$. The models satisfying the condition $c_s^2 - c_w^2 = \delta P_{nad} = 0$ are adiabatic on any scale, and because of this we call them globally adiabatic (GA). In GA models an explicit calculation can reveal the super-horizon behavior of $\mathcal{R}_c$, and $\zeta$, as was shown in[5] in the case of USR. Below, we develop an inversion method to find a new class of models that violate the conservation of $\mathcal{R}_c$ without solving the perturbations equations.

## 3. Globally adiabatic K-essence models

The condition $c_w^2 = c_s^2$ has been studied in the context of K-inflation[6] described by the action ($X \equiv -g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi/2$)

$$S = \frac{1}{2}\int d^4x\sqrt{-g}\left[M_{Pl}^2 R + 2P(X,\phi)\right] , \tag{8}$$

and it was shown that it is satisfied by scalar field models with the Lagrangian of the form,

$$P(X,\phi) = u(Xg(\phi)) \equiv u(Y) \tag{9}$$

where $u$ and $g$ are arbitrary functions. These models are equivalent to a barotropic perfect fluid, i.e. a fluid with equation of state $P(\rho)$. We note again that these models *are adiabatic on any scale* (GA), contrary to the slow-roll attractor models, which are adiabatic *only on super-horizon scales* (SHA). The fact that they are mutually exclusive can be readily seen by considering the hypothetical case of $\delta P_{nad} = 0$ *and* $c_w^2 \neq c_s^2$. In this case eq. (3) which is valid on any scale would mean $\mathcal{R}_c$ should be *frozen on all scales*. In contrast, the condition $c_w^2 = c_s^2$ allows for the curvature perturbation to *evolve* both on *sub-horizon* and *super-horizon* scales.

In[6] it was shown that is possible to associate any barotropic perfect fluid with an equivalent K-inflation model according to

$$2\int^P \frac{du}{F(u)} = \log(Y) , \tag{10}$$

where $F(P) = \rho(P) + P$ and $Y = g(\phi)X$. These models are the ones which could violate the conservation of $\mathcal{R}_c$ for adiabatic perturbations, since they satisfy $c_w^2 = c_s^2$. It is noted of course that the global adiabaticity is not the sufficient condition for the non-conservation of $\mathcal{R}_c$. Not all GA models violate the conservation of $\mathcal{R}_c$ on super-horizon scales.

## 4. General conditions for super-horizon growth of $\mathcal{R}_c$

From the equation for the curvature perturbation on comoving slices,

$$\frac{\partial}{\partial t}\left(\frac{a^3\epsilon}{c_s^2}\frac{\partial}{\partial t}\mathcal{R}_c\right) - a\epsilon\Delta\mathcal{R}_c = 0 , \tag{11}$$

we can deduce, after re-expressing the time derivative in terms of the derivative respect to the scale factor $a$, that on superhorizon scales there is (apart from a constant solution) a solution of the form,

$$\mathcal{R}_c \propto \int^a \frac{da}{a} f(a)\,; \quad f(a) \equiv \frac{c_s^2(a)}{Ha^3\epsilon(a)}\,, \tag{12}$$

where we have introduced the function $f(a)$ for later convenience. In conventional slow-roll inflation $c_s^2$ and $\epsilon$ are both slowly varying, hence the integral rapidly approaches a constant, rendering $\mathcal{R}_c$ conserved. The time dependent part of the above solution corresponds to the decaying mode.

The necessary and sufficient condition for super-horizon freezing is that there exists some $\delta > 0$ for which

$$\lim_{a\to\infty} a^\delta f(a) = 0. \tag{13}$$

By definition of inflation, $H$ must be sufficiently slowly varying; $\epsilon = -\dot{H}/H^2 \ll 1$. So we may neglect the time dependence of $H$ in eq. (12) at leading order, while $\epsilon$ and $c_s^2$ may vary rapidly in time. For models for which $\epsilon \approx a^{-n}$ and $c_s^2 \approx a^q$ we get

$$f \propto a^{q+n-3}\,, \tag{14}$$

hence the condition for freezing is

$$q + n - 3 < 0\,. \tag{15}$$

If this condition is violated, i.e. $q + n - 3 \geq 0$, then the solution (12) will grow on super-horizon scales. This happens for example in USR, which corresponds to $c_s^2 = 1$ and $\epsilon \propto a^{-6}$, i.e. $q = 0$, and $n = 6$. In general, we expect that $q$ would not become very large. This implies $\epsilon$ should decrease sufficiently rapidly. Conversely, if $\epsilon$ decreases sufficiently rapidly, then the growth of $\mathcal{R}_c$ on superhorizon scales will follow.

## 5. Conclusions

In conventional slow-roll models, one has $c_s^2 \neq c_w^2$ and the superhorizon freezing of $\mathcal{R}_c$ can be understood as a result of $\delta P_{\rm nad} \approx 0$ on superhorizon scales. When $c_s^2 = c_w^2$, one has $\delta P_{\rm nad} = 0$ on all scales, but following eq. (3) this does not constrain the superhorizon behaviour of $\mathcal{R}_c$ anymore. This behaviour now follows from $\mathcal{R}_c$'s equation of motion given in eq. (11), and the condition for superhorizon freezing is given in eq. (13). Violation of this condition leads to superhorizon growth of $\mathcal{R}_c$.

We have developed a method to construct the Lagrangian of a K-essence globally adiabatic (GA) model by specifying the behavior of background quantities such as $\epsilon\rho$ where $\epsilon$ is the slow-roll parameter, using the equivalence between barotropic fluids and GA K-essence models. We have applied the method to find the equations of state of the fluids and derive the Lagrangian of the equivalent single scalar field models. Interestingly, we have found that the requirement to avoid the gradient

instability, i.e., $c_s^2 > 0$ is almost identical to the condition for the non-conservation on superhorizon scales.

The advantage of our approach is that we did not have to solve any perturbation equation explicitly. We have begun from requiring some behaviour for $\epsilon$, or for $b \equiv 2\epsilon\rho$, and have then used our inversion method to find the Lagrangian that produces that behaviour.

We have shown that the main difference between attractor models and GA models is that the latter are adiabatic on all scales, while attractor models are approximately adiabatic in the sense of $\delta P_{nad} = 0$ only on super-horizon scales and $c_w^2 \neq c_s^2$.

The detailed study of the new models found in this paper will be done in a separate upcoming work but we can already predict that they can be compatible with observational constraints on the spectral index thanks to the extra parameter $n$ which is not present in USR. Furthermore they can violate the Maldacena's consistency condition and consequently produce large local shape non-Gaussianity.

In the future it will be interesting to apply the inversion method we have developed to other problems related to primordial curvature perturbations, or to develop a similar method for the adiabatic sound speed as function of the scale factor.

# No-Go theorems for ekpyrosis from ten-dimensional supergravity

K. Uzawa

*Department of Physics, School of Science and Technology, Kwansei Gakuin University, Sanda, Hyogo 669-1337, Japan*
*E-mail: kunihito.uzawa@gmail.com*

In this work, we discuss whether the new ekpyrotic scenario can be embedded into ten-dimensional supergravity. We use that the scalar potential obtained from flux compactifications of type II supergravity with sources has a universal scaling with respect to the dilaton and the volume mode. Similar to the investigation of inflationary models, we find very strong constraints ruling out ekpyrosis from analysing the fast-roll conditions. We conclude that flux compactifications tend to provide potentials that are neither too flat and positive (inflation) nor too steep and negative (ekpyrosis).

*Keywords*: Ekpyrosis; Type II string theory; Flux compactifications; Moduli.

## 1. Introduction

The strong no-go theorems which exclude tree-level de Sitter compactifications under a few simple assumptions with or without negative tension objects such as orientifold planes have been much explored because of the possible cosmological and phenomenological interests. However, the no-go theorems for ekpyrotic scenario which is alternative to inflation model in string theory is much less extensive. One motivation for the present work is to improve this situation. Since orientifold planes are a common ingredient in phenomenologically interesting type II string theory, it seems natural to explore the possibility of treelevel de Sitter vacua or inflation models in type II string theory with orientifolds. On the other hand, there is no constraint for ekpyrotic scenario in type II string theory at present.

The ekpyrosis inspired by string theory and brane world model suggests alternative solutions to the early universe puzzles such as inflation and dark energy, and assumes that two four-dimensional boundary branes which are located at the endpoints of orbifold in the higher-dimensional bulk spacetime[1–6]. For brane world picture, all forces except for gravity are localized on the branes while gravity can propagate freely in the bulk. When we assume that there is an attractive force between two branes, these branes approach to each other, which gives big bang. Since the big bang is described as a collision of branes there is not the beginning of time in the ekpyrotic scenario. Although two branes move through each other at once after collision, we can get a model so that the branes become closer again.

The motion of branes is described by the potential of scalar field in a four-dimensional effective theory. Non-perturbative effects result in a potential which attracts one brane towards the other brane[1]. In order to resolve a horizon and flatness problem, the potential during a period of slow contraction before the big bang is negative and steeply falling. There was plenty of time before the big bang for the universe to be in causal contact over large regions, and in this way the horizon and flatness problem is automatically solved[4]. Then, the usual statement

of the ekpyrosis is that the universe slowly contracts before the big bang with the equation of state $w = p/\rho \gg 1$. The scalar potential is expected to turn up towards zero at large negative value of scalar field in the ekpyrotic or cyclic models.

As two branes approach each other, the branes are rippled because of generating quantum fluctuations. Since the collision of branes cannot be happened at exactly the same time, the branes collide slightly earlier or later in some places. Our universe thus has a little bit more time to cool or hot. When we consider the curvature perturbation in the ekpyrotic scenario, it occurs a strong blueshift, which is in sharp contradiction with the small redshift of the scalar fluctuation in the CMB[7–15]. The occurrence of blueshift scalar perturbation is nonetheless a minor flaw of ekpyrotic theory which can be easily corrected. Hence, new ekpyrotic theory considers multiple scalar field and successfully generated a scalar spectrum which is scale invariant and slightly redshifted[16–20]. Producing primordial gravitational waves sourced by the gauge field in the ekpyrotic scenario was also studied in Ref. 21.

It is the purpose of this work to give a No-Go theorem of the ekpyrotic scenario in a ten-dimensional supergravity model which is low energy limit of a string theory. We study the dynamics of two scalar fields in the four-dimensional effective theory after a compactification in string theory. There are a dilaton and the volume modulus of the internal manifold in the effective theory, which is a four-dimensional theory of gravity minimally coupled to two-scalar fields. We will derive the two moduli fields with negative exponential potentials. Since this potential is steep, the scalar field should be satisfied by "fast-roll" condition instead of slow-roll parameter in inflation model[22,23]. Although the terms coupling the scalar fields to the scalar curvature of the internal space and orientifold plane contribute the negative value to the potential in the string theory, we find that the potential does not satisfy the fast-roll condition in general. Therefore, it is not possible for us to realize the ekpyrotic phase in a string theory.

Section 2 describes the potential of scalar field for ekpyrotic scenario and the way it derives the four-dimensional effective theory. We discuss the approach to the effective action in more detail. The No-Go theorem of the ekpyrosis thus given by the string theory is discussed. We also investigate the detailed properties of these models, their embedding in a string theory and their viability. For simplicity, we do not consider D-branes and the associated moduli except for the volume modulus (breathing mode) of internal space although the analysis would not be different. Finally, section 3 provides a brief summary and an outlook to future developments.

## 2. No-Go theorem of the ekpyrotic scenario in the type II theory

In this section, we consider compactifications of the type II theory to four-dimensional spacetime on compact manifold Y. The ten-dimensional low-energy

effective action for the type II theory takes the form[24]

$$S = \frac{1}{2\bar{\kappa}^2}\int d^{10}x\sqrt{-g}\left[\mathrm{e}^{-2\phi}\left(R + 4g^{MN}\partial_M\phi\partial_N\phi - \frac{1}{2}\left|H\right|^2\right) - \frac{1}{2}\sum_p \left|F_p\right|^2\right] - \sum_p \left(T_{\mathrm{D}p} + T_{\mathrm{O}p}\right)\int d^{p+1}x\sqrt{-g_{p+1}}\,\mathrm{e}^{-\phi}\,, \tag{1}$$

where $\bar{\kappa}^2$ is the ten-dimensional gravitational constant, $g$, $R$ denote the determinant, the Ricci scalar with respect to the ten-dimensional metric $g_{MN}$, respectively, $\phi$ is the scalar field, $H$ is the NS-NS 3-form field strength, $F_p$ are the R-R $p$-form field strengths ($p = 0, 2, 4, 6, 8$ for type IIA, and $p = 1, 3, 5, 7, 9$ for type IIB) that are sourced by D-branes, and $T_{\mathrm{D}p}$ ($T_{\mathrm{O}p}$) is the D$p$-brane (O$p$-plane) charge and tension. Although there are Chern-Simons terms in the ten-dimensional action, these are essentially independent of the dilaton and the scale of the background metric. Hence, we will not consider them.

To compactify the theory to four dimensions, we consider the a metric ansatz of the form[24]

$$ds^2 = q_{\mu\nu}dx^\mu dx^\nu + g_{ij}dy^i dy^j = q_{\mu\nu}dx^\mu dx^\nu + \rho\, u_{ij}(\mathrm{Y})dy^i dy^j\,, \tag{2}$$

where $\rho$ is breathing mode (volume modulus of the compact space), $x^\mu$ denote the coordinates of four-dimensional spacetime, $y^i$ are local coordinates on the internal space Y, and $q_{\mu\nu}$, $u_{ij}(\mathrm{Y})$ are the metrices of four-dimensional spacetime, six-dimensional internal space, respectively. We assume that $q_{\mu\nu}$, $u_{ij}(\mathrm{Y})$ depend only on the coordinates $x^\mu$, $y^i$, respectively. Since we factored out the overall volume modulus $\rho$ of the internal space in the ten-dimensional metric (2), the modulus $\rho$ is related to the total physical volume of the internal space $v_6$ and the volume of Y space $v(\mathrm{Y})$ as

$$\rho = \left[\frac{v_6}{v(\mathrm{Y})}\right]^{1/3}, \qquad v_6 = \int d^6y\sqrt{g_6}\,, \qquad v(\mathrm{Y}) = \int d^6y\sqrt{u}\,, \tag{3}$$

where $g_6$ and $u$ denote the determinant of the metric $g_{ij}$ and $u_{ij}(\mathrm{Y})$, respectively. The volume modulus $\rho$ is chosen such that the metric $u_{ij}(\mathrm{Y})$ of the internal space is normalized $v(\mathrm{Y}) = 1$.

Now let us consider the four-dimensional effective action $S_{\mathrm{E}}$ in the Einstein frame after we integrate over the internal space Y. It is especially interesting to understand the dynamics of moduli at negative potential energy. If there are non-trivial fluxes in the background, one notes that these make uplifting the moduli potential to positive energy. In this work, we consider the moduli potential without field strengths and D-branes. Then we obtain the four-dimensional effective action in the Einstein frame:

$$S_{\mathrm{E}} = \int d^4x\sqrt{-\bar{q}}\left[\frac{1}{2\kappa^2}\bar{R} - \frac{1}{2}\bar{q}^{\mu\nu}\partial_\mu\bar{\tau}\,\partial_\nu\bar{\tau} - \frac{1}{2}\bar{q}^{\mu\nu}\partial_\mu\bar{\rho}\,\partial_\nu\bar{\rho} - V(\bar{\tau}\,,\bar{\rho})\right], \tag{4}$$

where $\kappa^2$ is the four-dimensional gravitational constant, $V(\bar{\tau}\,,\bar{\rho})$ denotes the moduli potential, and we have defined the dilaton modulus[24]

$$\tau = \mathrm{e}^{-\phi}\rho^{3/2}\,, \qquad \bar{\rho} = \sqrt{\frac{3}{2}}\kappa^{-1}\ln\rho\,, \qquad \bar{\tau} = \sqrt{2}\kappa^{-1}\ln\tau\,. \tag{5}$$

We have performed a conformal transformation on the four-dimensional metric $q_{\mu\nu} = (\bar{\kappa}/\tau\kappa)^2\bar{q}_{\mu\nu}$, where $\bar{q}_{\mu\nu}$ is the four-dimensional metric in the Einstein frame. $\bar{q}$ and $\bar{R}$ in the four-dimensional action (4) are the Ricci scalar and the determinant constructed from the metric $\bar{q}_{\mu\nu}$, respectively. Orientifold planes occupy $(p-3)$-dimensional internal space due to extending our four-dimensional universe. Then, the contribution of O$p$-plane ($p \geq 3$) to moduli potential survives. The moduli potential of four-dimensional effective theory is given by

$$\begin{aligned} V(\bar{\tau}\,,\bar{\rho}) = V_{\mathrm{Y}} + \sum_p V_{\mathrm{O}p} = &-A_{\mathrm{Y}}\exp\left[-\kappa\left(\sqrt{2}\bar{\tau} + \frac{\sqrt{6}}{3}\bar{\rho}\right)\right]R(\mathrm{Y}) \\ &- \sum_p A_{\mathrm{O}p}\exp\left[-\kappa\left\{\frac{3\sqrt{2}}{2}\bar{\tau} + \frac{\sqrt{6}}{6}(6-p)\bar{\rho}\right\}\right]\int d^{p-3}x\sqrt{g_{p-3}}\,, \end{aligned} \tag{6}$$

where $R(\mathrm{Y})$ denotes the Ricci scalar constructed from the metric $u_{ij}(\mathrm{Y})$ and $A_{\mathrm{Y}}$, $A_{\mathrm{O}p}$ are coefficients to scale with numbers of O$p$-planes. These coefficients in general depend on the function of the moduli of the internal space $\mathrm{Y}$.

When the potential form for the ekpyrotic scenario gives the negative and steep, the fast-roll parameters for the ekpyrosis have to obey[23]

$$\varepsilon_{\mathrm{f}} \equiv \kappa^2\frac{V^2}{\left(\partial_{\bar{\tau}}V\right)^2 + \left(\partial_{\bar{\rho}}V\right)^2} \ll 1\,, \qquad |\eta_{\mathrm{f}}| \equiv \left|1 - \frac{V\left(\partial_{\bar{\tau}}^2V + \partial_{\bar{\rho}}^2V\right)}{\left(\partial_{\bar{\tau}}V\right)^2 + \left(\partial_{\bar{\rho}}V\right)^2}\right| \ll 1\,. \tag{7}$$

This is analogy with the standard slow-roll parameters in inflation. The potential form satisfying the condition (7) gives the ekpyrotic period of slow contraction before the big bang.

Now we consider IIA compactifications on an internal space (2), namely positive curvature and Ricci flat spaces, involving orientifold planes, and discuss the No-Go theorem for ekpyrotic scenario. The analysis will focus on the behavior of the moduli potential in the volume modulus and dilaton. In order to present the no-go theorem using these fields, we have to still make sure that there are no steep directions of the scalar potential in the $(\bar{\tau}\,,\bar{\rho})$-plane. In such cases one can then study directions involving $\bar{\tau}\,,\bar{\rho}$, and finds that the scalar potential satisfies

$$\varepsilon_{\mathrm{f}} = \frac{V^2}{2}\left[\left(V_{\mathrm{Y}} + \frac{3}{2}\sum_p V_{\mathrm{O}p}\right)^2 + \frac{\left(V_{\mathrm{Y}} + V_{\mathrm{O4}} - V_{\mathrm{O8}}\right)^2}{3}\right]^{-1} > \frac{6}{31}\,, \tag{8}$$

where $p = 4, 6, 8$. The fast-roll parameter $\varepsilon_{\mathrm{f}}$ has the bound $\varepsilon_{\mathrm{f}} > 6/31$. This result does not depend on the choice of coefficients $A_{\mathrm{Y}}$ and $A_{\mathrm{O}p}$. The value of parameter $\varepsilon_{\mathrm{f}}$ is not much less than one, which is the contradiction with the fast-roll condition for ekpyrosis (7). Hence, ekpyrosis is not allowed[25,26].

On the other hand, for type IIB compactifications in the ekpyrotic model, we have also seen that it is possible to obtain simple no-go theorems in the $(\bar{\tau}\,,\,\bar{\rho})$-plane if one includes orientifold planes and the curvature of the internal space. From the Eq. (7), we find a constraint of the fast-roll parameter $\varepsilon_{\rm f}$

$$\varepsilon_{\rm f} = \frac{V^2}{2}\left[\left(V_{\rm Y} + \frac{3}{2}\sum_p V_{{\rm O}p}\right)^2 + \frac{\left(2V_{\rm Y} + 3V_{\rm O3} + V_{\rm O5} - V_{\rm O7} - 3V_{\rm O9}\right)^2}{12}\right]^{-1} > \frac{1}{6}\,, \quad (9)$$

where $p = 3, 5, 7, 9$. Unfortunately, the form moduli potential is not steep again as $\varepsilon_{\rm f}$ parameter turns out to be large value[26]. Just as in the IIA analogue, one obtains the bound $\varepsilon_{\rm f} > 1/6$. If we choose different values for $A_{\rm Y}$ and $A_{{\rm O}p}$ in the moduli potential (6), we can find the same bound.

## 3. Discussions

In this work, we have studied the No-Go theorem of the ekpyrosis for string theory in a spacetime of ten dimensions. We gave a potential of the scalar fields in four-dimensional effective theory, in terms of the compactification with smooth manifold. The effective potential of two scalar fields can be constructed by postulating suitable emergent gravity, orientifold planes, and vanishing fluxes on the ten-dimensional background. The scalar potential depends only on two moduli: $\bar{\tau}$ and $\bar{\rho}$.

In such a simple setting, one can show that $\varepsilon_{\rm f} > 6/31$ for IIA theory and $\varepsilon_{\rm f} > 1/6$ for IIB theory whenever $V(\bar{\tau}\,,\bar{\rho}) < 0$. It has been known for some time that the effective potential of scalar fields requires the fast-roll parameter to be small during the ekpyrotic phase. However, with the help of the tools developed in section 2, this is prohibited in a string theory with a compactification we have considered. Hence, the explicit nature of the dynamics has made it impossible to realize the ekpyrotic phase in the present study. This is consistent with results in Ref. 25.

Let us comment about the No-Go theorem of ekpyrotic scenario in heterotic M-theory. The original ekpyrotic model was inspired by heterotic M-theory which is obtained by going from eleven to five dimensions first, and only at even lower energies to 4 dimensions. It arose precisely from the realization that in heterotic M-theory a realistic phenomenology is obtained by introducing non-perturbative effects in the scalar field potential. Otherwise, in the Heterotic theory with a simple Calabi-Yau compactification we have considered in this work, the four-dimensional effective potential form of scalar fields $\varphi_i$ is given by $V(\varphi_i) \propto {\rm e}^{c_i\varphi_i}$, where $c_i < \sqrt{6}$. Then, it is impossible for us to construct the ekpyrotic scenario in the heterotic M-theory without non-perturbative correction. Unfortunately, no one has obtained an exact calculation of the potential involving all non-perturbative effects at present.

We have not considered the warped compactification because it does not make the modification of fast roll condition even if it couples to matter field in the ten-dimensional theory. The effect of warped factor gives only the change of coefficients for each term in the four-dimensional effective action after integration of internal space.

In order to embed ekpyrotic or cyclic models in a ten-dimensional supergravity we have investigated in this work, we may consider some ingredients, for instance, the dynamics of remaining moduli, higher curvature correction other than orientifold and flux. We have not attempted an explicit construction here, since that will take us beyond the scope of this study. A lot of study remains to be done in string theory before a cosmologically realistic case is treated.

We derive a general equation for the evolution of the curvature perturbation on comoving slices $\mathcal{R}_c$ in the presence of anisotropy and non-adiabaticity in the energy-momentum tensor of matter fields. The equation is obtained by manipulating the perturbed Einstein equations in the comoving slicing. It could be used to study the evolution of perturbations for a system with an anisotropic energy-momentum tensor, such as in the presence of a vector field or in the presence of non-adiabaticity, such as in a multi-field system.

*Keywords*: Curvature perturbation, anisotropic stress, non-adiabatic pressure.

## 1. Introduction

The theory of cosmological perturbations is very useful to study the early stages of the Universe, especially during inflation, that is, an exponential expansion phase which the standard cosmological model hypothesizes to explain observations such as anisotropies in the cosmic microwave background radiation (CMB). One quantity which is particularly important in this context is the curvature perturbation on comoving slices, $\mathcal{R}_c$. In slow-roll single field inflationary models this quantity is conserved on super-horizon scales,[1,2] which has important implications on the relation between primordial perturbations and late-time observables such as CMB anisotropies. For a globally adiabatic system in a single field model this quantity may not be conserved.[3] Other possible causes of super-horizon evolution could be the presence of anisotropy or non-adiabaticity in the energy-momentum tensor. We derive the equations for the curvature perturbation on comoving slices, $\mathcal{R}_c$, including these two terms showing that they act, as expected, as source terms which are relevant also on super-horizon scales. Our approach is quite generic and can be applied to any system which can be described by an energy-momentum tensor of the form we use, not only to a multi-scalar fields system.

The derivation is based on manipulating the Einstein equations in order to obtain an equation involving only $\mathcal{R}_c$, the anisotropy and non-adiabatic pressure and background quantities. The equation can be used to study phenomenologically the effects of anisotropy and non-adiabaticity without assuming any specific model.

One useful application could be to study models which violate the non-Gaussianity consistency relation[4] that was derived in fact based on the assumption of the conservation of the comoving curvatue perturbation on superhorizon scales.

## 2. Evolution of comoving curvature perturbations

The Einstein equations in a spatially flat Friedmann-Lemaître-Robertson-Walker (FLRW) background are

$$3\mathcal{H}^2 = a^2\,\rho\,, \tag{1}$$

$$2(\mathcal{H}' - \mathcal{H}^2) = -a^2\,(\rho + P)\,. \tag{2}$$

Here a prime denotes a derivative with respect to the conformal time $\eta$ and $\mathcal{H}$ stands for the conformal Hubble parameter defined by $\mathcal{H} = a'/a$. $\rho$ and $P$ represent the background energy density and pressure of the matter field respectively. We use the units in which $8\pi G = c = 1$.

Scalar perturbations on a spatially flat FLRW metric can be written as

$$ds^2 = a^2\left[-(1+2A)\mathrm{d}\eta^2 + 2\partial_i B\mathrm{d}x^i\mathrm{d}\eta + \left\{(1+2C)\delta_{ij} + 2\partial_i\partial_j E\right\}\mathrm{d}x^i\mathrm{d}x^j\right], \tag{3}$$

where the Latin indices run from 1 to 3. The corresponding energy-momentum tensor takes the form:

$$T^0{}_0 = -(\rho + \delta\rho)\,, \quad T^0{}_i = \frac{\rho + P}{a}u_i\,, \quad T^i{}_j = (P + \delta P)\delta^i{}_j + \Pi^i{}_j\,, \tag{4}$$

where

$$u_i = a\,\partial_i(v + B)\,, \quad \Pi^i{}_j = \delta^{ik}\partial_k\partial_j\Pi - \frac{1}{3}\overset{(3)}{\Delta}\Pi\delta^i{}_j\,, \quad \Pi^i{}_i = 0\,. \tag{5}$$

In the above equations $\Pi^i{}_j$ is the anisotropic stress component of the energy-momentum tensor, $v$ is the velocity potential, $\Pi$ is the anisotropy potential and we have defined $\overset{(3)}{\Delta} \equiv \delta^{ij}\partial_i\partial_j$.

The curvature perturbation on comoving slices $\mathcal{R}_c$ is a gauge-invariant quantity defined as the curvature perturbation $C$ evaluated on the hypersurfaces in which $v + B$ vanish. The spatial Fourier expansion of the linearly perturbed Einstein equations on comoving slices[5] takes the form :

$$2k^2(\mathcal{R}_c - \mathcal{H}\sigma_c) = a^2\delta\rho_c\,, \tag{6}$$

$$\mathcal{R}_c' - \mathcal{H}A_c = 0\,, \tag{7}$$

$$2(\mathcal{H}' - \mathcal{H}^2)A_c = a^2\left[\delta P_c - (2k^2/3)\Pi_c\right], \tag{8}$$

$$\sigma_c' + 2\mathcal{H}\sigma_c - A_c - \mathcal{R}_c = a^2\Pi_c\,, \tag{9}$$

where $\sigma = E' - B$ is the scalar shear.

In general we can decompose the pressure perturbation as

$$\delta P_c = c_s^2(\eta)\delta\rho_c + \Gamma_c\,, \tag{10}$$

where we can interpret $c_s$ and $\Gamma_c$ as the adiabatic sound speed and the non-adiabatic part of the pressure respectively. For a minimally coupled scalar field model $c_s = 1$ and $\Gamma_c$ is zero, but in general one would expect that $\Gamma_c$ could be non-vanishing. Our goal is to derive an equation for $\mathcal{R}_c$ in the presence of both anisotropic stress $\Pi^i{}_j$ and non-adiabatic pressure $\Gamma_c$.

First we use Eq. (7) to express $A_c$ in terms of $\mathcal{R}_c$,

$$A_c = \frac{\mathcal{R}_c'}{\mathcal{H}}\,. \tag{11}$$

We substitute this $A_c$ and $\delta P_c$ given in Eq. (10) into Eq. (8), and solve it for $\delta\rho_c$ :

$$\delta\rho_c = \frac{\mathcal{H}\left(2k^2\Pi_c - 3\Gamma_c\right) - 3(\rho+P)\mathcal{R}_c'}{3\mathcal{H}c_s^2}\,. \tag{12}$$

We then insert this into Eq. (6) to get an expression for $\sigma_c$ :

$$\sigma_c = \frac{\mathcal{R}_c}{\mathcal{H}} - \frac{a^2\left[\mathcal{H}(2k^2\Pi_c - 3\Gamma_c) - 3(\rho+P)\mathcal{R}_c'\right]}{6k^2\mathcal{H}^2c_s^2}\,. \tag{13}$$

Finally we substitute $A_c$ and $\sigma_c$ given by Eqs. (11) and (13), respectively, into Eq. (9) to obtain

$$\mathcal{R}_c'' + \frac{(z^2)'}{z^2}\mathcal{R}_c' - c_s^2\,\overset{(3)}{\Delta}\,\mathcal{R}_c + \frac{\mathcal{H}}{\rho+P}Y_c = 0\,, \tag{14}$$

where we have defined

$$z^2 \equiv \frac{a^4(\rho+P)}{c_s^2\mathcal{H}^2}\,, \tag{15}$$

$$Y_c \equiv \left[\log\left(\frac{a^4}{\mathcal{H}c_s^2}\right)\right]'\left(\frac{2}{3}\,\overset{(3)}{\Delta}\,\Pi_c + \Gamma_c\right) + 2\mathcal{H}c_s^2\,\overset{(3)}{\Delta}\,\Pi_c + \frac{2}{3}\,\overset{(3)}{\Delta}\,\Pi_c' + \Gamma_c'\,. \tag{16}$$

As expected, for adiabatic ($\Gamma_c = 0$) and isotropic perturbations ($\Pi_c = 0$) the above equation takes the well-known form :

$$\mathcal{R}_c'' + \frac{(z^2)'}{z^2}\mathcal{R}_c' - c_s^2\,\overset{(3)}{\Delta}\,\mathcal{R}_c = 0\,. \tag{17}$$

## 3. Curvature perturbation for scalar fields

Given the generality of the form of the energy momentum tensor used in the derivation of Eq. (14) it can be applied to a wide class of physical scenarios, including multi-field systems. Let us consider the case of two minimally coupled scalar fields with Lagrangian

$$L = -\sum_{n=1}^{2} X_n - 2V(\Phi_1, \Phi_2)\,, \tag{18}$$

where $X_n = g^{\mu\nu}\partial_\mu\Phi_n\partial_\nu\Phi_n$ and $\Phi_n(x^\mu) = \phi_n(\eta) + \delta\phi_n(x^\mu)$. The perturbed energy-momentum tensor, without gauge fixing, is given by

$$\begin{aligned}
\delta\rho &= \frac{\phi_1'\delta\phi_1' + \phi_2'\delta\phi_2' - A(\phi_1'^{\,2} + \phi_2'^{\,2})}{a^2} + V_1\delta\phi_1 + V_2\delta\phi_2\,,\\
\delta P &= \frac{\phi_1'\delta\phi_1' + \phi_2'\delta\phi_2' - A(\phi_1'^{\,2} + \phi_2'^{\,2})}{a^2} - V_1\delta\phi_1 - V_2\delta\phi_2\,,\\
\Pi = 0 \quad &, \quad \delta T^0{}_i = \partial_i\left(-\frac{\phi_1'\delta\phi_1 + \phi_2'\delta\phi_2}{a^2}\right),
\end{aligned} \tag{19}$$

where we denote the partial derivatives as $V_n = (\partial V/\partial\Phi_n)(\phi_1, \phi_2)$.

The field perturbations transform under an infinitesimal time translation $\eta \to \eta + \delta\eta$

$$\widetilde{\delta\phi_1} = \delta\phi_1 - \phi_1'\delta\eta \quad , \quad \widetilde{\delta\phi_2} = \delta\phi_2 - \phi_2'\delta\eta\,. \tag{20}$$

The time translation $\delta\eta_c$ necessary to define the comoving slices can be found by imposing the condition $(\delta T^0{}_i)_c \propto \phi_1'\widetilde{\delta\phi_1} + \phi_2'\widetilde{\delta\phi_2} = 0$, giving

$$\delta\eta_c = \frac{\phi_1'\delta\phi_1 + \phi_2'\delta\phi_2}{\phi_1'^{\,2} + \phi_2'^{\,2}}\,. \tag{21}$$

The comoving curvature perturbation for the two scalar fields system is given by

$$\mathcal{R}_c = C - \mathcal{H}\delta\eta_c = C - \mathcal{H}\frac{\phi_1'\delta\phi_1 + \phi_2'\delta\phi_2}{\phi_1'^{\,2} + \phi_2'^{\,2}}\,. \tag{22}$$

The gauge invariant field perturbations in the comoving slices now can be defined

$$U_1 = \delta\phi_1 - \phi_1'\frac{\phi_1'\delta\phi_1 + \phi_2'\delta\phi_2}{\phi_1'^{\,2} + \phi_2'^{\,2}}\,, \tag{23}$$

$$U_2 = \delta\phi_2 - \phi_2'\frac{\phi_1'\delta\phi_1 + \phi_2'\delta\phi_2}{\phi_1'^{\,2} + \phi_2'^{\,2}}\,, \tag{24}$$

and similarly for the pressure and energy perturbations in the comoving slices we get

$$\delta\rho_c = \frac{\phi_1'U_1' + \phi_2'U_2' - A_c(\phi_1'^{\,2} + \phi_2'^{\,2})}{a^2} + V_1U_1 + V_2U_2\,, \tag{25}$$

$$\delta P_c = \frac{\phi_1'U_1' + \phi_2'U_2' - A_c(\phi_1'^{\,2} + \phi_2'^{\,2})}{a^2} - V_1U_1 - V_2U_2\,. \tag{26}$$

Note that all the above quantities are gauge invariant by construction.

Combining Eqs. (23), (24) and the background field equations of motion we find

$$\frac{\phi_1'U_1' + \phi_2'U_2'}{a^2} = V_1U_1 + V_2U_2 = -\frac{\phi_1'^{\,2} + \phi_2'^{\,2}}{4a^2}\Theta\,, \tag{27}$$

where we have defined the function $\Theta$ according to

$$\Theta = \left[\frac{\partial}{\partial\eta}\left(\frac{\phi_1'^{\,2} - \phi_2'^{\,2}}{\phi_1'^{\,2} + \phi_2'^{\,2}}\right)\right]\left(\frac{\delta\phi_1}{\phi_1'} - \frac{\delta\phi_2}{\phi_2'}\right). \tag{28}$$

Assuming a classical field trajectory parameterized as $\phi_2 = \phi_2(\phi_1)$ we can write $\Theta$ in this form

$$\Theta = -4\frac{\mathrm{d}^2\phi_2}{\mathrm{d}\phi_1^2}\left[\left(\frac{\mathrm{d}\phi_2}{\mathrm{d}\phi_1}\right)^2 + 1\right]^{-2}\left(\frac{\mathrm{d}\phi_2}{\mathrm{d}\phi_1}\delta\phi_1 - \delta\phi_2\right). \tag{29}$$

From the above expression we can see that in order for $\Theta$ to be different from zero the trajectory has to have non vanishing second derivative, i.e. there must be some turn in the field space.

After replacing Eqs. (7) and (27) into Eqs. (25) and (26) we get

$$\delta\rho_c = -\frac{\phi_1'^2 + \phi_2'^2}{a^2\mathcal{H}}\mathcal{R}_c' - \frac{\phi_1'^2 + \phi_2'^2}{2a^2}\Theta\,, \tag{30}$$

$$\delta P_c = -\frac{\phi_1'^2 + \phi_2'^2}{a^2\mathcal{H}}\mathcal{R}_c'\,. \tag{31}$$

It follows from Eqs. (30) and (31) that

$$\delta P_c = \delta\rho_c + \frac{\phi_1'^2 + \phi_2'^2}{2a^2}\Theta\,, \tag{32}$$

and comparing this with Eq. (10) we obtain the sound speed and the entropy perturbations

$$c_s^2(\eta) = 1\,, \qquad \Gamma_c = \frac{\phi_1'^2 + \phi_2'^2}{2a^2}\Theta\,. \tag{33}$$

From these relations we get

$$\mathcal{R}_c'' + 2\frac{z'}{z}\mathcal{R}_c' - \overset{(3)}{\Delta}\mathcal{R}_c = -\frac{a^2\mathcal{H}}{(\phi_1'^2 + \phi_2'^2)}Y_c\,, \tag{34}$$

where

$$z^2 = \frac{a^2(\phi_1'^2 + \phi_2'^2)}{\mathcal{H}^2}\,, \tag{35}$$

$$Y_c = \left[\log\left(\frac{a^4}{\mathcal{H}}\right)\right]'\Gamma_c + \Gamma_c'\,. \tag{36}$$

Eq. (34) is in agreement with Ref. [6], confirming that Eq. (14) is general and can also be applied to multi-field systems once the entropy has been appropriately defined. In general in order to use Eq. (14) it is first necessary to compute the energy momentum tensor in the comoving slices with a procedure similar to the one shown above for two fields.

## 4. Conclusions

We have derived a general equation for the evolution of the comoving curvature perturbation by taking into account the effects of anisotropy and non-adiabaticity in the energy-momentum tensor. The equation can be applied to multi-field systems. This approach does not require the decomposition of field perturbations in

components parallel and perpendicular to the classical field trajectory, but is based just on the fundamental definition of non-adiabatic pressure. In the future it will be interesting to apply the equation to more complex systems where both entropy and anisotropy are present.

# Horndeski charged boson stars and black holes

Yosef Verbin* and Yves Brihaye**

*Department of Natural Sciences, The Open University of Israel, Raanana 43107, Israel

**Physique Théorique et Mathématiques, Université de Mons, Place du Parc, B–7000 Mons, Belgique

We find two distinct families of new charged boson star solutions of a complex scalar field coupled non-minimally to gravity by a "John-type" term of Horndeski theory. The end points of one of the branches are extremal Reissner-Nordström black hole solutions.

## 1. Introduction and general considerations

Although the main motivation for the resurrection[1] of Horndeski scalar-tensor theory[2] was cosmological, a large number of investigations of its small scale aspects was also carried out. To mention just a few, black hole solutions[3,4] were discovered in the "John"-type version of Horndeski theory which contains a non-minimal coupling term of the scalar kinetic term to the Einstein tensor, $\mathcal{L}_{NM} \sim G^{\mu\nu}\partial_\mu\phi\partial_\nu\phi$ and in another version known as the Sotiriou-Zhou model[5] which has a $\phi\Re_{GB}$ term in the Lagrangian where $\Re_{GB}$ is the Gauss-Bonnet term. Black hole solutions were found[6] also in a "biscalar extension" of the theory and boson stars were found[7] in a different biscalar version where the scalar field becomes complex. On the other hand, the real scalar system was also studied in the presence of a radial electric field[8] and black holes were found in that case too. These latter black hole solutions are essentially a "superposition" of the pure scalar black holes with the electric field of a point charge at their centers. Further study[9] of the real scalar system produced magnetic black holes as well.

In some of these studies the scalar field ceases to play a role of a gravitational degree of freedom, and the Horndeski theory is used as an inspiration for new kinds of couplings between scalar matter and gravity. These scalar fields may be interpreted as dark matter candidates. This is the attitude we take in this work where we analyze the gauged version of the "John" Lagrangian thus producing the conventional minimal coupling between the scalar and Abelian vector fields. The dynamics of such a system is determined by the following action which is a simple generalization of that for self-gravitating solitons like boson stars or Q-stars[10,11]:

$$S = \int d^4x\sqrt{-g}\left(\frac{R}{2\kappa} - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{2}|D_\mu\Phi|^2 - U(|\Phi|) - \beta G^{\mu\nu}D_\mu\Phi^* D_\nu\Phi\right). \quad (1)$$

The non-minimal coupling term to the Einstein tensor is known to introduce in the field equations of the pure scalar case derivatives of order not higher than two.[2] It is easy to show that the gauged version still has this property.

Now we assume a static spherically symmetric metric and a radial "electric" configuration for the scalar and vector fields:

$$ds^2 = A(r)^2dt^2 - B(r)^2dr^2 - r^2d\Omega_2^2, \qquad \Phi = f(r)e^{i\omega t}, \qquad A_\mu dx^\mu = a_0(r)dt. \quad (2)$$

We take the simplest potential of a mass term only and obtain 4 independent field equations for the 4 functions $f(r)$, $a_0(r)$, $A(r)$ and $B(r)$. We do not present them here due to lack of space, but refer the readers instead to Ref. 12 where a more detailed study of this system can be found.

We will characterize the solutions by their total mass, electric charge and particle number. We will define the mass function $\mathcal{M}(r)$ by $1/B^2(r) = 1 - 2\mathcal{M}(r)/r$ so the ADM mass may be read of the asymptotic decay of the metric, i.e. $\mathcal{G}M = \mathcal{M}(\infty)$.

The local $U(1)$ charge is readily obtained from the time component of the conserved total current:

$$\mathcal{J}^\nu = J^\nu - 2\beta G^{\mu\nu} J_\mu, \quad J_\nu = -\frac{ie}{2}\left(\Phi^* D_\nu \Phi - \Phi D_\nu \Phi^*\right) \tag{3}$$

which in the spherically-symmetric case yields the following expression:

$$Q = 4\pi e \int_0^\infty dr \frac{r^2 B}{A}(\omega - e a_0) f^2 \left(1 + \frac{4\beta \mathcal{M}'}{r^2}\right). \tag{4}$$

Without loss of generality we will take $\omega > 0$, so $Q > 0$ as well.

These two quantities, mass and charge determine the asymptotic behavior of the localized solution that we seek, i.e. the exterior Reissner-Nordström solutions:

$$A(r)^2 = 1/B(r)^2 = \left(1 - \frac{\kappa M}{4\pi r} + \frac{\kappa Q^2}{2(4\pi)^2 r^2}\right), \;\; a_0 = \frac{Q}{4\pi r}. \tag{5}$$

So, we may extract also the charge from the asymptotic behavior of the solutions.

The total electric charge is carried in our case by $N$ particles of mass $m$ and charge $e$. We can therefore define a particle density and particle number by

$$\rho_N = (\omega - e a_0) f^2 \left(1 + \frac{4\beta \mathcal{M}'}{r^2}\right), \quad N = 4\pi \int_0^\infty dr \frac{r^2 B}{A} \rho_N. \tag{6}$$

Thus, we can use the mass to particle number ratio, or more precisely, $M/mN$ in order to study the stability of these solutions against "fission" into a number of smaller stable structures: this ratio $M/mN$ needs to be less than 1 in order for the solutions to be stable against this kind of processes. The condition $M/mN < 1$ is however not sufficient to guarantee the stability under linear perturbations[11]. We will postpone this issue to a future work.

The field equations[12] depend a priori on $m$, $e$, $\beta$ and Newton's constant $\mathcal{G}$. The equations can be written in a dimensionless form which reveals a dependence on two independent parameters only: $\overline{\beta} = \beta m^2$ and $\overline{e} = e/\sqrt{\kappa m^2}$. The rescaled and original versions of the charge, particle number and mass are related to one another by $\bar{M} = Mm/\mu^2 = \kappa m M$, $\bar{Q} = Qm^2/\mu^2 = Q\kappa m^2$ and $\bar{N} = Nm^2/\mu^2 = N\kappa m^2$. The stability ratio may be calculated both ways: $M/mN = \bar{M}/\bar{N}$.

The mass function $\mathcal{M}(r)$ which we defined above has a dimension of length and is rescaled therefore similarly as $\bar{\mathcal{M}} = m\mathcal{M}$. The total mass may therefore be expressed in terms of $\bar{\mathcal{M}}(\infty)$ or $\bar{M}$ as $M = 8\pi\bar{\mathcal{M}}(\infty) m_{Pl}^2/m = \bar{M} m_{Pl}^2/m$, where we use the Planck mass $m_{Pl} = 1/\sqrt{\kappa}$. Similarly the rescaled particle number $\bar{N}$ may be used to express the total particle number as $N = 8\pi\bar{N}(m_{Pl}/m)^2$.

## 2. Solutions and their properties

Although in some special cases of this theory solutions were obtained explicitly, we found it unlikely to achieve this in the present system we study here. We therefore revert to numerical analysis in order to construct our solutions.

Within our ansatz (2), the unknown functions $B, A, f, a_0$ appear with maximal derivatives $B', A'', f'', a_0''$ in the system of field equations. These maximal derivatives appear linearly, so that the equations are symbolically written as

$$M(B', A'', f'', a_0'')^T = K \tag{7}$$

where $M$ represents a *non-diagonal* $4\times4$ matrix and $K$ a $4\times1$ matrix (vector) whose entries depend on the lower derivatives. The quantity $\Delta(r) \equiv \det M$ plays a major role in the existence of regular solutions over space-time. Indeed zeroes of $\Delta(r)$ correspond to singular points of the system. In particular, the occurrence of such a point renders impossible the construction of numerical solutions on $r \in [0, \infty]$.

For a given set of $\beta$ and $e$, the solutions comprise a one-parameter set parametrized by $f(0)$ or alternatively by $\omega$ or $A(0)$, although in some regions of parameter space the correspondence is not one to one as will become evident shortly.

In other areas of parameter space we find a second branch of solutions with significantly different behavior with respect to the first ("ordinary") branch. Fig. 1-Left shows the general structure in the $(f(0), A(0))$ plane for $e = 0.7$ and five values of $\beta$: $\beta = \pm1, \pm0.5$ and the minimally coupled case $\beta = 0$. The two-branch structure appears for $\beta > 0$ only and above a certain value of $e$.

In order to understand the situation better, we calculate the main properties of the solutions: mass, particle number and their ratio which is in one to one correspondence with the binding energy per particle $1 - M/N$. We study their

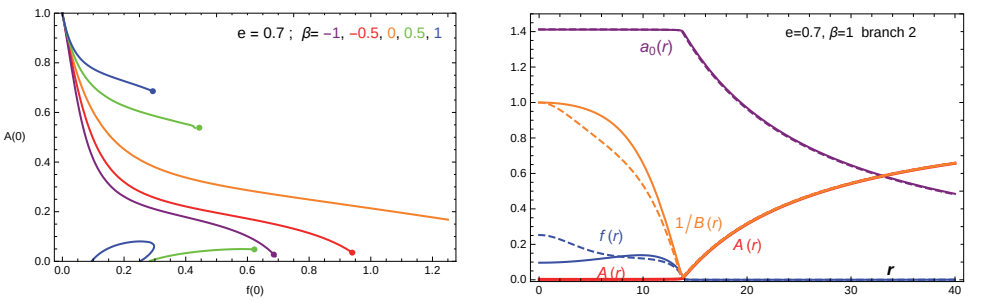

Fig. 1. Left panel: Families of solutions for $e = 0.7$ and 5 values of $\beta$. Note the two branch structure for $\beta > 0$ and the different behavior of branch 2 families appearing at the lower part. The "bullets" mark the end point solutions without back-bending, i.e. $\Delta = 0$ solutions. The other end points at $A(0) = 0$ have almost extremal Reissner-Nordström behavior - Right panel: The two end-point solutions for $e = 0.7$ and $\beta = 1.0$. Both solutions have $N = 348.2$ and $M = 344.7$ and the same external structure (with $A(r)$ and $1/B(r)$ almost identical), but very different internal structure: $f(0) = 0.096255$ and $f''(0) > 0$ - solid; $f(0) = 0.2525$ and $f''(0) < 0$ - dashed.

dependence on the parameters of the theory $\beta$ and $e$ as well as their behavior within a given family corresponding to specific $(\beta, e)$ and parametrized by $f(0)$.

Fig. 2 contains some of these aspects: the mass as a function of the central scalar field and the dependence of binding energy per particle on the particle number.

First we observe from our results that the mass and particle number decrease with $\beta$ which is in accord with the fact that gravity becomes stronger with increasing $\beta$, so a smaller number of particles can form bound states.

The dependence on the coupling constant $e$ is expected to cause the opposite effect since increasing its value amounts to a stronger electrostatic repulsion. This is indeed the general behavior as we will see in what follows. The electrostatic repulsion is also responsible for a critical value of $e$ which in terms of the dimensionless parameter reads $\overline{e}_{cr} = 1/\sqrt{2}$. Actually, this bound was obtained[11] for minimal coupling ($\beta = 0$), but it still holds here with a weak dependence on $\beta$.

Branch 1 of the solutions is quite similar to that of charged ordinary (i.e. $\beta = 0$) boson stars for both signs of $\beta$: it starts at $f(0) = 0$ with $M = N = 0$, then the mass and particle number grow steeply, attain (together) a maximum and then decrease. However, unlike the case of ordinary charged boson stars, the solutions hit an end point beyond which no solutions exist. This end point has a similar origin as reported for the ungauged counterpart[7] where the function $\Delta(r)$ was found to develop a zero at the end point excluding solutions beyond that point.

Branch 2 solutions exists only in restricted regions of parameter space: for a given $e$, $\beta$ should be larger than a certain value. For given $e$ and $\beta$, branch 2 starts at a minimal non-zero $f(0)$ and $A(0) = 0$ and has also a maximal $f(0)$. This maximal $f(0)$ point can be either: (i) An end point of a similar kind of branch 1 where solutions cease to exist because $\Delta(r)$ gets a zero. In this case $A(0) > 0$ at that point. (ii) A turning point in which back-bending occurs and solutions still exist down to some final $f(0)$ which is an end point because $A(0) = 0$.

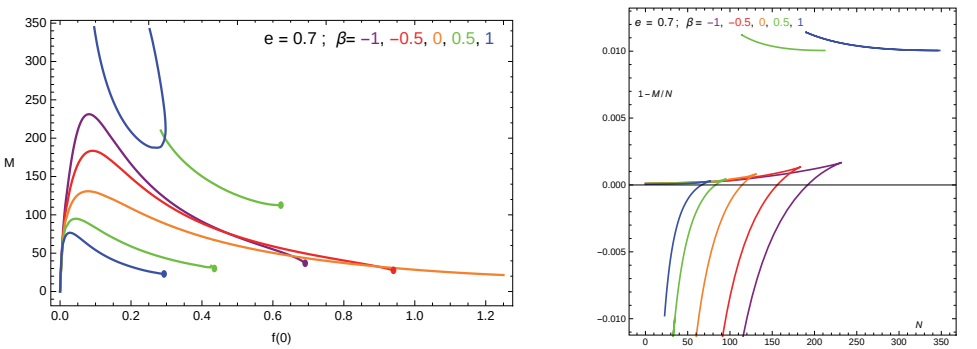

Fig. 2. Mass and binding energy per particle for $e = 0.7$ and 5 values of $\beta$: $\beta = \pm 1, \pm 0.5$ and $\beta = 0$. Left panel: Mass versus the central value of the scalar field; Right panel: Binding energy per particle as a function of particle number. The branch 2 curves are the upper ones at both figures. The "un-bulleted" ends of the branch 2 curves in the left represent the extremal Reissner-Nordström solutions. These correspond to the $A(0) = 0$ points of Fig. 1.

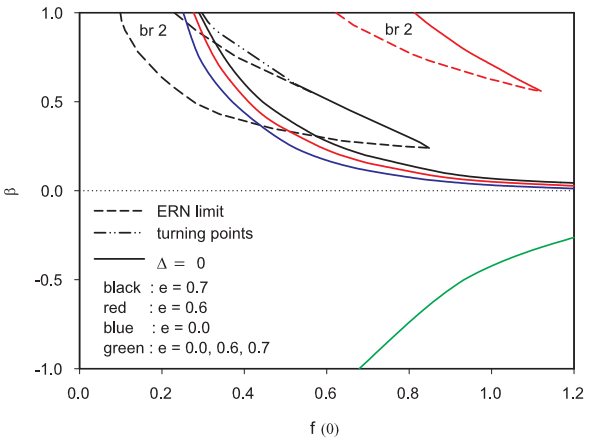

Fig. 3. The branch structure of parameter space for $e = 0$, 0.6, 0.7 and $-1 \leq \beta \leq 1$. Note that branch 1 extends from the vertical axis at $f(0) = 0$ up to the curves. Branch 2 regions are indicated explicitly. For further explanation - see text.

To sum up, there are two kinds of end points of curves in parameter space as is seen clearly in Fig. 1 and 2: The first kind are the "bulleted" which correspond to the $\Delta = 0$ termination condition. These appear on the $\beta \neq 0$ branch 1 curves and the higher $f(0)$ end point of the $\beta = -0.5$ branch 2 curve. End points of the second kind are the two "un-bulleted" end points of the $\beta = -1$ branch 2 curve and the lower $f(0)$ end point of the $\beta = -0.5$ branch 2. These correspond to the $A(0) = 0$ termination condition.

At the end points of branch 2 where $A(0) \to 0$ and the scalar field becomes confined within a ball with a sharp boundary at $r = r_S$, we find that the solutions approach extremal Reissner-Nordström black hole solutions (ERN or ERNS in the following) which have identical mass and particle number, but correspond to very different internal structure. In our parametrization the ERNS have the characteristic relation $M = \sqrt{2}Q$ or in terms of particle number, $M = \sqrt{2}eN$. The right panel of Fig. 1 shows for $e = 0.7$ and $\beta = 1.0$ the identical exterior solutions of the end-point solutions that correspond to the two different internal structures. The $M$ and $N$ values of these solutions $M = 344.7$ and $N = 348.2$ satisfy this relation very nicely. Another characteristic of the ERNS, is the equality $A(r) = \omega - ea_0(r)$ which we do not show in our plots, but was checked to hold very well.

As a summary of the branch structure of this theory we present Fig. 3 which illustrates the structure of parameter space in the $(f(0), \beta)$ plane for $e = 0.6$, 0.7 and for comparison with previous work[7] also $e = 0$. Note that the line for the $\beta < 0$ solutions is the line of end points for any value of $e$: the maximal $f(0)$ depends on $\beta$ but not on $e$.

## 3. Conclusion

In this work we studied the parameter space of a new kind of charged boson stars with a non-minimal coupling to gravity of the "John-type" of Horndeski theory. We found two distinct families according to their position in parameter space. More widespread are those of branch 1 existing for a finite interval of the central value of the scalar field, $f(0)$ starting from zero and ending at some finite maximal value. This branch contains as a special case the charged boson stars of the minimally coupled theory. In some regions of parameter space we found a new second branch of solutions which are more massive and more stable than those of branch 1. This second branch exists also in a finite interval of $f(0)$, but its end points (either both or in some cases only one) are extremal Reissner-Nordström solutions.

It would be interesting to study whether the intriguing solutions of branch 2 could exist in different versions of the tensor scalar gravity as well. As a first step in this direction, one could check whether a self-interacting potential would lead to branch 2-type of solutions with smaller values of the non-minimal parameter $\beta$.

The existence of hairy black holes in some modification of this system is also of much interest. It might be sufficient to introduce a bare cosmological constant as was done previously[4] for the neutral system.

# 21-cm signal of neutral hydrogen from high cosmological redshifts

Anastasia Fialkov

*Astronomy Centre, Department of Physics and Astronomy, University of Sussex, Brighton BN1 9QH, UK*

The high-redshift 21-cm signal of neutral hydrogen is expected to be a sensitive probe of primordial star formation as well as of the heating and ionization histories of the Universe. The recent tentative detection by the EDGES Low-Band of the cosmological 21-cm signal, if confirmed, is the first ever signature from the dawn of star formation. However, the magnitude and the shape of this signal are incompatible with standard astrophysical predictions, requiring either colder than expected gas, or an excess radio background above the Cosmic Microwave Background (CMB) radiation. Here we provide a brief overview of 21-cm cosmology, the status of the global 21-cm experiments and proposed theoretical explanations for the EDGES detection.

## 1. Introduction

The dawn of star formation at redshifts $z \sim 15 - 30$ remains veiled in mystery being out of reach of existing observations. Large scale structure surveys map cosmic structure only out to redshift of $z \sim 3$. Observations of lensed fields with the Hubble Space Telescope (HST) reach further and have revealed galaxies at the Epoch of Reionization (EoR, $z \sim 6 - 10$) with the most distant galaxy detected at redshift $z \sim 11.1$[31]; the Atacama Large Millimeter Array (ALMA) sees dusty bright galaxies at $z \sim 9.1$[21]; while the record-holder high-redshift quasar is located at $z = 7.54$[2]. Existence of so massive and metal-rich objects when the Universe was less than a billion years old suggests an early formation of the first stars (e.g., as early as $z \sim 15$ in the case of the metal-rich galaxy at $z = 9.1$[21]). However, even with the most powerful telescopes, only the brightest out of the high-redshift sources are currently within the reach, while more typical objects – those that reheated and reionized the Universe – remain unobserved. As a result, the process of heating and ionization of the intergalactic medium (IGM) during the first few hundred million years after the Big Bang, as well as the processes of the primordial star formation, remain poorly understood. The 21-cm signal of neutral hydrogen, reviewed here, provides a unique way to fill in the gap.

## 2. Expected 21-cm Signal: Dependence on Astrophysical Processes

As the Universe evolves, astrophysical processes strongly affect the thermal and ionization states of the IGM. Right after recombination high fraction of free residual electrons mediates thermal coupling between the gas and the Cosmic Microwave Background (CMB) radiation. The IGM and the CMB are cooling together until the coupling becomes inefficient at around $z_{\rm th} \sim 200$ as a result of the cosmic expansion. At lower redshifts, and prior to the formation of the first astrophysical heating sources, gas is cooling faster than the CMB. This period in cosmic history, prior to star formation, is called the dark ages and is characterized by cold and

neutral IGM. Emergence of first stars and first X-ray sources marks the onset of cosmic dawn, completely changing the high-redshift environment. During this epoch stars produce Ly-$\alpha$ background, and the IGM is reheated by X-ray photons to temperatures higher than that of the CMB. At that epoch, the heating rate of the IGM depends on the properties of the X-ray sources, such as their spectral energy distribution (SED) and bolometric luminosity[13,14,32]. The process of reionization happens slower than heating. This is because the first small galaxies are inefficient in ionizing the gas. The appearance of massive galaxies in dark matter halos of mass $\mathrm{M_h} \gtrsim 10^9\ \mathrm{M_\odot}$ leads to a more efficient process of reionization which, as observations suggest, starts not long before $z = 7.5$ and terminates at $z \sim 6$[19,20]. This sequence of cosmic events is imprinted in the neutral hydrogen signal.

The lowest energy level of the hydrogen atom is split due to the interaction between proton and electron spins (hyper-fine splitting) which gives rise to the rest-frame $\nu_{21} = 1.42$ GHz radio signal with the equivalent wavelength of 21 cm (see Barkana (2016)[3] for a recent review). The cumulative signal of neutral IGM at redshift $z$ observed against the background radiation depends on the processes of cosmic heating and ionization and can be written as

$$T_{21} \propto x_{\mathrm{HI}} \left(1 - T_{\mathrm{rad}} T_{\mathrm{S}}^{-1}\right), \tag{1}$$

where $x_{\mathrm{HI}}$ is the fraction of neutral hydrogen, $T_{\mathrm{rad}}$ is the brightness temperature of the background radiation at 1.42 GHz (which is usually assumed to be the temperature of the CMB[1] at redshift $z$) and $T_{\mathrm{S}}$ is the spin temperature of the transition which encodes complex astrophysical dependence. The spin temperature can be written as $T_{\mathrm{S}} = (1 + x_{\mathrm{tot}}) \left(T_{\mathrm{rad}}^{-1} + x_{\mathrm{tot}} T_{\mathrm{K}}^{-1}\right)^{-1}$, where $x_{\mathrm{tot}} = x_C + x_\alpha$ (see Eqs. 46 and 48 of Barkana (2016)[3]), $x_\alpha$ is the Wouthhausen-Field (WF[17,37]) coupling coefficient which depends on the intensity of the Ly-$\alpha$ background radiation produced by stars, $x_C$ is the collisional coupling coefficient, and $T_{\mathrm{K}}$ is the kinetic temperature of the neutral IGM. $x_C$ is important at high redshifts when the Universe was dense and intra-atomic collisions were frequent enough to couple $T_{\mathrm{S}}$ to $T_{\mathrm{K}}$. This effect became sub-dominant as the Universe expanded and the gas rarefied. $x_\alpha$, which is negligible before the onset of star formation, became important at cosmic dawn. Ly-$\alpha$ photons produced by stars coupled $T_S$ to the color temperature of the Ly-$\alpha$ radiation, which at cosmic dawn is close to $T_{\mathrm{K}}$. Finally, ionizing radiation depletes the amount of neutral gas in the IGM, reducing $x_{\mathrm{HI}}$. Owing to its dependence on the underlying astrophysics and cosmology, the 21-cm signal is a powerful tool to characterize the formation and the evolution of the first populations of astrophysical sources and, potentially, properties of dark matter, across cosmic time.

Figure 1 shows a cartoon of the evolution of the global (sky-averaged) 21-cm signal and corresponding power spectrum of the 21-cm fluctuations (shown at a fixed comoving angular scale) as a function of redshift. The shapes of the global signal and the power spectrum reflect the thermal and ionization histories, and are affected by properties of the sources. In particular, the deep absorption trough in the global 21-cm signal (around $z \sim 20$ in the figure) is visible only thanks to

the stellar Ly-$\alpha$ photons and is a direct evidence of the initially cold IGM which was gradually heated by X-rays. Features of the absorption trough depend on the properties of stars and X-ray sources and can be used to put constraints on the first luminous populations. Our poor understanding of high-redshift astrophysics translates into a vast landscape of plausible 21-cm signals in addition to what is shown in Figure 1. A large compilation of possible scenarios was presented recently by Cohen et al. (2017)[8] and Cohen et al. (2018)[9]. Here we focus on the global signal as the probe of the high-redshift environment and star formation.

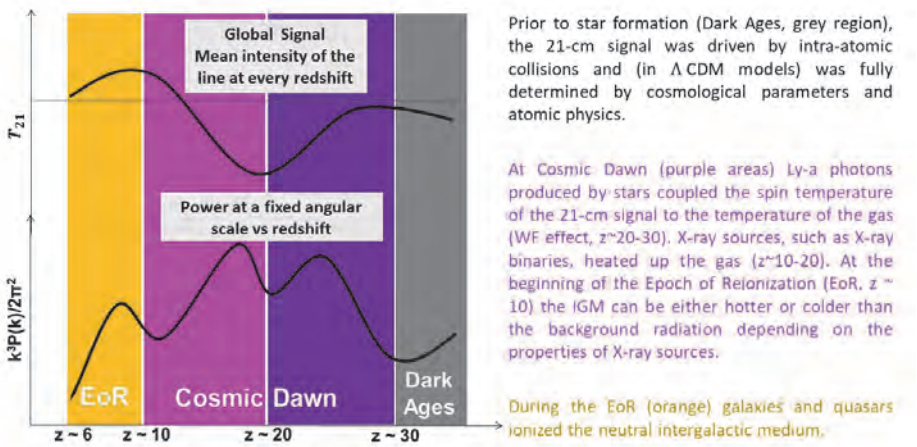

Fig. 1. Cartoon of the evolution of the global 21-cm signal (top) and of the power spectrum (bottom, shown at a fixed comoving angular scale) as a function of redshift. Cosmic epochs are shown with different colors including the Epoch of Reionization (EoR, orange), Cosmic Dawn (purple/magenta), and Dark Ages (grey). At each epoch, different types of sources had the dominant impact on the 21-cm signal (see the text on the right of the plot).

## 3. Global Signal Observations

The global 21-cm signal (computed by averaging Eq. (1) over the entire sky) is targeted by several observational teams around the world including the EDGES collaboration with the observational site located in Western Australia, SARAS based in India, LEDA observing from Owens Valley (California), PRIZM located on Marion Island. All these telescopes feature a very wide beam that measures the total sky radio signal composed of the cosmic microwave background which carries the imprint of neutral hydrogen at the intrinsic 21 cm wavelength, foreground emission of the Galaxy, integrated contribution of numerous radio sources as well as radio frequency interference. The signal is distorted by ionosphere and is convolved with

the instrumental beam. Extracting the cosmological contribution is very challenging and requires superb understanding of each component (e.g., calibration of the instrument[25]).

### 3.1. *Probing the EoR*

Observations with the EDGES High-Band antenna[24,26,27] and SARAS2[33,34] above 100 MHz yield consistent upper limits on the 21-cm signal from the EoR. In the framework of standard astrophysical modelling, the non-detections suggest that stars formed in small dark matter halos[27] and rule out extremely non-efficient X-ray heating sources[27,33,34]. As we have pointed out in Monsalve et al. (2019)[27], out of all existing observations (including the CMB optical depth[1] and constraints on the neutral fraction from high-redshift quasars[2,19,20]), properties of the high-redshift X-ray sources are uniquely constrained by the 21-cm data.

### 3.2. *Cosmic Dawn Signal*

Recently, the first detection of the sky-averaged 21-cm signal from $z \sim 13 - 27$ has been claimed based on two years of observations with the EDGES Low-Band antenna in the $50 - 100$ MHz frequency range[6]. The reported cosmological signal is centred at $\nu = 78.2$ MHz corresponding to $z = 17.2$, and features an absorption trough of $T_{21} = -500^{+200}_{-500}$ mK with the errors corresponding to 99% confidence including both thermal and systematic noise. If confirmed, this is the first (and only) observational evidence of the primordial star formation at $z \sim 20$ ($\sim 180$ million years after the Big Bang) and of the early X-ray heating at $z \sim 17$.

The frequency and width of the detected feature are in agreement with theoretical expectations requiring star formation in relatively small halos and subsequent efficient X-ray heating. Therefore, the location and width of the detected signal in the Low Band is consistent with the non-detections by EDGES High-Band and SARAS2.

However, the EDGES Low signal is at least twice as strong as predicted in standard astrophysical scenarios (based on the assumption of ΛCDM cosmology and hierarchical structure formation and assuming the CMB as the background radiation) where the strongest possible feature at $z = 17$ is $-209$ mK, with $T_{\rm CMB} = 49.5$ K and the coldest possible temperature of the IGM of $\sim 7.2$ K in the absence of X-ray heating sources. The observed $T_{21} < -300$ mK requires either the gas to be much colder (around 5.2 K) or the background radiation to be much stronger (around 67.2 K). Both requirements are impossible to satisfy by changing astrophysical modelling.

To explain the depth of the reported feature, exotic mechanisms have to be invoked. The amplitude of the observed 21-cm profile can be explained by non-gravitational interaction between dark matter and baryons, e.g., via Rutherford-like scattering, first proposed by Barkana (2018)[4] as a solution to the EDGES Low-Band anomaly. Because dark matter is cold, scattering could drain excess energy

from the gas lowering its kinetic temperature[11,28]. Even though this scenario is strongly constrained by observations, it is not completely ruled out and is still plausible for a narrow range of parameters including the dark matter mass, electric charge of dark matter particle and cross-section[5,23]. A smoking gun signature of the baryon-dark matter scattering with a velocity-dependent cross-section was shown to be an enhanced pattern of Baryon Acoustic Oscillations (BAO) in the 21-cm power spectrum[15,30]. The power spectrum itself could be boosted by as much as three orders of magnitude calling for verifications of the EDGES Low signal by interferometers.

An excess radio background above the CMB at the rest-frame 1.42 GHz at $z = 17$, even though is not expected in most theories, would also explain the detected feature[6,12]. Interestingly, evidence of excess radio background at low radio frequencies was reported by ARCADE2 at $3 - 90$ GHz[18] and recently confirmed by LWA1 at $40 - 80$ MHz[10]. However, it is still not clear what part of the observed excess is extragalactic[36]. The effect of an extra radio background is to deepen and widen the absorption trough. In our exploration[16] we found that the reported global signal is consistent with values of the amplitude of the excess radio background of $1.9 - 418$ relative to the CMB at the 78 MHz reference frequency (corresponding to $0.1 - 22\%$ of the CMB at 1.42 GHz). With the additional radio background, the EDGES Low-Band detection requires efficient star formation occurring in small dark matter halos of $M_h \sim 7.8 \times 10^8$ $M_\odot$ at $z = 17$ (or lower), which is consistent with the non-detections by High-Band instruments. If exists, the excess radio background is also expected to boost the 21-cm power spectrum compared to the standard astrophysical scenarios[16]. However, compared to the case of baryon-dark matter scattering, the power spectrum in the case of the extra radio background has a smooth shape (no BAO) and is not as strongly enhanced on large scales, as can be seen in Figure 5 of Fialkov & Barkana (2019)[16].

### 3.3. *Follow-ups and Concerns*

The reported global 21-cm signal is stronger than expected, implying that fluctuations in the signal might be stronger than predicted within standard astrophysical modelling. Therefore, low frequency observations with interferometers, such as LOFAR, which is currently conducting observations in the Low Band within the framework of the ACE proposal (1000 hours), and, once operational, the SKA, HERA and NenuFAR, will be able to verify the discovery. Interferometers can assess the nature of the enhanced 21-cm signal (if confirmed) by measuring the amplitude of the BAO. Verification with independent global signal experiments is also on the way using EDGES Mid-Band antenna, SARAS3, LEDA, and PRIZM. However, part of the community remains sceptical regarding the interpretation of the EDGES Low data, and concerns have been voiced in the literature[7,22,35].

### 3.4. *Conclusions*

With the first observational constraints at high radio frequencies (above 100 MHz) by EDGES High-Band and SARAS2, and the first claimed detection from $z \sim 17$, this is a truly exciting time for 21-cm cosmology. More than a year after the EDGES team claimed discovery of the global 21-cm signal from Cosmic Dawn, the nature and origin of this signal are still mysterious. If this signal is genuine, it is the first evidence of primordial star formation some 200 million years after the Big Bang.

The rotation of the galactic objects has been seen by asymmetric Doppler shift in the CMB data. Molecular hydrogen clouds at virial temperature may contribute to the galactic halo dark matter and they might be the reason for the observed rotational asymmetry in the galactic halos. We present a method to constrain the parameters of these virial clouds given that they are composed of a single fluid. The method is such that it should be possible to extend it to more than one fluid.

*Keywords*: Cosmic microwave background; virial theorem; dark matter; molecular hydrogen clouds.

## 1. Introduction

Half of the baryonic matter in the Universe is dark,[1–4] some of it may consist of molecular hydrogen clouds left over from the process of star formation, which would continue to collapse till their virial temperature reaches the CMB. To observe them one could look for $\gamma$-ray scintillation due to strikes by cosmic rays on $H_2$ molecules. A $\gamma$-ray corona around the Milky Way *was* discovered[5] with the expected angular distribution,[6] but it was not not clear how much, if any, of the carpet might be due to the proposed clouds. An alternative suggestion was to look for an asymmetric Doppler shift of these clouds in M31.[7]

The predicted effect was seen at a sufficient but low level in the WMAP data in 2011[8] and confirmed in the Planck data in 2014.[9] Objections that the blue shift may be due to "hot spots" were countered by the argument that the red shift could not be "cold spots" and were soon dispelled. The precision was sufficient to be

able to use for studying the rotation of the M31. This was followed by the same effect being seen in NGC 5128, M33, M82, M81.[10–13] However, the verification of the effect that it is due to the molecular clouds which led to its prediction, does not prove that it is due to the cause that led to the prediction. It could be partially or totally due to other interstellar matter. To be able to determine the nature of the cause, we need to model the molecular hydrogen clouds or dust clouds produced by the mechanism mentioned, or some mixture of the two, and compare with the data. One could then try to look at whether contamination of the spectrum by radiation from higher temperature sources could be distinguished.

## 2. The Virial Cloud Model

As these clouds are immersed in a heat bath of the CMB, they are isothermal. Since they have formed due to the Jeans instability, they must have a precisely defined Jeans radius and consequent Jeans mass. The density profile would then be given by the solution of the Lane-Emden equation subject to the boundary conditions that the density be literally *zero* (not approximately zero) at the boundary and the density profile be flat at the core. The latter condition says that the derivative of the density be zero at the core. We call them "virial clouds". Since James Jeans had applied the analysis for the formation of a normal star, he had taken the boundary condition that the density of the cloud merge with that of the interstellar medium (ISM) (which has been called "the Jeans fiddle").[14] In that case the central density had to be put in on an ad hoc basis. We do not need to do this. Further, we will want to extend the analysis (in later work) to a two-fluid model. As such, we obtain the equations from first principles in any case.

For an isothermal gas sphere, the temperature, $T$, is directly related to the mass of the molecule, $m_H$ in our case, and the average speed. The speed of the perturbation would have to be taken to be the speed of sound in the cloud, $c_s$. This gives

$$c_s = \sqrt{\frac{\gamma k T_{CMB}}{m_H}} \ , \tag{1}$$

where $\gamma$ is the adiabatic factor given by the ratio of the heat capacity at constant pressure to that at constant volume. At the densities and temperatures that we are considering no higher degrees of freedom would be excited and we would only have the translational degree, making the ideal gas approximation extremely good and so $\gamma = 5/3$. For our purpose, $m_H \approx 2.016$ g/mol and $T \approx 2.726^o K$, so

$$c_s \simeq 1.110 \times 10^4 \text{ km s}^{-1} \ . \tag{2}$$

Now the virial theorem $2K + U = 0$ gives the Jeans mass as[15]

$$M_J^2 \simeq \left(\frac{81}{32\pi\rho_c}\right)\left(\frac{3c_s^2}{5G}\right)^3 \ , \tag{3}$$

and the corresponding Jeans radius as

$$R_J^2 = \frac{27c_s^2}{20\pi\rho_c G} \ , \tag{4}$$

where, $\rho_c$ is the central density of the virial cloud, and $G$ is Newton's gravitational constant. We need to use the canonical ensemble distribution in order to calculate the density profile of the clouds which is given by the relation[16]

$$f(r,p) = \frac{1}{h^{3N}N!}\frac{1}{Z}exp\left(-\frac{H(r,p)}{kT_{CMB}}\right) \ , \tag{5}$$

where, $H(r,p)$ is the Hamiltonian of the system. The partition function $Z$ is the normalization factor, thus being the integral over phase space of the rest of this distribution function. The Hamiltonian is position dependent

$$H(r,p) = \frac{p^2}{2m_H} + \frac{GM(r)m_H}{r} \ , \tag{6}$$

and so the density distribution, is given by

$$\rho(r) = 8m_H^{5/2}\left(\frac{G\ \rho_c}{3k\ T_{CMB}}\right)^{3/2} exp\left(-\frac{GM(r)m_H}{rkT_{CMB}}\right), \tag{7}$$

where $M(r)$ is the mass of the cloud interior to $r$ given by

$$GM(r) = 4\pi\int_0^r \rho(q)q^2dq \ . \tag{8}$$

Our problem, then, is that the density is defined in terms of the integral of the density, i.e. we have an integral equation. Taking the natural logarithm of Eq. (7) we obtain

$$\int_0^r q^2\rho(q)dq = -\frac{rkT_{CMB}}{4\pi Gm_H}\ln\left(\frac{\rho_(r)}{\zeta}\right) \ , \tag{9}$$

where $\zeta = 8m_H^{5/2}(G\rho_c/3kT_{CMB})^{3/2}$. Taking the derivative of the above equation with respect to $r$, and substituting Eq. (7) we obtain the ordinary differential equation

$$r\frac{d\rho(r)}{dr} - r^2\left(\frac{4\pi Gm_H}{kT_{CMB}}\right)\rho^2(r) - \rho(r)\ln\left(\frac{\rho(r)}{\zeta}\right) = 0 \ . \tag{10}$$

It will be noticed that this is a nonlinear differential equation that cannot be solved by separation of variables. However, we do have the initial condition $\rho'(r)|_{r=0} = 0$ and the boundary condition that $\rho(R_J) = 0$. As such, we can solve it numerically by assuming a central density and the initial condition. If the density at the boundary is too high, we lower the central value and try again, till it becomes too low. At that stage we raise the central density a bit till it again becomes too high. Iteratively we bring the boundary density close enough to zero to be acceptable. The resulting density profile is shown in Fig. 1. One sees that the central density of the cloud is $\rho_c \simeq 1.60 \times 10^{-18}\ kgm^{-3}$, the radius is $R_J \simeq 0.030$pc, and the mass is $M_J \simeq 0.798M_\odot$.

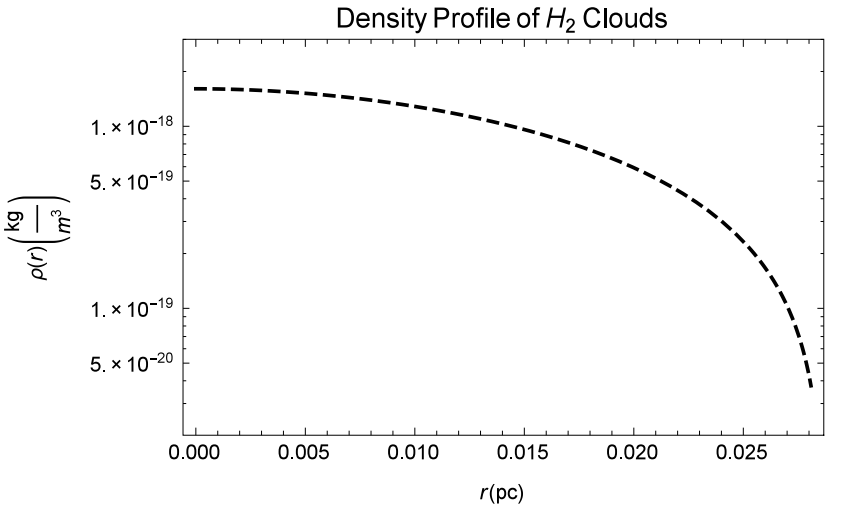

Fig. 1. The density of the virial molecular hydrogen cloud. It decreases monotonically from the central density, $\rho_c \simeq 1.60 \times 10^{-18}\ kgm^{-3}$, to zero at $r = R_J \simeq 0.030$ pc.

## 3. Luminosity of the Clouds

Since the virial clouds are at the CMB temperature, their luminosity is the CMB luminosity, except for their Doppler shift. Thus, we only need to look at the differential frequency shift, $\Delta\nu/\nu = -(v_{rot}/c)\cos\theta$, where $v_{rot}$ is the rotational velocity of the galactic halo, $c$ the speed of light and $\theta$ the angle between the direction of the velocity and the line of sight. Now $\Delta\nu/\nu = \Delta E/E = \Delta T/T$, so the differential energy is given by $\Delta E = (\Delta T/T)E$, where $E$ is the energy in the radiation for a patch of the sky corresponding to the size of the cloud. Now, as the luminosity, $L$, is proportional to the energy, we get the luminosity of the CMB for that patch. Then the luminosity of the cloud will be[17]

$$L_c = (\Delta\nu/\nu)L \simeq 1.486 \times 10^{-4} L\cos\theta\ . \tag{11}$$

Thus, as we scan across the halo, the luminosity will not change linearly but with $\cos\theta$. We can use this check for the Doppler shift explanation and obtain the energy associated with each cloud. This would directly give an estimate of the total number of clouds being seen.

## 4. Results and Discussions

The virial clouds are completely constrained by physical requirements, and so precisely determinable. They provide a satisfactory explanation of the observed asymmetry of the CMB Doppler shift in galactic halos. We have only considered pure molecular hydrogen clouds, but we also need to model these molecular hydrogen clouds contaminated with more or less interstellar dust which will be dealt with

elsewhere. We have not discussed the possible contamination of radiation by matter at high temperature. That needs to be done. The effect is probably negligible, but cannot be neglected without checking. One also needs to investigate how the clouds would evolve over billions of years, from the time when the CMB temperature was higher than it is now to the present value. Precisely how did the clouds lose energy over this period?

# Diffuse cosmic dipoles

Tiziana Trombetti*

*INAF, Istituto di Radioastronomia*
*Via Piero Gobetti, 101, 40129 Bologna, Italy*
**E-mail: trombetti@ira.inaf.it*

The boosting effects induced by the peculiar motion of an observer with respect to the Cosmic Microwave Background (CMB) rest frame can be explored to analyze the frequency dependence of the dipole. The improvements achievable with future CMB missions on our knowledge of CMB spectral distortions and Cosmic Infrared Background spectrum are discussed considering realistic uncertainties in relative calibration and foreground subtraction.

*Keywords*: CMB experiments, spectral distortions, reionization.

## 1. Introduction

The cosmic dipoles have a crucial relevance in cosmology since they are linked with the isotropy and homogeneity of the Universe at the largest scales. The observed dipole is a mixture of different contributions, including the observer motion with respect to the Cosmic Microwave Background (CMB) rest frame as well as dipoles from astrophysical (extragalactic and Galactic) sources. The CMB and Cosmic Infrared Background (CIB) spectra can be investigated by future anisotropy missions, as CORE[1] or LiteBIRD,[2] by exploring the frequency spectral behaviour of the dipole amplitude, thus without requiring an independent absolute calibration. Tiny CMB spectral distortions are predicted to be generated at different cosmic times in the evolving plasma. In the present work, I will focus on two well-defined types of signal, namely Bose-Einstein (BE) and Comptonization distortions. The precise interpretation of these signals could contribute to constraint primordial cosmological processes otherwise unexplored. The CIB spectrum amplitude and shape, still not well known, can provide a better understanding of the dust-obscured star-formation phase of galaxy evolution.

## 2. The CMB spectrum

One of the main features of the CMB is its frequency spectrum. To first approximation, it emerges from the thermalization epoch ($z \sim 10^6 - 10^7$) with a thermal black body (BB) shape owing to highly efficient interaction processes in the cosmic plasma, able to re-establish matter-radiation thermal equilibrium. Since COBE/FIRAS, no remarkable improvements have been achieved in the knowledge of CMB spectrum at $\nu \gtrsim 30$ GHz. Although gaining an absolute calibration precision of 0.57 mK, the FIRAS characterization of CIB amplitude and shape still presents a substantial uncertainty. To overcome the absolute calibration problem, it is possible to investigate the CMB and CIB spectra by looking at the frequency spectral behaviours of their dipole amplitude thanks to future CMB missions, as e.g.

CORE. The CMB spectrum can set constraints on various types of non-standard processes, including non evaporating BH spin, small scale magnetic fields power spectra, vacuum energy density and particle decay.

### 2.1. *Spectral distortions*

Different energy injections in the radiation field due to fundamental unavoidable processes occurring at different cosmic times cause the departure of CMB spectrum from a perfect BB.

At early times, a BE-like distorted spectrum with a positive (dimensionless) chemical potential is produced by the dissipation of primordial perturbations at small scales,[3] damped by photon diffusion and non-linear processes and then invisible in CMB anisotropies.[4] Moreover, because of the matter temperature faster decrease with respect to that of radiation temperature in an expanding Universe, colder electrons induce Bose condensation of CMB photons, mainly resulting into a BE-like distortion with negative chemical potential. The photon occupation number of the BE spectrum is $\eta_{BE} = 1/(e^{x_e+\mu} - 1)$, where $\mu$ is the chemical potential that quantifies the fractional energy, $\Delta\varepsilon/\varepsilon_i$, exchanged in the plasma during the interaction, $x_e = x/\phi(z)$, $\phi(z) = T_e(z)/T_{CMB}(z)$, being $T_e(z)$ the electron temperature, $T_{CMB} = T_0(1+z)$, $T_0$ the present CMB temperature in the BB approximation and $x = h\nu/kT_{CMB}$ a redshift independent, dimensionless frequency. For small distortions, $\mu \simeq 1.4\Delta\varepsilon/\varepsilon_i$ and $\phi_{BE} \simeq (1 - 1.11\mu)^{-1/4}$.[a]

Cosmological reionization associated with the early stages of structure and star formation induces electron heating that is responsible for late type distortions, described, at high frequency,[b] by a Comptonization spectrum.[7] It is quantified by the Comptonization parameter $u(t) = \int_{t_i}^{t}[(\phi - \phi_i)/\phi](k_B T_e/m_e c^2) n_e \sigma_T c dt$. For small energy injections and integrating over the relevant epochs $u \simeq (1/4)\Delta\varepsilon/\varepsilon_i$.

## 3. Future CMB missions

Among the many different classes of CMB missions, here I will focus on three recent proposals with concepts and designs aimed at improving the measure of polarization anisotropies and at minimizing the impact of foregrounds on CMB maps using a large number of frequency channels, with relevant outcomes for e.g. our knowledge of the reionization process and the primordial background of gravitational waves.

The Primordial Inflation Explorer[8] (PIXIE) is an Explorer-class mission submitted to NASA in 2011 aimed at mapping the CMB and the diffuse astrophysical foregrounds over the full sky, from 30 GHz to 6 THz (1 cm to 50 $\mu$m) with degree

[a] At decreasing frequencies, photon emission processes produce a frequency dependent, decreasing chemical potential and the convergency to a blackbody at matter temperature at extremely low frequencies.[5] For positive (negative) $\mu$ they imply a minimum (maximum) in the brightness temperature, as well as the avoiding of the divergency of the BE spectrum for negative $\mu$.

[b] Associated free-free distortions are instead relevant at low frequencies.[6]

resolution and high signal to noise ratio in absolute intensity and linear polarization. It is designed to perform absolute spectroscopy measurements and to simultaneously observe the large-scale CMB B-modes. It will provide crucial constraints on Universe ionization history, on CIB spectrum and anisotropies. Indeed, PIXIE will trace CIB monopole, dipole and higher order power spectrum up to $z \sim 3$ for matter distribution analyses. The cross correlation of temperature and polarization anisotropies will produce more stringent constraints on the optical depth parameter, the gas temperature and the Universe reionization at $z \sim 10$. Great hopes on CMB spectral distortion parameters are expected from PIXIE, thanks to its absolute calibration of the CMB temperature measure with a precision about $10^3$ times better than FIRAS.

LiteBIRD is a Lite (Light) Satellite for the studies of B-mode polarization and Inflation from cosmic background Radiation Detection at the extremely early Universe proposed to JAXA in February 2015. It is a highly-targeted, low-cost Japanese B-mode mission concept, aimed at the B-modes detection at the level of $r \sim 10^{-3}$, its main scientific goal being one order of magnitude better than what can be done from the ground. Its primary strategy is the focus on $r$ measurement in synergy with ground based super telescopes which are necessary for an accurate subtraction of the lensing contribution to B-mode.

Cosmic ORigins Explorer (CORE), submitted to the European Space Agency (ESA) in October 2016 in response to a call for future medium-sized space mission proposals for the M5 launch opportunity of ESAs Cosmic Vision programme, is a satellite dedicated to microwave polarization. CORE is targeted to provide and exploit definitive maps of CMB polarization anisotropies at large and medium angular scales, with a suppression of all systematic effects at an extreme accuracy level. The instrument will host about 19 frequency channels over a range spanning the 60–600 GHz interval, in order to control astrophysical foreground emissions.

## 4. CMB and CIB dipoles

A relative velocity between an observer and the CMB rest frame induces a dipole in the observed CMB sky temperature through the Doppler effect. This dipole, the so called $\ell = 1$ anisotropy, is likely dominated by the velocity of the Solar System, $\vec{\beta_S} = \vec{v_S}/\vec{c}$, with respect to the CMB (Solar dipole), with a seasonal modulation due to the velocity of the Earth or the satellite, $\vec{\beta_o}$, with respect to the Sun (orbital dipole).

In addition, an intrinsic dipole is induced by the Sachs-Wolfe effect at the last-scattering surface and by a large-scale dipolar Newtonian potential.[9] In a ΛCDM cosmology, this dipole should be of order of the Sachs-Wolfe plateau amplitude ($10^{-5}$), but it could be larger in the case of more exotic models. Neglecting the orbital dipole (useful for calibration aims), and denoting with $\vec{\beta}$ the relative velocity of the Solar dipole, it is possible to forecast the CORE improvements in the dipole recovery including also potential foreground and calibration residuals.[10] The

dipole amplitude is directly proportional to the first (logarithmic) derivative with respect to the frequency of the photon occupation number, $\eta(\nu)$, which is related to the thermodynamic temperature, $T_{therm}(\nu)$, defined as the temperature of the blackbody having the same $\eta(\nu)$ at the frequency $\nu$, by:

$$T_{therm} = \frac{h\nu}{k_B \ln(1 + 1/\eta(\nu))}. \tag{1}$$

Differencing the measure of $T_{therm}$ in the direction of motion and in its perpendicular direction one gets:[11]

$$\Delta T_{therm} = \frac{h\nu}{k_B} \left\{ \frac{1}{\ln[1 + 1/\eta(\nu)]} - \frac{1}{\ln[1 + 1/\eta(\nu(1+\beta))]} \right\}. \tag{2}$$

To first order in $\beta$, $\Delta T_{therm}$ is approximated by:

$$\Delta T_{therm} \simeq -\frac{x\beta T_0}{(1+\eta)\ln^2(1+1/\eta)} \frac{d\ln\eta}{d\ln x}. \tag{3}$$

A direct determination of the CIB spectral shape is not trivial since it requires absolute intensity measurements and it is also limited by foreground signal, that, in the case of Galactic emission, has a similar shape. Even though the dipole amplitude is about $10^{-3}$ of the monopole, its spatial distribution is known, hence, an indirect approach may provide in the future a robust measurement of the CIB. The analytic form of the CIB spectrum, observed at present time, is:[12]

$$\eta_{CIB} = \frac{c^2}{2h\nu^3} I_{CIB}(\nu) = I_0 \left( \frac{k_B T_{CIB}}{h\nu_0} \right)^{k_F} \frac{x_{CIB}^{k_F}}{e^{x_{CIB}} - 1}, \tag{4}$$

with $T_{CIB} = (18.5 \pm 1.2)$ K, $x_{CIB} = h\nu/k_B T_{CIB} = 7.78(\nu/\nu_0)$, $\nu_0 = 3 \times 10^{12}$ Hz and $k_F = 0.64 \pm 0.12$. Here $I_0$ sets the CIB spectrum amplitude, its best-fit value being $(1.3 \pm 0.4) \times 10^{-5}$. The CIB dipole should be detectable by CORE in its highest frequency bands. Defining the motion vector of the observer, from the dipole direction of the *Planck* 2015 release, I produced the maps at a given observational frequency, $\nu_{obs}$, from the photon distribution function, $\eta_{BB,dist}$, for the assumed type of spectra (BB, CIB, BE or Comptonization (C)) at the frequency $\nu_{obs}$ multiplied by $(1 - \hat{n} \cdot \vec{\beta})/(1 - \beta^2)^{1/2}$ to account for all the possible sky directions with respect to the observer peculiar velocity. The observed signal map in thermodynamic temperature is a generalization of Eq. (1):

$$T_{therm}^{BB/dist}(\nu, \hat{n}, \vec{\beta}) = \frac{xT_0}{\ln(1/(\eta(\nu, \hat{n}, \vec{\beta})^{BB/dist} + 1))}, \tag{5}$$

where $\eta(\nu, \hat{n}, \vec{\beta}) = \eta(\nu')$ with $\nu' = \nu((1 - \hat{n} \cdot \vec{\beta})/(1 - \beta^2)^{1/2}$. Decomposing the maps into spherical harmonics and reproducing them from the $a_{\ell m}$ up to a desired multipole $\ell_{max}$, I derived the expected signal (see Fig. 1) finding that it is important for the dipole, can be considerable for the quadrupole and, depending on the distortion parameters, still not negligible for the octupole (although depending on the amplitude relative to experimental noise levels). For higher-order multipoles, the signal is essentially negligible.

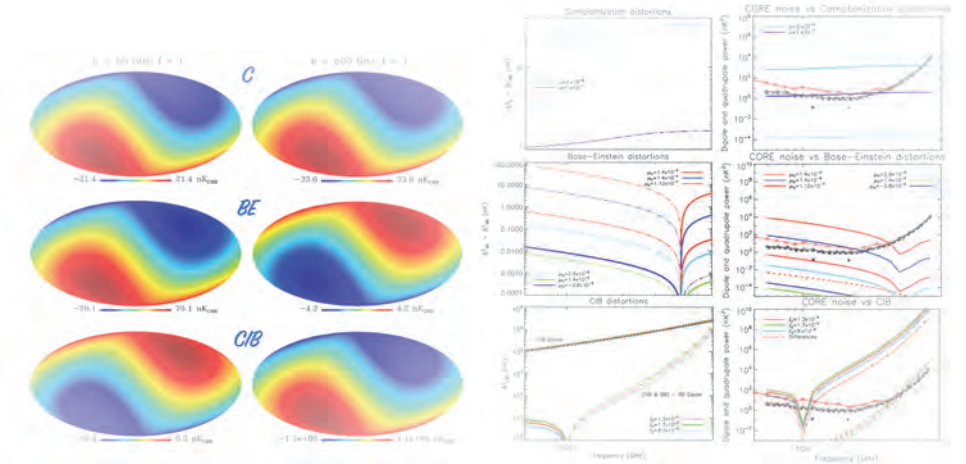

Fig. 1. Left: typical maps of dipole pattern (after the subtraction of the CMB blackbody dipole) for the three considered types of signal. Middle: dipole frequency behaviour. Right: angular power spectrum of the maps of dipole pattern compared with the sensitivity (diamonds) of CORE (black) and LiteBIRD (red). The quadrupole signal (dashes) is also shown in one case of BE distortion and in the case of CIB. See also the legend and the text. A dapted from Ref. 10 [©SISSA Medialab Srl. Reproduced by permission of IOP Publishing. All rights reserved].

## 5. Results and Conclusions

To recover the dipole parameters (amplitude and direction) it is essential to perform Markov Chain Monte Carlo (MCMC) analyses. I assumed the *Planck* common mask 76 (in temperature), publicly available from the *Planck* Legacy Archive (PLA),[13] exploiting its extension that excludes all the pixels at $|b| \leq 30°$. I first explored the dipole reconstruction ability for different frequency channels and then the implications for CMB spectral distortions and CIB starting from the ideal case (i.e., without calibration errors or sky residuals). The dipole can be parametrized as $d(\hat{n}) = A\hat{n} \cdot \hat{n}_0 + T_0$, where $\hat{n}$ and $\hat{n}_0$ are the unit vectors defined respectively by the Galactic longitudes and latitudes $(l, b)$ and $(l_0, b_0)$. The dipole map used in the simulations was generated assuming the measured dipole amplitude best-fit values, $A = (3.3645 \pm 0.002)$ mK, and direction, $l_0 = 264.00 \pm 0.03$ and $b_0 = 48.24 \pm 0.02$, as found in *Planck* 2015 release.[14]

To quantify the ideal CORE sensitivity to spectral distortion parameters and CIB amplitude, I carried out detailed simulations assuming a certain model and quantifying the accuracy level at which (in the presence of noise and of potential residuals) the key parameters can be recovered. I consider twelve, physically or observationally motivated, reference cases, from a (reference) blackbody spectrum, a CIB spectrum at the FIRAS best-fit amplitude, BE and C spectra with different $\mu_0$ and $u$ values. For each model I generate an ideal sky (the prediction) and a sky with white Gaussian noise realizations (simulated data). I calculated $\Delta\chi^2$ to quantify the significance level at which each model can be potentially detected or

ruled out. I consider three approaches: (a) analyzing each of the 19 frequency channels (assumed independent from each other); (b) using the 171 (19 ·18/2) combinations of the maps differences from pairs of frequency bands; (c) combining (a) and (b).

Approach (a) compares the dipole amplitude of a distorted spectrum with that of the blackbody, being sensitive to the overall difference between the two cases, while approach (b) compares the dipole signal at different frequencies for each type of spectrum, being so sensitive to its slope. The significance of the CIB amplitude recovery is increased in case b), because of the very steep frequency shape of its dipole spectrum. In general, this does not occur for CMB distortion parameters, and, in particular, approach (b) can make the recovery of the Comptonization distortion more difficult. Method c) typically results in an overall advantage. Including potential residuals from imperfect foreground subtraction and calibration (characterized by effective parameters $E_{\rm cal}$ and $E_{\rm for}$) may affect these results, but still the improvement for $I_0^{CIB}$ ranges from a factor of 4 (a) to a factor of about 15 or 20 for (b) and (c), respectively. The recovery of CMB spectral distortion parameters is also very promising. Including the extended mask in case c), I find a significant improvement with respect to the full sky: the significance of the CIB amplitude recovery improves by about 50% and that on the BE distortion by about 20%, indicating the relevance of optimising the selection of the sky region. Tab. 1 summarizes the main results expressed in terms of a factor characterizing the improvement with respect to FIRAS.

Table 1. Predicted improvement in the recovery of the distortion parameters with respect to FIRAS for different calibration and foreground residual assumptions. "P06" stands for the *P*lanck common mask, while "P06ext" is the extended P06 mask. When not stated, all values refer to $E_{\rm cal}$ and $E_{\rm for}$ at $N_{\rm side} = 64$. From Ref. 10 [].

The *Planck* mission has clearly demonstrated that, although not specifically designed for the observation of extragalactic sources, the space-borne experiments aimed at investigating the Cosmic Microwave Background (CMB) have the potential to bring breakthrough science also in this field. One example is the detection of high-$z$ galaxies with extreme gravitational amplifications. The combination of flux boosting and of stretching of the images has allowed the investigation of the structure of galaxies at $z \simeq 3$ with the astounding spatial resolution of $\simeq 60$ pc. Another example is the detection of proto-clusters of dusty galaxies at high $z$, when they may not yet possess the hot intergalactic medium allowing their detection in X-rays or via the Sunyaev-Zeldovich effect.

## 1. Introduction

Extragalactic sources are one of the foregrounds that contaminate the maps produced by experiments aimed at mapping the Cosmic Microwave Background (CMB). On the other hand, space borne CMB experiments, like *Planck*, have properties that allow them to produce unique surveys of extragalactic sources:

- they cover a broad spectral range hardly, if at all, accessible from the ground and only lightly covered by other space missions;

- they offer an all-sky coverage, ideal to look for rare phenomena;
- they have a poor angular resolution that is, in general, a strong limitation for extragalactic surveys but, as we will see, becomes a resource to detect high-$z$ proto-clusters of dusty galaxies.

Two main populations of extragalactic sources show up in *Planck*'s frequency range, extending from 30 to 857 GHz: blazars, that dominate up to about 150–200 GHz, and active star-forming galaxies dominating at higher frequencies (Fig. 1).

*Planck* has provided unique information on these source populations. In this paper we will confine ourselves to only two examples: strongly gravitationally lensed high-$z$ galaxies (Sect. 2) and proto-clusters of dusty galaxies (Sect. 3). In Sect. 4 we summarize our main conclusions.

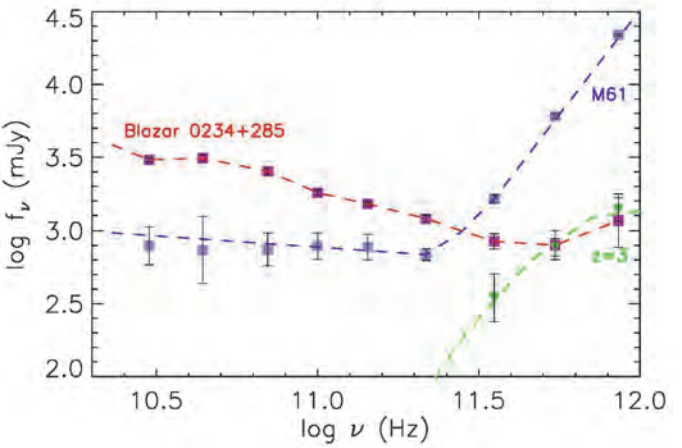

Fig. 1. Examples of spectral energy distributions (SEDs) of the extragalactic sources detected by *Planck*: a blazar, a nearby star-forming galaxy (M61) and a strongly lensed galaxy at $z \simeq 3$. Data points are *Planck* measurements.

## 2. Strongly lensed galaxies

*Herschel* surveys have demonstrated that bright sub-mm galaxies, such as those detected by *Planck*, have a strikingly bimodal redshift distribution (Fig. 2). Unlensed galaxies are local (only a few are at $z \geq 0.06$), while the gravitationally lensed ones are at $z > 1$. This implies that the two sub-populations can be easily distinguished[2,3].

Another nice property of sub-mm selected strongly lensed galaxies is that they show up in a waveband different from that of the foreground lens: the former are bright at far-IR/sub-mm wavelengths but very faint in the optical because of dust obscuration; on the contrary, the latter are mostly passively evolving early-type galaxies, essentially invisible at far-IR/sub-mm wavelengths, but bright in the

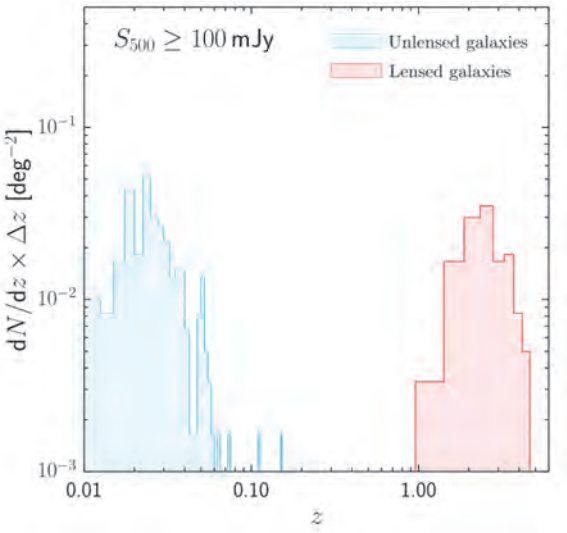

Fig. 2. Redshift distribution of dusty galaxies detected by the *Herschel*–ATLAS survey with $S_{500\mu m} > 100$ mJy (Ref. 1).

optical and in the near-IR. Hence there is no mutual contamination of the two images.

The 11 strongly lensed galaxies discovered on *Planck* maps[4] have redshifts in the range 2.2–3.6. For comparison, those discovered by optical searches have mostly $z < 1$ (cf. Fig. 7 of Ref. 5). Thus optical/near-IR and (sub-)mm surveys are nicely complementary: the former see evolved galaxies while the latter catch them in the most active star-formation phase.

This brings us to the main reason why the (sub-)mm selection of strongly lensed galaxies is important: high spatial and spectral resolution follow-up of these objects will have a crucial role in providing answers to major, still open issues on galaxy formation and evolution: which are the main physical mechanisms shaping the galaxy properties: in situ processes? interactions? mergers? cold flows from the intergalactic medium? How do feedback processes work? To settle these issues we need direct information on the structure and the dynamics of high-$z$ galaxies. But these are compact, with typical sizes of 1–2 kpc (e.g., Ref. 6), corresponding to angular sizes of 0.1–0.2 arcsec at $z \simeq 2$–3. Thus they are hardly resolved even by ALMA and by the HST. If they are resolved, high enough S/N ratios per resolution element are achieved only for the brightest galaxies, probably not representative of the general population.

Strong gravitational lensing provides a solution to these problems. The *Planck* dusty GEMS (Gravitationally Enhanced subMillimetre Sources)[4] have estimated magnifications, $\mu$, in the range 10–50, making them the brightest sub-mm sources in the sky. The gravitational stretching of the images has allowed ALMA observations

of one of them, PLCK_G244.8+54.9 at $z \simeq 3.0$ with $\mu \simeq 30$, to reach the astounding spatial resolution of $\simeq 60$ pc, substantially smaller than the size of Galactic giant molecular clouds[7].

Cañameras et al.[7] have also obtained CO spectroscopy, measuring the kinematics of the molecular gas with an uncertainty of 40–50 km/s. This spectral resolution makes possible a direct investigation of massive outflows driven by AGN feedback at high $z$. In this way Spilker et al.[8] were able to detect a fast (800 km/s) molecular outflow due to feedback in a strongly lensed galaxy at $z = 5.3$. The outflow carries mass at a rate close to the SFR and can thus remove a large fraction of the gas available for star-formation.

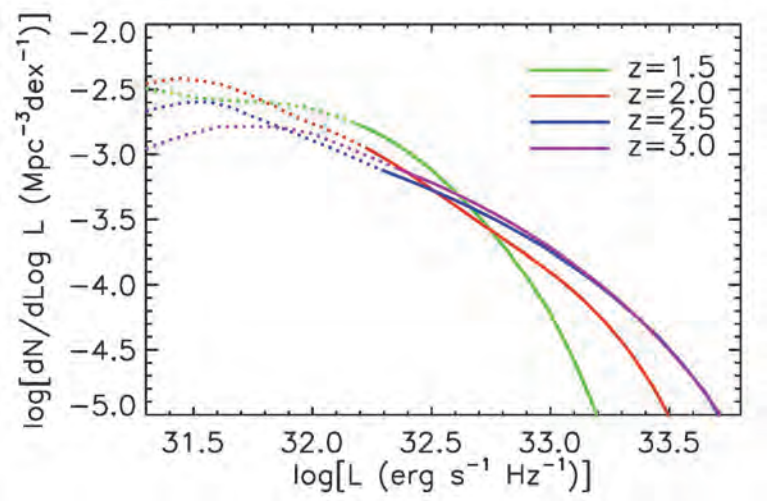

Fig. 3. Portions of the 500 $\mu$m galaxy luminosity function at various $z$ covered by *Herschel* surveys to a flux limit of 50mJy. The corresponding fraction of resolved luminosity density ranges from 29% to 66%.

## 3. Protoclusters

Classical techniques for detecting galaxy clusters (optical/near-IR "red sequence", X-ray emission, Sunyaev-Zeldovich (SZ) effect) preferentially or exclusively select evolved objects, with mature galaxy populations and a hot intra-cluster medium. As a result, most known clusters are at $z < 1.5$, i.e. below the peak of global star-formation activity.

This reflects the anti-correlation between density and specific star-formation rate (sSFR), well established in the low-$z$ universe. However the sSFR in clusters increases with increasing redshift faster than in the field matching field values at $z \gtrsim 1.2$[11]. Correspondingly the "red sequence" disappears and the hot intergalactic gas, making clusters visible in X-rays or via the SZ effect, is no longer necessarily in place.

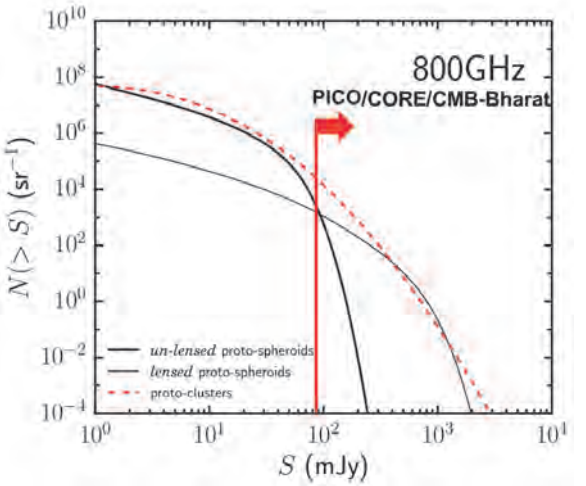

Fig. 4. Integral number ounts at 800 GHz of lensed and unlensed dusty galaxies predicted by the model by Ref. 9 and of proto-clusters[10]. The vertical red line shows the estimated detection limit of planned next generation CMB experiments.

On the other hand, member galaxies become increasingly bright at far-IR/sub-mm wavelengths. As mentioned above, individual high-$z$ galaxies are not detectable by space-borne CMB experiments unless their flux densities are boosted by gravitational lensing. However, the summed emission of galaxies within a strong over-density (proto-cluster) shows up as an intensity peak in the maps.

As illustrated by Fig. 3, proto-clusters stand out more clearly in low-resolution sub-mm maps, such as those that have been provided by *Planck* or will hopefully be provided by planned next-generation experiments like PICO, CORE and CMB Bharat, than in much higher resolution point source surveys at the same wavelengths because the available point source surveys miss a substantial fraction of the cluster. This is in keeping with the findings[12,13] that the sub-mm flux densities of proto-cluster candidates measured by *Planck* are about 2 to 3 times larger than the summed luminosities of member galaxies detected with *Herschel* within the *Planck* beam, although part of the difference is to be attributed to the 'flux boosting' affecting the low signal-to-noise *Planck* measurements.

Although *Planck* has demonstrated the power of low-resolution surveys for the study of large-scale structure, its resolution was too poor to detect individual proto-clusters[10]. Studies of the high-$z$ 2-point correlation function and *Herschel* images of the few sub-mm bright protoclusters detected so far, at $z$ of up to 4, indicate sizes of $\simeq 1'$ for the cluster cores, nicely matching the FWHM of the highest frequency channels of planned next generation experiments.

As illustrated by Fig. 4, such experiments will detect many tens of thousands of these objects as peaks in sub-mm maps, in addition to the evolved ones, detected by the SZ effect. This will constitute a real breakthrough in the observational

validation of the formation history of the most massive dark matter halos, traced by clusters, a crucial test of models for structure formation. Follow-up observations will characterize the properties of member galaxies, probing the galaxy evolution in dense environments and shedding light on the complex physical processes driving it.

## 4. Conclusions

Planck has demonstrated the unique capability of all-sky CMB experiments to explore astrophysical phenomena otherwise unaccessible to the present day instrumentation.

Those presented are only examples. Other examples are blazar astrophysics and high frequency polarization of extragalactic sources, including dusty galaxies.

Proposed next generation CMB experiments, like PICO, CORE and CMB Bharat, have the capability to make a giant leap forward in these fields by detecting several thousands high-$z$ strongly lensed galaxies at least up to $z \simeq 5$ and proto-clusters at least up to $z \simeq 4$.

We study the effects of a uniform magnetic field on the evolution of cosmological perturbations, in a full relativistic framework, considering the effects of anisotropies. We take advantage of the synchronous gauge to simplify the equations. We study both super-horizon scales in radiation dominated universe and sub-horizon scales in both a full relativistic framework and the Newtonian limit in case of adiabatic sound speed.

*Keywords*: Cosmology; Cosmological perturbations; Magnetic fields.

## 1. Introduction

There is strong evidence of the presence and importance of magnetic fields in cosmology[1] and it is possible that such fields, although small,[2–4] are related to the anisotropy of large scale structures (for a detailed introduction, see[5]). There are a lot of studies in literature about their effects in both Newtonian limit, considering the full anisotropy[5], and in full relativistic treatment, but inside a FRW model and discarding anisotropic effects.[6,7] Our aim is to incorporate anisotropic effects inside the full relativistic treatment, while using the synchronous gauge to manage the increased mathematical complexity.

In Sec. 2 we develop some corrections to a former analysis of the background model,[3] then in Sec. 3 we obtain the perturbed equations. We discuss the problem of gauge freedom in Sec. 4 and we analyse the solutions in physical interesting regimes in Sec. 5.

## 2. Background model

We study a uniform Bianchi I model with a perfect barotropic fluid and a magnetic field aligned in the $z$ direction. Our metric is

$$g_{\mu\nu} = \mathrm{diag}\left(-1, a^2(t), a^2(t), c^2(t)\right). \tag{1}$$

The background fluid has velocity $u^\mu = (1, 0, 0, 0)$, energy density $\rho$ and pressure $p = w\rho$, with $w = \text{const}$. The magnetic field is $B^\mu = (0, 0, 0, B^3)$, with energy density $B^2 = B_\mu B^\mu = c^2 B^3 B^3$ in the Lorentz–Heaviside units.

We follow exactly[3] to solve this system, however we find slightly different solutions due to different assumptions and we add isotropic corrections, while that paper only cares about anisotropic ones.

Defining the isotropic expansion $H$ and the anisotropy parameter $S$ as

$$3H = 2\frac{\dot{a}}{a} + \frac{\dot{c}}{c}, \qquad HS = \frac{\dot{a}}{a} - \frac{\dot{c}}{c} \tag{2}$$

and using the Alfvn speed

$$v_A^2 = \frac{B^2/2}{\rho} \tag{3}$$

to describe the magnetic field we write the evolution equations for the system. The Einstein equation with components 00 reads

$$3\dot{H} + H^2\left(3 + \frac{2}{3}S^2\right) = -\left[\frac{1}{2}(1 + 3w) + v_A^2\right]\rho, \tag{4}$$

subtracting the Einstein 33 equation from the 11 equation we get

$$H\dot{S} + \dot{H}S + 3H^2 S = 2v_a^2\rho \tag{5}$$

and contracting the Einstein equations over the spatial indices

$$3\dot{H} + 9H^2 = \left[\frac{3}{2}(1 - w) + v_A^2\right]\rho. \tag{6}$$

The fluid energy conservation and the magnetic field energy conservation read

$$\dot{\rho} + 3H(1 + w)\rho = 0, \qquad (\dot{B^2}) + 4\frac{\dot{a}}{a}B^2 = 0; \tag{7}$$

the last one gives

$$(\dot{v_A^2}) = v_A^2 H\left(3w - 1 - \frac{4}{3}S\right). \tag{8}$$

Considering the magnetic field small and solving the equations perturbatively, at 0-order one simply recovers FRW

$$H_{(0)} = \frac{2}{3(1 + w)t}, \qquad \rho_{(0)} = 3H_{(0)}^2, \qquad S_{(0)} = 0. \tag{9}$$

Substituting this solution inside the equations we solve in order Eq. (8) that gives the temporal law of $v_A^2$, Eq. (5) that describes the evolution of $S$, Eq. (4) and Eq. (6) that describe together the isotropic corrections to $H$ and $\rho$. We find the following solutions.

### 2.1. *Radiation dominated universe*

The background fluid is ultra-relativistic with $w = 1/3$ and the solution is

$$v_A^2 = v_{A0}^2 = \text{const}, \qquad t_0 = \text{const}, \qquad S = 6v_A^2 = 6v_{A0}^2 \tag{10}$$

$$a \propto \left(\frac{t}{t_0}\right)^{1/2} \left(1 + v_{A0}^2 \ln\left(\frac{t}{t_0}\right)\right), \qquad c \propto \left(\frac{t}{t_0}\right)^{1/2} \left(1 - 2v_{A0}^2 \ln\left(\frac{t}{t_0}\right)\right) \tag{11}$$

$$H = \frac{1}{2t}, \qquad \rho = \frac{3}{4t^2}(1 - v_{A0}^2). \tag{12}$$

### 2.2. *Matter dominated universe*

The background fluid is non-relativistic with $w = 0$ and the solution is

$$v_A^2 = v_{A0}^2 \left(\frac{t}{t_0}\right)^{-2/3}, \qquad v_{A0}^2, t_0 = \text{const}, \qquad S(t) = 12v_A^2(t) \tag{13}$$

$$a \propto \left(\frac{t}{t_0}\right)^{2/3} - 3v_{A0}^2, \qquad c \propto \left(\frac{t}{t_0}\right)^{2/3} + 9v_{A0}^2 \tag{14}$$

$$H = \frac{2}{3t}(1 - v_A^2(t)), \qquad \rho = \frac{4}{3t^2}\left(1 - 3v_A^2(t)\right). \tag{15}$$

## 3. Perturbed model

We perturb the background model allowing small inhomogeneities. We take the starting equations from[6], but instead of solving them in full covariant formalism we focus on the synchronous gauge; this choice will make their solution a lot easier. Enforcing the synchronous gauge and the spatiality of the magnetic field, represented by $B_\mu u^\mu = 0$, the perturbed variables are

$$g_{\mu\nu} = g_{\mu\nu}^{\text{back}} + \delta g_{\mu\nu}, \qquad \gamma_{\mu\nu} = \delta g_{\mu\nu}, \qquad \gamma_{0\nu} = \gamma_{\mu 0} = 0 \tag{16a}$$

$$g_{\mu\rho} g^{\rho\nu} = \delta_\mu^\nu \implies \delta g^{\mu\nu} = -\gamma^{\mu\nu} \tag{16b}$$

$$u^\mu = u^\mu_{\text{back}} + \delta u^\mu, \qquad u_\mu u^\mu = -1 \implies \delta u^0 = 0 \tag{16c}$$

$$\rho = \rho^{\text{back}} + \delta\rho, \qquad p = p^{\text{back}} + \delta p, \qquad \delta p = v_S^2 \delta\rho \tag{16d}$$

$$B^2 = B^2_{\text{back}} + \delta(B^2), \qquad \delta\left(B_\mu B^\mu\right) = \delta\left(B^2\right) = \gamma_{33} B^3 B^3 + 2c^2 B^3 \delta B^3 \tag{16e}$$

$$B_\mu u^\mu = 0 \implies \delta B^0 = c^2 B^3 \delta u^3, \tag{16f}$$

where "back" marks background variables and the indices of $\gamma_{\mu\nu}$ are raised and lowered with the unperturbed metric. For simplicity, we define the following perturbation variables:

$$\Delta = \frac{\delta\rho}{(1+w)\rho}, \qquad G = \frac{1}{2}\gamma_i^i, \qquad T = \frac{1}{2}\gamma_3^3, \qquad M = \frac{\delta\left(B^2\right)}{B^2}. \tag{17}$$

We will now write the relevant equations in synchronous gauge. The full covariant equations can be found in[6]; they form a very complicated system, so we will write them and solve them in the limit of small magnetic fields: we will make a

Fourier expansion for the spatial components $e^{ik_j x^j}$ and keep only terms up to first order in $v_A^2$. The sound speed is related to the barotropic index $w$ through

$$\dot{w} = -3H(1+w)(v_S^2 - w) \implies v_S^2 = w \text{ if } w = \text{const}, \tag{18}$$

but we will distinguish them if $v_S^2$ is multiplied by $k_i k^i$ or $k_3 k^3$ and we will simplify them in all other circumstances in which they cancel each other; we will explain this choice in the following.

Through some algebraic manipulations, the perturbed equations take the following forms (we refer to[8] for the full calculations): the fluid energy conservation is

$$\dot{G} = -\dot{\Delta} - \partial_i \delta u^i; \tag{19}$$

the magnetic energy conservation is

$$\dot{M} = -2\left(\partial_i \delta u^i - \partial_3 \delta u^3 + \dot{G} - \dot{T}\right) = 2\left(\dot{\Delta} + \dot{T} + \partial_3 \delta u^3\right); \tag{20}$$

the Einstein 00 equation, through the use of Eq. (19), reads

$$\begin{aligned} &\ddot{\Delta} + 2H\left(1 + \frac{1}{3}S\right)\dot{\Delta} - \frac{1}{2}(1+3v_S^2)(1+w)\rho\Delta + \partial_0\partial_i\delta u^i \\ &\quad + 2H\left(1+\frac{1}{3}S\right)\partial_i\delta u^i + \frac{4}{3(1+w)}S\frac{\dot{T}}{t} - \frac{4}{3(1+w)^2}v_A^2\frac{M}{t^2} = 0. \end{aligned} \tag{21}$$

from the Einstein 33 and 03 equations we get

$$\begin{aligned} &3(1+w)(k_i k^i \dot{T} - k_3 k^3 \dot{G}) + 3(1+w)\dddot{T} + 10\frac{\ddot{T}}{t} + 2\frac{1-3w}{1+w}\frac{\dot{T}}{t^2} + \frac{2}{3}\frac{1-3w}{1+w}\frac{\dot{G}}{t^2} \\ &\quad + 2\frac{\ddot{G}}{t} - 2\left[1 - v_S^2 - (\dot{v_S^2})\right]\frac{\dot{\Delta}}{t^2} + \frac{4}{3}(1-v_S^2)\frac{1+3w}{1+w}\frac{\Delta}{t^3} - 8\frac{\partial_3\delta u^3}{t^2} = 0; \end{aligned} \tag{22}$$

the divergence of the momentum conservation is

$$\begin{aligned} &\left(1 + \frac{2}{1+w}v_A^2\right)\partial_0\partial_i\delta u^i + \left[(2-3w)H + \left(\frac{v_A^2}{1+w} + \frac{1}{3}S\right)\frac{4}{3(1+w)}\frac{1}{t}\right]\partial_i\delta u^i \\ &\quad = -v_S^2\partial_i\partial^i\Delta - \frac{v_A^2}{1+w}\partial_i\partial^i M \\ &\qquad + \frac{2}{1+w}v_A^2\partial_0\partial_3\delta u^3 - 2\left(\frac{v_A^2}{1+w} + S\right)\frac{2}{3(1+w)}\frac{\partial_3\delta u^3}{t} \\ &\qquad - \frac{2}{1+w}v_A^2\left[\ddot{T} + \frac{2}{1+w}\frac{\dot{T}}{t} + \frac{2}{3(1+w)}\frac{\dot{G}}{t}\right] + \frac{4}{3(1+w)}(1-v_S^2)v_A^2\frac{\Delta}{t^2}; \end{aligned} \tag{23}$$

the momentum conservation along the background magnetic field at 0-order in $v_A^2$, $v_S^2$, but keeping the Laplacian gives

$$\partial_0\partial_3\delta u^3 + (2-3w)H\partial_3\delta u^3 + \partial_3\partial^3(v_S^2\Delta) = 0. \tag{24}$$

## 4. Gauge modes

The synchronous gauge does not end the freedom of choice of the reference frame: the residual sub-gauge freedom is itself a solution of the perturbed equations, so we must find and discard it. Following a standard procedure, shown for example in[9], one can calculate the exact residual gauge freedom and show that the resulting gauge mode for the energy density is[8]

$$\delta\rho_{\rm gauge} \propto \dot{\rho}^{\rm back} \propto H(\rho^{\rm back} + p^{\rm back}) \propto H\rho^{\rm back}. \tag{25}$$

We must find this solution solving the perturbed equations, and we must discard it because it is a pure mathematical effect and it is unphysical.

## 5. Solutions

### 5.1. *Large scale, radiation dominated universe*

We study two kind of solutions. At large scales and during radiation dominated universe we have $k_i \approx 0$, $w = v_S^2 = 1/3$ and the density perturbations follow a power law solution:

$$\Delta = \frac{\Delta_{\rm gauge}}{t} + \Delta_{\rm phys} t^{1-2v_{A0}^2}; \tag{26}$$

the decaying solution is the gauge one, while the growing one is the physical solution. This is slightly different from the solution of[6].

### 5.2. *Small scales, matter dominated universe*

We will now ignore Eq. (18) and use an adiabatic sound speed, with adiabatic index $\gamma$, as in[5,10]:

$$v_S^2 \propto t^{2(1-\gamma)}; \tag{27}$$

after recombination and before baryon decoupling (for perturbations, the decoupling happens effectively at $z \approx 100$, see[5]) we have $\gamma = 4/3$, while after baryon decoupling $\gamma = 5/3$.[5,10] This is valid in the Newtonian approximation,[5,10] where we do not have Eq. (18), but assuming $v_S^2 = 0$ we recover the full relativistic case of[6]. We define the constants

$$\Lambda_S^2 = v_S^2 k_i k^i t^{2\gamma-2/3}, \qquad \Lambda_A^2 = v_A^2 k_i k^i t^2 \tag{28}$$

ad we solve the system at 0-order in $v_S^2$, $v_A^2$, considering $k_i k^i \gg H^2$ and so keeping $k_i k^i v_S^2$, $k_i k^i v_A^2 \gg v_S^2$, $v_A^2$. Defining an anisotropy parameter $\mu$ through $k_3 k^3 = \mu^2 k_i k^i$, with some algebra we find the same final equation of[5]: this solutions is different from[6] and shows that anisotropies induced by the magnetic field are important and must be considered with more care. Considering the correct relativistic treatment, with $v_S^2 = 0$, this solves the open problem of the former study of Bianchi I model of[11]. It can be shown[5] that for $\mu \neq 0$ it holds the usual Jeans

threshold $k_J$, while for $\mu = 0$ there is an additional critical value determined by the magnetic field:

$$k_J = \sqrt{\frac{24\pi G(\gamma - 4/3)^2 \rho^{\rm back}}{v_S^2}}, \qquad k_A = \sqrt{\frac{12\pi^2 G\rho^{\rm back}}{B^2_{\rm back}}}, \tag{29}$$

where $G$ is Newton's constant. For a more accurate analysis of the results see[8].

## 6. Conclusions

We highlighted the importance of the anisotropy in studies regarding cosmological perturbations with magnetic fields and we showed that the equations describing cosmological perturbations take a simpler form when expressed in the synchronous gauge, once we are able to recognize and discard the unphysical gauge modes. We incorporated anisotropic effects in the full relativistic analysis and we found corrections to the usual solutions in isotropic FRW models due to the anisotropy, controlled by the background magnetic field.

# Neutrino properties and the cosmological tensions in the ΛCDM model

Stefano Gariazzo

*Instituto de Física Corpuscular (CSIC-Universitat de València), Paterna (Valencia), Spain*
*E-mail: gariazzo@ific.uv.es*

In this talk I will review the current status of the constraints on the neutrino properties from cosmological measurements, with a particular focus on their mass and effective number. I will also discuss the existing tensions within the context of the ΛCDM model, including the discrepancies on the Hubble parameter and on the matter fluctuations at small scales, and how neutrinos could help to alleviate the aforementioned problems.

*Keywords*: Neutrinos; Neutrinos in Cosmology.

One of the most amazing experimental results of the recent years has been achieved by the Planck collaboration, which measured the Cosmic Microwave Background (CMB) radiation with an unprecedented precision.[1–4] Such result allowed us to improve our knowledge of the Universe history, which can be very well described by the six-parameters model named ΛCDM, after the cosmological constant (Λ) and the Cold Dark Matter (CDM) fluids, which represent most of the current energy density in the Universe.

Within the context of the ΛCDM model and using CMB data, we can derive constraints on a number of cosmological quantities, as for example the Hubble parameter $H_0$ or the matter perturbations at small scales, usually quantified through the parameter $\sigma_8$, which describes the mean matter fluctuations in a sphere with a radious of $8h^{-1}$ Mpc. The values of $H_0$ and $\sigma_8$ obtained from a fit of the CMB data within the context of the ΛCDM model are not in agreement with the values that are measured in the local universe, at small redshifts. For instance, while Planck data[2] point towards $H_0 = 67.27 \pm 0.66$ km s$^{-1}$Mpc$^{-1}$, estimates from the local Universe[5] indicate $H_0 = 73.24 \pm 1.74$ km s$^{-1}$Mpc$^{-1}$: a $\sim 3.4\sigma$ tension exists. In the same way, cosmological and local determinations of $\sigma_8$ typically exhibit a $\sim 2\sigma$ tension with local determinations, as performed for example by the KiDS[6] or DES[7] experiments. These tensions may be the result of an incomplete understanding of systematics in the experimental determinations or of the presence of new physics which is not considered in the ΛCDM model.

Under a different point of view, cosmology is nowadays one of the most powerful tools to study particular aspects of particle physics, such as some neutrino properties, and in particular their absolute masses or the way the interact and thermalize in the early universe. In the standard cosmological analyses, neutrinos are usually treated in the minimal way, assuming minimal masses ($\Sigma m_\nu = 0.06$ eV, corresponding to a massless lightest neutrino and two massive neutrinos, for which the masses come from the mass splittings measured in neutrino oscillation experiments and assuming normal ordering, see e.g. Ref. 8) and a contribution to the effective number of relativistic species in the early Universe $N_{\rm eff} = 3.05$.[9] Non-standard

neutrino properties may alter the cosmological evolution and have an effect on the CMB spectrum, as well as the formation of structures at later times, so that both parameters ($\Sigma m_\nu$ and $N_{\rm eff}$) can be well constrained.

First of all, neutrinos decoupled in the early universe when they were still relativistic and contribute to $N_{\rm eff}$. Variations of $N_{\rm eff}$ influence the universe evolution before the photon decoupling, and as a consequence the CMB spectrum through a variation of the amplitude of the peaks and their angular scale. In order to compensate the effects of having $N_{\rm eff}$ different from 3.05, as it would be in non-standard cases (modified neutrino properties or presence of new neutrino-like particles), one can alter the energy densities of CDM and of dark energy. In this case, the angular scale of the CMB peaks can be left unvaried, at the expense of increasing $H_0$ and having a damping of the CMB spectrum at small scales.

After the non-relativistic transition, which occurs at different times for each neutrino eigenstate depending on its mass, neutrinos contribute as regular massive particles and must be considered when computing the energy density of matter. Their influence on the CMB spectrum is related to the modification of the late-time expansion, both through the variations of the amplitude of the first peak, related to the early integrated Sachs-Wolf (ISW) effect, and of the angular position of the CMB peaks, which comes from the modifications of the angular diameter distance in presence of massive neutrinos. This latter effect can be partially compensated with a rescaling of the Hubble parameter $H_0$, so that an anti-correlation between $H_0$ and $\Sigma m_\nu$ appears.

Massive neutrinos, however, have a proportionally more important impact on the evolution of large scale structures than on the CMB spectrum. Neutrinos, indeed, possess a large thermal velocity which allows them to escape the gravitational attraction at very small scales. For this reason, no neutrino overdensity can grow at scales smaller than a characteristic scale, named the free-streaming scale, which depends on the neutrino mass. When one compares two universes which share the same total amount of matter, one with massless and the other with massive neutrinos, the universe with massive neutrinos will therefore have a suppressed matter power spectrum at the smallest scales, because the free-streaming impedes the growth of neutrino perturbations and meanwhile reduces the possibility for the gravitational attraction to accrete the total matter overdensities. The fact that for massive neutrinos there is a reduction of the matter fluctuations at small scales means that an increase of the neutrino masses correlates with a decrease of $\sigma_8$.

Given these main effects that neutrinos produce on the cosmological quantities and the resulting degeneracies between the neutrino properties ($\Sigma m_\nu$ and $N_{\rm eff}$), $H_0$ and $\sigma_8$, one may be tempted to say that neutrinos can reduce or even solve the tensions that appear within the context of the ΛCDM model between the CMB preferred cosmology and local universe probes. Unfortunately, this does not happen. The analyses of CMB data, indeed, show that it is difficult to alleviate both the tensions at the same time. If one considers CMB measurements from Planck 2015,[2]

the best fit values for $N_{\rm eff}$ and $\Sigma m_\nu$ lie very close to the expected values: $N_{\rm eff} = 3.0 \pm 0.2$ (68% CL) and $\Sigma m_\nu < 0.17$ eV (95% CL). Naively, in order to allieviate the $H_0$ tension, an higher $N_{\rm eff}$ would be useful. In the same way, heavier neutrinos would allow to reduce the matter fluctuations at small scales, $\sigma_8$. The problem is that an increase in $N_{\rm eff}$ requires to be compensated by a larger matter density at all times, so that at the practical level also $\sigma_8$ increases. In the same way, heavier neutrinos require a smaller $H_0$: it is therefore easy to see that the two tensions cannot be solved at the same time solely varying neutrino properties.

One last word on Planck measurements in connection with neutrino masses. The Planck 2015 estimates of CMB lensing from the distortions of the TT spectrum[2] are in slight tension with the reconstruction of the lensing profile from the 4-point correlation function,[10] as quantified by the phenomenological lensing amplitude parameter, $A_L = 1.22 \pm 0.10$ (68% CL), which is expected to be 1 in general relativity. Massive neutrinos, again thanks to their free-streaming, can allieviate the tension. This is the reason for which the 95% CL limits change from $\Sigma m_\nu < 0.17$ eV (Planck TT,TE,EE + lowP + BAO) to $\Sigma m_\nu < 0.22$ eV (Planck TT,TE,EE + lowP + BAO + lensing) when the lensing information is considered in the analyses.

Let us now discuss non-standard neutrino degrees of freedom. In the very recent years, for the first time we have had model-independent indications that neutrino oscillations at a baseline that is not compatible with the standard three-neutrino oscillations may exist: the NEOS[11] and DANSS[12] reactor experiments observed electron antineutrino disappearance at distances of $\sim 24$ m and $\sim 10 - 12$ m, respectively. Combined model-independent analyses[13,14] show that the combination of the two experiments give a $\sim 3.5\sigma$ preference for the three active plus one light sterile (3+1) neutrino scenario over the standard three neutrino case, implying the existence of a fourth neutrino, with a mass around 1.1 eV. When considering the global picture, one must also take into account data from muon neutrino disappearance (e.g. from MINOS+[15] or IceCube[16,17]) or electron neutrino appearance in a muon neutrino beam (e.g. from LSND[18] or MiniBooNE[19]). The first problem is that there is a tension between appearance (lead by LSND and MiniBooNE) and disappearance data (lead by NEOS, DANSS and MINOS+), see e.g. Ref. 20, so that the situation is still unclear. The second problem is that if the 3+1 neutrino oscillation parameters as obtained from the global fit are considered to compute the neutrino decoupling in the early universe, one would have a fully thermalized fourth neutrino, with $N_{\rm eff} \simeq 4$,[21,22] which is in clear tension with the constraints on $N_{\rm eff}$. This means that if the light sterile neutrino will be confirmed, some additional mechanism will be needed to suppress its thermalization in the early universe. As in the case of active neutrinos, the additional sterile neutrino and its properties can only marginally reduce the tension between the local universe probes of $H_0$ and $\sigma_8$ and the corresponding values inferred by CMB observations in the context of an extended $\Lambda$CDM model.

As a summary, our current knowledge of the universe and its history shows a number of mild tensions, in particular regarding the Hubble parameter $H_0$ and the matter fluctuations at small scales, encoded by $\sigma_8$. A mild tension is also present among the two different determinations of the CMB lensing by Planck.[2] Neutrino properties (considering both active or sterile states) can alleviate each of these tensions if considered separately, but in the global picture the situation cannot be easily solved. If these cosmological tensions or the existence of a light sterile neutrino will be confirmed in the future, some new physical mechanism will be needed in order to obtain a consistent model that can explain the entire evolution of the universe.

We derive new constraints on the Hubble parameter $H_0$ using the available data on $H(z)$ from cosmic chronometers (CCH), and the Hubble rate data points from the supernovae of Type Ia (SnIa) of the Pantheon compilation and the Hubble Space Telescope (HST) CANDELS and CLASH Multy-Cycle Treasury (MCT) programs. We employ two alternative techniques, Gaussian Processes (GPs) and the Weighted Polynomial Regression (WPR) method, to reconstruct the Hubble function, determine the derived values of $H_0$, and compare them with the local HST measurement provided by Riess *et al.* (2018), $H_0^{\rm HST} = (73.48 \pm 1.66)$ km/s/Mpc, and with the Planck+ΛCDM value, $H_0^{\rm P18} = (66.88 \pm 0.92)$ km/s/Mpc. With GPs we obtain $H_0 = (67.99 \pm 1.94)$ km/s/Mpc, and with the WPR method $H_0 = (68.90 \pm 1.96)$ km/s/Mpc. Both are fully compatible at $< 1\sigma$ c.l., and also with $H_0^{\rm P18}$. In contrast, they are in $\sim 2\sigma$ tension with $H_0^{\rm HST}$.

*Keywords*: Dark energy experiments; supernova type Ia - standard candles; cosmological parameters.

## 1. Introduction

The Hubble-Lemaître constant, $H_0$, is a crucial parameter in Cosmology. It does not only tell us about the current velocity of recession of distant astronomical objects due to the cosmological dynamics, but it is also essential to compute cosmic distances and spans of time. Now, ninety years after the discovery of the Universe's expansion and first measurement of $H_0$ by Edwin Hubble[1], and after the many works in the literature since then aiming to improve the estimations of this parameter, we can state with high statistical confidence level that $H_0$ lies in the range of $65 - 75$ km/s/Mpc. Nevertheless, this parameter is still a matter of many discussions between the members of the cosmological community, mainly focused on the origin of the huge tension between the local (distance ladder) determination of $H_0$ obtained with the Hubble Space Telescope (HST)[2] and the value inferred from the temperature and polarization anisotropies of the cosmic microwave background (CMB) radiation measured by the Planck satellite[3], by assuming the ΛCDM theoretical framework. The former reads $H_0^{\rm HST} = (73.48 \pm 1.66)$ km/s/Mpc, whereas the TT+lowE CMB Planck+ΛCDM analysis leads to $H_0^{\rm P18} = (66.88 \pm 0.92)$ km/s/Mpc.

*Speaker

These values are in $\sim 3.5\sigma$ tension. Finding the ultimate reason that generates this mismatch has become one of the most important issues in Cosmology. In principle, unaccounted systematics affecting the HST and/or Planck measurements could play a role here. Regarding this point, it is important to mention that many other works making use of the cosmic distance ladder find values of $H_0$ also lying in the high region preferred by Ref. 2, see e.g. Refs. 4, 5, 6. There are also discrepant voices in the literature, though. For instance, the author of Ref. 7 argues that the use by Riess et al. of the 2M++ density field map (which covers redshifts $z \leq 0.06$) to compute peculiar velocity flows could be biasing their results, since there is evidence of the existence of local radial inhomogeneities extending in different directions up to a redshift of about 0.07[8], and according to Ref. 7 the 40% of the Cepheids used in Ref. 2 would be affected. Moreover, the authors of Ref. 9 claim that the GAIA parallax distances of Milky Way Cepheids employed in Ref. 2 in the first step of the cosmic distance ladder may be underestimated a $\sim 7 - 18\%$. This would produce an important decrease of their measured value of $H_0$. The discussion on the validity of these arguments is, though, still open and intense.[10]

In regards to the potential systematics affecting Planck's data, it is worth to highlight the study of Ref. 11, in which the authors showed that the use of CMB data independent from Planck together with data from baryon acoustic oscillations (BAO) and the big bang nucleosynthesis (BBN) gives rise to values of $H_0$ fully compatible with the Planck preferred range and, hence, it seems quite improvable that systematics affect Planck's analysis in a decisive way.

Assuming the $\Lambda$CDM, the authors of Refs. 12, 13 analyzed the gravitational time delay of the light rays coming from multiply imaged quasar systems and found values of $H_0$ unable to discriminate between the two values in dispute due to their large error bars. It has also been possible to measure the Hubble parameter using the gravitational wave signal of the neutron star merger GW17081716 and its electromagnetic counterpart[14–16], but still with very big uncertainties too. This method is interesting because it is cosmology-independent and represents an alternative to the cosmic distance ladder measurement[2]. According to Ref. 17, a sample of $\sim 50$ binary neutron star standard sirens (detectable within the next decade) will be able to arbitrate between the local and CMB estimates. The impact of the cosmic variance on the local determination of $H_0$ has been also studied in Refs. 18, 19, 20. The authors conclude that its effect cannot explain the whole discrepancy between the HST and Planck's values.

In view of all these facts and the unsuccessful efforts of the community of finding a theoretical model able to relieve in an efficient way the $H_0$-tension (see e.g. Refs. 21, 22), it is important to go on with the investigations on the value of the Hubble parameter. Particularly relevant are those studies that try to extract values from observations at intermediate redshifts, as model-independent as possible, and also utilizing approaches different from the one applied in Ref. 2, where the authors made use of the cosmic distance ladder and low-redshift SnIa ($z < 0.15$). We present

here the main results of our dedicated work[23], in which we employed data on cosmic chronometers (CCH) and supernovae of Type Ia (SnIa), and two different methods – Gaussian Processes (GPs) and the novel Weighted Polynomial Regression (WPR) technique – to reconstruct the Hubble function and derive an extrapolated value of $H_0$.

## 2. Data

In this section we limit ourselves to cite the references from which we have collected the data on CCH and SnIa, and confer the reader to Ref. 23 and references therein for a more detailed account and description of these data sets. On the one hand, we employ the first 5 (correlated) effective points on the normalized Hubble rate, i.e. $E(z) = H(z)/H_0$, from the Pantheon+MCT sample[24,25], which includes 1063 SnIa. As it is shown in Ref. 25, the compression of the information contained in such SnIa sample is carried out in a very efficient way. It is well-known that SnIa cannot be used alone to determine $H_0$, since this parameter is fully degenerated with the SnIa absolute magnitude. To break such degeneracy, we use the 31 (uncorrelated) Hubble function data points from cosmic chronometers provided in Refs. 26, 27, 28, 29, 30, 31, 32, 33. These data cover a redshift range up to $z \sim 2$ and are obtained without assuming any particular cosmological model, by applying spectroscopic dating techniques of passively-evolving galaxies. They do not rely neither on the Cepheid distance scale nor parallaxes. There are, though, other sources of systematic uncertainties, as the ones associated to the modeling of stellar ages, which is carried out making use of the so-called stellar population synthesis (SPS) models, e.g. the BC03[34] and MaStro[35] ones. Let us detail which SPS models have been used in obtaining the CCH data points of Refs. 26, 27, 28, 29, 30, 31, 32, 33. In Refs. 30, 28, 33 the authors only provide the values of $H(z_i)$ obtained with the BC03 model. This constitutes a $\sim 25\%$ of the whole CCH data set. In Ref. 31 only the combined MaStro/BC03 values are available, whereas in Refs. 26, 27 an alternative SPS model is used, different from the MaStro and BC03 ones. These points constitute the $\sim 32\%$ of the CCH data set. In contrast, in Refs. 29, 32 the authors provide both, the BC03 and MaStro values. This group includes the remaining $\sim 43\%$ of the data. We have opted to use the BC03 values of these two references in our main analyses so as to incorporate consistently the data from Refs. 30, 28, 33, namely to avoid the use of a mixture of MaStro and BC03 values while maximizing the number of data points entering the calculations. The impact of considering alternative data sets has been discussed in detail in Sect. 3.4 of Ref. 23. We will also comment later on on (*sic*) the effect of using a more conservative data set which takes into account the combination of BC03 and MaStro values of Refs. 29, 32 instead of only the BC03 ones. This data set coincides with the one provided in Table 2 of Ref. 36. We refer the reader to this paper for details.

## 3. Reconstructing $H(z)$ from observations

### 3.1. *With Gaussian Processes*

Gaussian distributions are defined for a finite set of quantities, and are characterized by a vector of mean values and the corresponding covariance matrix, which is in charge of controlling the uncertainties' size and the correlations. Gaussian Processes are their direct generalization to the continuum, and are analogously characterized by a mean function $\mu(z)$ and a two-point covariance function $\mathcal{C}(z,z')$, see e.g. Ref. 37,

$$\xi(z) \sim \mathcal{GP}\left(\mu(z), \mathcal{C}(z,z')\right) , \tag{1}$$

where the curve $\xi(z)$ is a realization of the Gaussian process. The covariance $\mathcal{C}(z,z')$ is defined as follows: (i) when $z$ and/or $z'$ do *not* coincide with any point contained in the data set that we want to use to reconstruct the function, then $\mathcal{C}(z,z') = \mathcal{K}(z,z')$, where $\mathcal{K}(z,z')$ is the so-called kernel function, which must be of course symmetric and at this stage is unknown; (ii) when both, $z$ and $z'$, *do* coincide with the $z$-values of one or more points contained in our data set, then $\mathcal{C}(z,z') = \mathcal{D}(z,z') + \mathcal{K}(z,z')$. Here we incorporate the information of the known covariance matrix $\mathcal{D}(z,z')$ of our data points. The kernel function plays a crucial role in the GPs, and must be selected beforehand. Three of the most famous ones with only two degrees of freedom are the following: (a) The Gaussian kernel, $\mathcal{K}(z,z') = \sigma_f^2 \mathrm{Exp}\left[-\frac{1}{2}\left(\frac{z-z'}{l_f}\right)^2\right]$; (b) The Cauchy kernel, $\mathcal{K}(z,z') = \sigma_f^2 l_f/[(z-z')^2 + l_f^2]$; and (c) The Matérn kernel, $\mathcal{K}(z,z') = \sigma_f^2\left[1+\frac{\sqrt{3}}{l_f}|z-z'|\right]\mathrm{Exp}\left[-\frac{\sqrt{3}}{l_f}|z-z'|\right]$. They all depend on $\sigma_f$ and $l_f$, the so-called hyperparameters of the kernel function. The first one controls the uncertainties' size and the strength of the correlations, whereas the second somehow limits the scope of these correlations in $z$. Although it is possible to construct more elaborated kernels, e.g. kernels which do not only depend on the distance $|z-z'|$, but also on the locations $z$ and $z'$ themselves, in such a way that the symmetry under the interchange $z \leftrightarrow z'$ is kept intact, we will stick to the more simple ones mentioned above and, more concretely, only to the Gaussian one, since as we showed in Ref. 23 the reconstructed $H(z)$ obtained with these three kernels are compatible at $< 1\sigma$ c.l. for all the redshift range under study. Of course, the results also depend on the values of the hyperparameters. Once we choose the kernel, how can we properly select $\sigma_f$ and $l_f$? To do so we must make use of our data. In the GPs philosophy, our data set is conceived as part of a subset of realizations of the Gaussian process. The hyperparameters are usually chosen so as to maximize the probability of the GP to produce our data set. If we marginalize the GP (1) over the points at $z^*$, i.e. those at which we do not have data, we get the following multivariate normal distribution,

$$\vec{\xi} \sim \mathcal{N}\left(\{\mu_i(\tilde{z}_i)\}, \mathcal{C}\right) , \tag{2}$$

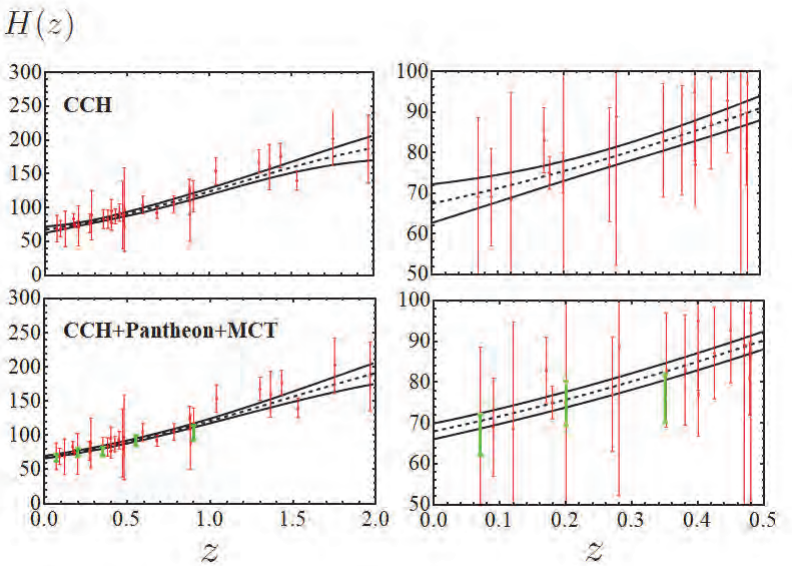

Fig. 1. Reconstructed $H(z)$ in [km/s/Mpc] with the corresponding $1\sigma$ bands obtained with GPs when only CCH are used (figures on the top), and when we add the Pantheon+MCT data (the ones at the bottom). In both cases we zoom in the redshift range $z \in [0, 0.5]$ (plots on the right) so as to better appreciate our determination for $H_0$ and how the uncertainty bands narrow down when the SnIa data are included. The processed ($E(z_i) \to H(z_i)$) Pantheon+MCT points are plotted in green, whereas the CCH data are in red. See related comments in the main text.

where $i = 1, ..., N$, with $N$ being the dimension of the vector of data points $\vec{y} \equiv \{\tilde{z}_i, y_i\}$ at our disposal, and $\mu_i(\tilde{z}_i)$ can be set e.g. to $\vec{0}$ $\forall i$, since the result is almost insensitive to this. Thus, the hyperparameters will be obtained upon the minimization of

$$-2\ln\mathcal{L}(\sigma_f, l_f) = N\ln(2\pi) + \ln|\mathcal{C}(\sigma_f, l_f)| + \vec{y}^T\mathcal{C}^{-1}(\sigma_f, l_f)\vec{y}, \tag{3}$$

with $\mathcal{L}$ being the marginal likelihood and $|\mathcal{C}|$ the determinant of $\mathcal{C}$. Having done this, and using (1), we can compute the conditional probability of finding a given realization of the Gaussian process in the case in which $\xi(\tilde{z}_i) = y_i(\tilde{z}_i)$. The resulting mean and variance functions extracted from such conditioned GP read, respectively,

$$\bar{\xi}(z^*) = \sum_{i,j=1}^{N} \mathcal{C}^{-1}(\tilde{z}_i, \tilde{z}_j) y(\tilde{z}_j) \mathcal{K}(\tilde{z}_i, z^*)\,, \tag{4}$$

$$\sigma^2(z^*) = \mathcal{K}(z^*, z^*) - \sum_{i,j=1}^{N} \mathcal{C}^{-1}(\tilde{z}_i, \tilde{z}_j) \mathcal{K}(\tilde{z}_i, z^*) \mathcal{K}(\tilde{z}_j, z^*)\,. \tag{5}$$

The results derived using this formalism are shown in Fig. 1. When only CCH are included in the analysis we obtain an extrapolated value of $H_0 = (67.42 \pm 4.75)$ km/s/Mpc. This result coincides with the one provided in Ref. 38. We have

incorporated the SnIa information with the following procedure. We have firstly used the value of $H_0$ extracted from the GP-reconstruction of $H(z)$ with CCH to promote (via a Monte Carlo routine) the Hubble rates of Ref. 25 to values on $H(z_i)$. They can be used now in combination with the CCH data in a new GP-reconstruction to obtain the corresponding new value of $H_0$. The result reads, $H_0 = 67.99 \pm 1.94$ km/s/Mpc. The error bars has decreased a factor $\sim 2.5$ with respect to when only CCH are employed. The central value is fully compatible with the Planck+ΛCDM result, and it is in $2.2\sigma$ tension with $H_0^{\rm HST}$. Using the more conservative CCH data set of Ref. 36 in combination with the Pantheon+MCT data one obtains $H_0 = 69.00 \pm 2.35$ km/s/Mpc. In this case the tension with the HST value loosens, being now of $1.7\sigma$. For a discussion on the effect of the propagation of the hyperparameters' uncertainties we refer the reader to Sect. 3.3 of Ref. 23.

### 3.2. *With the Weighted Polynomial Regression method*

Cosmographical analyses are based on truncated expansions (in $z$ or some other variable) of cosmological quantities, e.g. cosmic distances or the Hubble function, around $z = 0$, see e.g. Ref. 39. People usually truncate these expansions (which do not rely on any particular cosmological model) at a concrete order and subsequently fit the resulting expression to the data in order to extract kinematic information of our Universe. The truncation order should not be determined in an *ad hoc* way, but applying some well-motivated criterion, e.g. looking for the order that makes the value of the reduced chi-squared statistic to be as close to one as possible, the one that maximizes the Bayesian evidence (see e.g. Ref. 40), or just the one that minimizes some approximate information criterion statistic, as the Akaike[41] or Bayesian[42] ones. But even these approaches can prove insufficient to obtain objective (non-biased) constraints on the fitting parameters, as it has been highlighted in Refs. 23, 36. However, it is possible to improve the usual cosmographical methodology by making use of the so-called Weighted Function Regression technique, which does not consist on choosing only one particular order of the truncated series, but on weighting in a consistent way the contribution of the various truncated expansions.

Let us explain how it works. Firstly, imagine that we have the following function, which is linear in the parameters,

$$f(z) = \sum_{i=0}^{n} a_i b_i(z)\,, \tag{6}$$

with the $b_i$'s being the so-called basis functions and $\vec{a}$ the vector of coefficients. If we have the vector of mean values $\vec{\bar{a}}$ and the associated covariance matrix $D$, then we can compute the mean function $\bar{f}_M(z)$ and covariance matrix $\mathrm{cov}[f_M(z), f_M(z')]$ as follows:

$$\bar{f}_M(z) = \sum_{i=0}^{n} \bar{a}_i b_i(z)\,, \qquad \mathrm{cov}[f_M(z), f_M(z')] = \sum_{i,j=0}^{n} D_{ij} b_i(z) b_j(z')\,. \tag{7}$$

$\vec{a}$ and $D$ can be computed exactly in the case of Gaussian-distributed data with flat priors (cf. Ref. 23) or, in a more general case, computationally making use of a Monte Carlo routine. The variance of the reconstructed function is just $\sigma_M^2(z) = \mathrm{cov}[f_M(z), f_M(z)]$. These tools can be used, e.g. to reconstruct $H(z)$ in the cosmographic scenario. We just have to Taylor-expand $H(z)$ around e.g. $z = 0$,

$$H(z) = H_0 + \frac{dH}{dz}\Big|_{z=0} z + \frac{1}{2}\frac{d^2H}{dz^2}\Big|_{z=0} z^2 + ... \tag{8}$$

In this case $b_i(z) = z^i$, $a_0 = H_0$, $a_1 = H_0(q_0 + 1)$, etc. Let us call $M_0$, $M_1$,..., $M_{N-1}$ the cosmographic polynomials of order $n = 0$, 1,..., $N-1$, respectively, with $N$ being again the number of data points entering the analysis. That is, let us conceive each polynomial as a different model, and compute the probability density associated to the fact of having a certain shape of the function $f(z)$ as follows,

$$P[f(z)] = k \cdot [P(f(z)|M_0)P(M_0) + ... + P(f(z)|M_{N-1})P(M_{N-1})]\,, \tag{9}$$

where $k$ is just a normalization constant that must be fixed by imposing $\int [\mathcal{D}f]\, P[f(z)] = 1$. Taking into account that $\int [\mathcal{D}f]\, P(f(z)|M_J) = 1 \quad \forall J \in [0, N-1]$ and $\sum_{J=0}^{N-1} P(M_J) = 1$, we find $k = 1$ and therefore:

$$P[f(z)] = \sum_{J=0}^{N-1} P(f(z)|M_J)P(M_J)\,. \tag{10}$$

We now denote $M_*$ as the most probable model and identify $\frac{P(M_J)}{P(M_*)}$ with the Bayes ratio $B_{J*}$[40]. The last expression can be finally written as

$$P[f(z)] = \frac{\sum\limits_{J=0}^{N-1} P(f(z)|M_J)B_{J*}}{\sum\limits_{J=0}^{N-1} B_{J*}}\,. \tag{11}$$

This is the central expression of the WPR method, where the weights are directly given by the Bayes factors. Notice that using (11) we can compute the (weighted) moments and related quantities too, e.g. the weighted mean and variance read,

$$\bar{f}(z) = \frac{\sum\limits_{J=0}^{N-1} \bar{f}_J(z)B_{J*}}{\sum\limits_{J=0}^{N-1} B_{J*}}\,, \qquad \sigma^2(z) = \frac{\sum\limits_{J=0}^{N-1} [\sigma_J^2(z) + (\bar{f}_J(z))^2]B_{J*}}{\sum\limits_{J=0}^{N-1} B_{J*}} - (\bar{f}(z))^2\,, \tag{12}$$

where $\bar{f}_J(z)$ and $\sigma_J^2(z)$ can be computed by means of (7). For the obtention of the Bayes factors we invoke the time-honored Bayesian and Akaike information criteria, BIC and AIC, defined as[41,42]:

$$\mathrm{AIC}_J = \chi^2_{\mathrm{min},J} + \frac{2n_J N}{N - n_J - 1}\,, \qquad \mathrm{BIC}_J = \chi^2_{\mathrm{min},J} + n_J \ln N\,, \tag{13}$$

Table 1. Fitting results obtained for the models with largest weight entering the WPR-reconstruction of $H(z)$ with the CCH data

| Polyn. degree (d) | $\chi^2_{\rm min}$ | BIC | AIC | $H_0$ | $B_{\rm d1}$ (BIC) | $B_{\rm d1}$ (AIC) |
|---|---|---|---|---|---|---|
| 1 | 16.62 | 23.48 | 21.04 | $62.3 \pm 3.1$ | 1 | 1 |
| 2 | 14.74 | 25.04 | 21.63 | $67.8 \pm 5.1$ | 0.47 | 0.74 |
| 3 | 14.78 | 28.51 | 24.31 | $68.9 \pm 4.5$ | 0.08 | 0.19 |
| 4 | 14.80 | 31.97 | 27.20 | $68.2 \pm 4.2$ | 0.014 | 0.05 |
| 5 | 14.95 | 35.56 | 30.45 | $68.4 \pm 4.0$ | 0.002 | 0.009 |
| 6 | 15.01 | 39.05 | 33.88 | $68.6 \pm 4.4$ | $4 \times 10^{-4}$ | 0.002 |
| 7 | 15.27 | 42.74 | 37.82 | $68.3 \pm 4.2$ | $6 \times 10^{-5}$ | $2 \times 10^{-4}$ |
| 8 | 15.72 | 46.63 | 42.29 | $68.8 \pm 4.4$ | $9 \times 10^{-6}$ | $2 \times 10^{-5}$ |
| 9 | 16.38 | 50.72 | 47.38 | $68.9 \pm 3.9$ | $1 \times 10^{-6}$ | $2 \times 10^{-6}$ |

*Note*: Some quantities obtained from the fitting analysis of the first nine (cosmographic) polynomials involved in the WPR-reconstruction, by only using the CCH data. In the second column we show the minimum value of the $\chi^2$ function. The third and fourth columns contain the values of the Bayesian and Akaike information criteria, as defined in (13). In the fifth column we show the values of the Hubble parameter in [km/s/Mpc] together with its $1\sigma$ uncertainty. The last two columns contain the values of the Bayes ratio that are obtained by using the BIC and AIC, respectively, as defined in (14). See comments in the text.

with $\chi^2_{{\rm min},J}$ being the minimum of the $\chi^2$ function in the model $M_J$, and $n_J = J+1$ the dimension of $\vec{a}_J$. In this way the Bayes factor between the model $M_J$ and the most probable model $M_*$ can be approximated by

$$B_{J*} = e^{\frac{BIC_* - BIC_J}{2}} \qquad \text{or} \qquad B_{J*} = e^{\frac{AIC_* - AIC_J}{2}}\,, \tag{14}$$

depending on the criterion used, the BIC or AIC, respectively. The most probable model $M_*$ is defined as the one with lowest BIC or AIC, depending again on the chosen criterion. It is crystal-clear from these expressions that the competing models with more parameters used to analyze the same data receive a suitable penalty and, therefore, our weighted method implements in practice Occam's razor principle.

We apply the WPR formalism to the family of models for $H(z)$ that result from truncating the Taylor series (8) at different orders. We force the coefficients to be positive so as to fulfill: (i) $H_0 \neq 0$; (ii) $H'(z=0) \neq 0$; and (ii) $dH/dz(z) > 0\,\forall z > 0$, cf. Ref. 23 for further details. We present in Table 1 the most relevant quantities obtained from the individual fitting analyses of the truncated expansions entering the WPR-reconstruction with CCH data. Therein we show the values of $H_0$ and the associated uncertainties derived from the individual fits and also the relative weight with respect to the most probable result, which in this case is obtained for the linear polynomial. Applying (12) we are led to $H_0 = (64.44 \pm 4.72)$ km/s/Mpc [$H_0 = (65.27 \pm 4.98)$ km/s/Mpc] when BIC [AIC] is used. When we add the Pantheon+MCT data we obtain $H_0 = (68.90 \pm 1.96)$ km/s/Mpc regardless of the information criteria. If we use the conservative CCH data set from Ref. 36 we obtain $H_0 = (70.50 \pm 2.60)$ km/s/Mpc. These results are completely compatible with the ones obtained using GPs.

## 4. Conclusions

In this work we have presented some estimations of $H_0$ obtained with two alternative reconstruction techniques and data on cosmic chronometers and supernovae of Type Ia. The results are independent from those obtained in Ref. 2, in which the authors made use of low-redshift SnIa and the cosmic distance ladder. Our results do not rely on any particular cosmological model, and seem to favor the low estimates of $H_0$ provided by the Planck Collaboration[3]. Our results are also resonant with the conclusions of Ref. 43, where the authors provided some indication that the local measurement[2] of the Hubble-Lemaître constant is an outlier, by using the so-called index of inconsistency to test the consistency between the preferred values of $H_0$ derived from alternative data sources: CMB from Planck, SnIa+BAO+BBN, data on large scale structure formation, gravitational time delay, and local determination of $H_0$. Other authors[17,38,44,45] have also obtained values of $H_0$ lying in the lower range preferred by Planck, using model-independent techniques and different combinations of intermediate-redshift data from BAO, SnIa, and CCH. Moreover, several analyses have shown that it is possible to loosen or even solve the $\sigma_8$-tension at the expense of keeping the one concerning $H_0$, see e.g. Refs. 22, 46, 47. A low value of $H_0$ would automatically allow to remove the existing tension in the $\sigma_8$-parameter.

Our methodology has proved to be a viable route for estimating $H_0$. Revisiting it in the future, when new and more precise data are available, would be interesting, especially when the theoretical uncertainties associated to the SPS models employed to extract the CCH data from observations decreases in a significant way.

## Acknowledgements

AGV would like to thank Prof. Joan Solà for his invitation to give this talk as part of the CM4 parallel sessions on "Tensions on ΛCDM cosmological model and model-independent constraints" at the 15th Marcel Grossmann Meeting, in the beautiful city of Rome. He is also grateful to the organizers and the *Department of Quantum Physics and Astrophysics* of the University of Barcelona for their economical support. LA is supported by the DFG through TRR33 "The Dark Universe".

# Lambda-CDM model and small-scale-cosmology "crisis": from astrophysical explanations to new fundamental physics models

Nick E. Mavromatos

*Theoretical Particle Physics and Cosmology Group, Department of Physics, King's College London, Strand, London WC2R 2LS, UK*
*Nikolaos.Mavromatos@kcl.ac.uk*

I review briefly three problems where tensions between predictions based on numerical simulations of the Lambda-CDM prototype and observations at small (galactic) scales occur. These include (i) the core-cusp problem on the galactic profiles, (ii) the missing satellite problem, and the (ii) too-big-to-fail problem. I explain what these problems are and present potential resolutions, first through some astrophysical mechanisms, which however, as I argue, fail to alleviate completely the problems, at least currently. Then, I discuss fundamental modifications of the Lambda-CDM model, through the inclusion of self-interacting dark matter (SIDM). I argue that a simple model of SIDM, with (warm) self-interacting right-handed neutrinos (RHN), that exist in minimal extensions of the Standard model of particle physics, appears promising in providing a resolution of the aforementioned "small-scale-Cosmology crisis", in particular the core-cusp problem, and an observationally consistent description of the core-halo structure in galaxies.

*Keywords*: Cosmological observations; self-interacting interacting dark matter; right-handed-neutrinos.

## 1. Introduction

A plethora of precision cosmological observations[1], based on type Ia supernovae, cosmic microwave background (CMB) radiation, large scale structure, baryon acoustic oscillations and strong and weak lensing data, point towards the fact that only $\sim 4\%$ of the current energy budget of the Universe consists of the known form of matter (mainly baryons), while the rest seems to be of uknown nature, specifically $\sim 69\%$ dark energy (DE) and $\sim 27\%$ dark matter (DM). The current universe appears to enter an acceleration phase (for a second time after inflation), and the data point towards an equation of state for the dark energy to be close to that of a de Sitter space-time, $w \simeq -1$, corresponding to a positive cosmological-constant, $\Lambda > 0$. The best fit to the large-scale data seems to be provided by the so-called $\Lambda$-Cold-Dark-Matter ($\Lambda$CDM) model for the Universe, according to which the DE is provided by a positive cosmological constant $\Lambda > 0$, while the DM content of the Universe is thermal, of "Cold" type, corresponding to a mass range for the (assumed) dominant DM particle species $m_\chi > 100$ keV. Several particle physics models, in particular Supersymmetry, provide candidates for this type of DM, although currently there is no experimental evidence from collider experiments that such extensions of the Standard Model (SM) are realised in nature[2], thus leaving us only with Cosmological evidence for the existence of DM.

Despite the success of the $\Lambda$CDM model at large (cosmological) scales, however, there are tensions at galactic scales which, if not due to observational fluctuations, or admitting astrophysical resolution, may hint new physics beyond the $\Lambda$CDM

paradigm. In this talk we mention briefly some of these challenges, and discuss their potential resolution by modifying the ΛCDM model via the inclusion of self interactions in the Dark Matter sector.[a]

## 2. Small Scale Challenges of the ΛCDM Model

There are three challenges to the ΛCDM model at galactic scales, collectively called some times as "*small-scale cosmology crisis*, which we focus our attention upon in this section:

**(i)** *The Core-Cusp problem*, that is, a discrepancy between the observed dark matter density profiles of low-mass galaxies and the density profiles predicted by cosmological N-body simulations. Characteristically, all the ΛCDM-based (DM only) simulations form dark matter halos which have "cuspy" dark matter distributions, with the density increasing steeply, i.e. as $\rho \propto r^{-1}$, at small radii. This is, e.g., evidenced in the standard Navarro-Frenk-White (NFW) DM profile.[5] On the contrary, the rotation curves of most of the observed dwarf galaxies indicate flat central density profiles ("cores").[6]

**(ii)** *The "missing satellite or dwarf galaxy problem"*, which pertains to a discrepancy between observations and ΛCDM-based numerical cosmological simulations, which predict the evolution of the distribution of matter in the universe. Such simulations point towards a hierarchical clustering of DM, where smaller halos merge to form larger halos. Although there seem to be enough observed normal-sized galaxies to account for such a numerical distribution, the number of (observed) dwarf galaxies is orders of magnitude lower than that expected from the simulations.[7]

**(iii)** *The too big to fail problem*, which is a discrepancy arising between the most massive subhaloes predicted in (dissipationless) ΛCDM simulations and the observed dynamics of the brightest dwarf spheroidal (dSph) galaxies in the Milky way. In other words, the ΛCDM simulations predict that the most massive subhaloes of the Milky way are too dense to host any of its bright satellites, with luminosity higher than $10^5$ the luminosity of the Sun.[8]

The problems may admit astrophysical explanations, and some of them may be alleviated by improved measurements. For instance, many studies have shown that including baryonic feedback (particularly feedback from supernovae and active galactic nuclei) can "flatten out" the core of a galaxy's dark matter profile, since feedback-driven gas outflows produce a time-varying gravitational potential that transfers energy to the orbits of the collisionless dark matter particles.[9] The missing satellite problem also admits standard Astrophysical solutions.[10] One is that the smaller halos do exist but only a few of them end up becoming visible because they have not been able to attract enough baryonic matter to create a visible dwarf

[a] We do not discuss here other recent challenges of ΛCDM, e.g. those associated with the different value of the Hubble parameter $H_0$, obtained between CMB/Planck-Coll. measurements[1] and Cepheid-galaxies observations[3], which could be alleviated via modified DE models, such as the "running vacuum".[4]

galaxy. In support of this, Keck observations in 2007 of eight newly discovered ultra-faint Milky Way dwarf satellites showed that six were almost exclusively composed of DM, around 99.9% (with a mass-to-light ratio of about 1000).[11] Such ultra-faint dwarfs substantially alleviate the discrepancy between the predicted and observed numbers of satellites around the Milky Way, but there are still discrepancies by a factor of about four too few dwarf galaxies over a significant range of masses. See also the recent work Ref. 12 in this direction. Other solutions may be that dwarf galaxies tend to be merged into or tidally stripped apart by larger galaxies due to complex interactions. This tidal stripping has been part of the problem in identifying dwarf galaxies in the first place, which is an extremely difficult task since these objects have low surface brightness and are highly diffused, so much that they are virtually unnoticeable. Finally, the Too-Big-to-Fail Problem may also be tackled by taking into account baryonic feedback.

From the point of view of the ΛCDM simulations, all three problems have their root in the fact that the cold DM particles, which the ΛCDM simulations rely upon, have too short free streaming length during the epochs of galaxy formation, and therefore they form too clumped and too many structures compared to those observed. The interesting question therefore is whether these problems, especially the core-casp problem, provide hint towards a paradigm shift of the underlying fundamental physics, implying deviations from ΛCDM framework. One such deviation is to include self interactions among the DM particles.

## 3. Resolution through Self Interacting Dark Matter Models

Self interactions have been argued to play an important rôle in galactic structure already in Ref. 13. The original idea of Self-Interacting DM (SIDM) was implemented for CDM particles with rest masses above 1 MeV/$c^2$ (up to 10 GeV/$c^2$), consistent with the nature of the effective interactions and the mean free paths considered in that work. This way of thinking regarding self-interactions was applied uniquely on DM halo scales with typical densities of $10^{-2} M_\odot/\mathrm{pc}^3$, suggesting that normalized total cross-sections of order $\sigma/m \sim 0.1 - 100$ cm$^2$/g, would imply observational effects in the inner regions of the DM halos. It was also shown that a SIDM regime with these values of $\sigma/m$ would generate shallower inner DM profiles, with a necessary reduction in the amount of sub-structures, thereby alleviating the core-cusp and the missing satellite problems of collisionless ΛCDM[14]. However, contemporaneously, some tension with upper limits in the DM cross sections as obtained from lensing studies on galaxy cluster scales emerged. In a subsequent work,[15] motivated by updated analysis of the Bullet Cluster,[16] new cosmological simulations within CDM were performed, with the aim of further scrutinizing the effects of SIDM on inner halo cores of galaxies and galaxy clusters. The authors of Ref. 15 concluded that $\sigma/m \sim 0.2$ barn GeV$^{-1} = 0.1$ cm$^2$ g$^{-1}$ is consistent with all the observational constraints. In general, SIDM would make no difference from ΛCDM at large scales,

but individual galaxies would appear more cored and spherical, with higher velocity dispersion.

Stringent constraints of the interaction cross section of SIDM have been inferred in Ref. 17 by means of new DM observables in merging galaxies, taking into account *the DM drag*. In particular, the study of 72 mergers using this new technique imposed a more stringent upper bound on the SIDM cross section per unit DM mass, thus defining a new range for the total SIDM cross section[b]

$$0.1 \leq \frac{\sigma_{\rm SIDM}/m}{{\rm cm}^2\, g^{-1}} \leq 0.47 \tag{1}$$

This might lead to a potential resolution of the three "small scale cosmology problems" of DM, discussed previously. For instance, self interactions may tackle the core-cusp and too big to fail problems by reducing the central density. In this latter respect we mention the works of Ref. 20, according to which self interactions can lead to both deceleration and evaporation of a DM halo when the latter moves through a background of DM particles. This results in a shift of the halo's centroid relative to the collisionless stars and galaxies.

## 4. Self-Interacting Right-Handed Neutrinos as (Warm) DM and Galactic Structure

A concrete model of SIDM, which may have significant effects on the galactic structure, and which plays an important rôle in particle physics, has been studied in Ref. 21. It is based on a class of self-interacting models of massive right-handed neutrinos that exist in minimal extensions of the standard model[22]. The model constitutes a microscopic (particle physics) realisation of previous ideas that populations of electrically neutral fermionic particles might play an important rôle for the galactic core-halo structure[23]. In such a scenario, the DM fermion is played by the right-handed neutrino (RHN), which has a mass of a order a few tens of keV, and implies a universal and novel DM density profile (*compact core - dilute halo*), with important implications for the very central and halo regions of galaxies. The model is in agreement with observations, provided sufficiently strong self-interactions among the RHNs are considered[21]. The Lagrangian of the right-handed neutrino sector, including gravity, reads (in units $\hbar = c = 1$, which we use throughout here):

$$\mathcal{L} = \mathcal{L}_{GR} + \mathcal{L}_{N_{R\,1}} + \mathcal{L}_V + \mathcal{L}_I \tag{2}$$

[b]However, some tension with the upper bound of (1) still remains, since the analysis and assumptions of Ref. 18 on their study of the Abell Cluster 3827 have been questioned in Ref. 19, which presented corrected estimates for the SIDM cross section: $\sigma_{\rm SIDM}/m \simeq 3\ {\rm cm}^2\, g^{-1}$, when self interactions result in a drag force, and $\sigma_{\rm SIDM}/m \simeq 1.5\ {\rm cm}^2\, g^{-1}$ in the case of contact interactions.

where

$$\mathcal{L}_{GR} = -\frac{R}{16\pi G},\ \mathcal{L}_{N_{R\,1}} = i\,\overline{N}_{R\,1}\gamma^{\mu}\,\nabla_{\mu}\,N_{R\,1} - \frac{1}{2}m\,\overline{N^{c}}_{R\,1}N_{R\,1},$$
$$\mathcal{L}_{V} = -\frac{1}{4}V_{\mu\nu}V^{\mu\nu} + \frac{1}{2}m_{V}^{2}V_{\mu}V^{\mu},\ \mathcal{L}_{I} = -g_{V}V_{\mu}J_{V}^{\mu} = -g_{V}V_{\mu}\overline{N}_{R\,1}\gamma^{\mu}N_{R\,1}\,, \quad (3)$$

with $R$ the Ricci scalar for the static spherically symmetric metric background considered in Ref. 21, $\nabla_{\mu}$ the gravitational covariant derivative acting on a Majorana spinor, $m$ the mass of the sterile RHN neutrino, and $m_V$ the mass of the dark vector boson providing the carrier of the self-interactions among RHN. When the Lagrangian (3) is expressed in terms of the Majorana field $N^c = N$, the massive-vector-mesons $V_\mu$ couple to the axial current $\overline{N}\gamma^{\mu}\gamma^{5}N$.

In general one may add to (2) a Yukawa term, coupling RHNs to the active neutrino sector (see, e.g., the case of $\nu$MSM in Ref. 22)

$$\mathcal{L}_{\rm Yuk} = \sum_{\alpha,\,I} F_{\alpha I}\,\overline{\ell}_{\alpha}\,N_{R\,I}\phi^{c} + \text{h.c.}\,, \quad I = 1,2,3, \quad \alpha = e,\mu,\tau, \quad (4)$$

where $\ell_\alpha$ are the lepton doublets of the SM, $\alpha = e,\mu,\tau$, $F_{\alpha I}$ are appropriate Yukawa couplings, and $\phi^c$ is the SM conjugate Higgs field, *i.e.* $\phi^{c} = i\tau_{2}\phi^{\star}$, with $\tau_2$ the $2\times 2$ Pauli matrix. If one ignores self interactions among the RHN, then, upon considering such a coupling, one obtains stringent X-ray and Big Bang Nucleosynthesis (BBN) constraints[24] of the mixing angle and mass of $N_{R\,1}$, given that (4) implies decays of the heavy neutrinos $N_I \to \nu H$, where $H$ is the Higgs excitation field, $\phi = v + H$, with $v$ the vacuum expectation value. In the context of $\nu$MSM[22], the decay time of the lightest of the RHN neutrinos can be longer than the age of the universe, hence the latter can be considered as stable for all practical purposes, thus playing the rôle of the entirety of DM. This assumption requires sufficiently low mixing with the standard model sector, with the corresponding mixing angle given by $\sin^2\theta = \sum_{\alpha=e,\mu.\tau}\frac{\langle\phi\rangle^2 F_{\alpha\,I}}{m^2}$. On the other hand, the requirement that the sterile neutrino constitutes the entirety of DM, requires it to be produced in sufficient amounts in the early Universe, and hence, if no self-interactions are assumed, there are lower bounds for $\theta$, depending on the RHN mass $m$. The best fit to date[24] points to a narrow allowed region in the RHN mass $m \sim 10$ keV and mixing angle $\sin^2(2\theta) \sim 10^{-12}$ (slightly wider regions for $m$ are allowed[25] if one uses the galactic density profile of Ref. 23).

In the RHN SIDM model of Ref. 21 the mixing with the SM sector was ignored, $F_{\alpha 1} = 0$, in which case the lightest neutrino is absolutely stable. The important feature are the self-interactions of the right-handed neutrino, which ensured phenomenologically correct values for the radius and mass of the galactic core within certain mass density profiles[23]. Such interactions among RHNs also lead to production mechanisms of the RHN DM that no longer require lower bounds on the mixing angle $\theta$ with the standard model sector, hence the stringent X-ray constraints of Ref. 24 can be evaded. The analysis of Ref. 21 showed that, under the assumption of the absence of a central black hole in the galaxy[23], the allowed range for RHN

DM mass that fit the Milky Way observables is: 47 keV/$c^2 < m <$ 350 keV/$c^2$, the upper bound being set by reaching the critical core mass for gravitational collapse, $M_c^{cr} \propto M_{\rm Pl}^3/m^2 \approx 4.4 \times 10^6 M_\odot$. One also concludes that the inclusion of sufficiently strong interactions in the dark sector among the sterile neutrinos can lead to significantly more compact cores and higher central degeneracies than in the free case[23c].

The total RHN-RHN scattering cross-section in the quantum core of the Galaxy has been calculated in Ref. 21 in a perturbative regime $g < 1$ for the dimensionless interaction coupling, $\sigma_{core}^{tot} \approx 29\,\frac{(g_V/m_V)^4}{4^3\pi}\,m^2$ $(p^2/m^2 \ll 1)$. This allows for a comparison of these results with the generic ones existing in the literature and mentioned in the previous section, on the required range of the total cross section per unit DM mass, $\sigma/m$, in order to resolve the small-scale Cosmology "crisis" (Eq. (1)). To put things in perspective, one can normalize the interaction field strength in terms of the visible sector (SM) weak interaction dimensionfull coupling, the Fermi "constant" $G_F$. Thus, if, e.g. one constrains the total cross-section to the N-body simulation value $\sigma^{tot}/m = 0.1$ cm$^2$/g (or, in general, to lie in the region (1) discussed above), the coupling constant $\overline{C}_V$ would be constrained to the value $\overline{C}_V \in (2.6 \times 10^8, 7 \times 10^8)$, for RHN-DM masses in the range $m \in (47, 350)$ keV. It worths noticing that for $C_V \sim 10^8\, G_F$, the mass of the massive-vector meson would be constrained to values $m_V \lesssim 3 \times 10^4$ keV, in order to satisfy $g_V \lesssim 1$ as requested by the self-consistency of the perturbation scheme applied to the computation of the cross-section[21].

As stressed in Ref. 21, the inclusion of baryonic matter is not expected to change the basic conclusions that the introduction of WDM fermion self interactions affects the core/halo structure and in particular induces higher central degeneracies and higher compactness of the inner quantum core of galaxies. Moreover, the model of self-interacting sterile neutrinos provides a natural resolution to the core-cusp problem of DM at small scales, because the density profiles based on fermionic phase-space distributions develop always an extended plateau on halo scales, in a way that resemble Burkert or cored Einasto profiles. Another important feature is the fact that the right-handed neutrino DM mass is 'colder' by a few keV as compared to most of the Warm Dark Matter (WDM) models available in the literature, which implies that the model does not suffer from such standard WDM problems.

It goes without saying, that the presence of self-interacting right-handed neutrinos with a mass range of a few tens of keV may co-exist harmonically with other types of DM, given that the latter may consist (like ordinary matter) of more than one dominant species. In this way, at large scales, the predictions of the Lambda-CDM model might still be valid, while at galactic scales the rôle of self-interacting

[c]If the assumption that the RHN DM co-exists with a central black hole is made, then one may accommodate the narrow window of Ref. 24 in the analysis of Ref. 21, although, as already mentioned, the existence of self interactions of RHN evades the constraints of Ref. 24.

RHN WDM may play a crucial rôle in providing agreement of the predicted galactic structure and the pertinent DM distribution with observations.

The goal of this short report is to summarise some key results based on our previous works on model independent tests of gravity at large scales in the Universe, their connection with the properties of gravitational waves, and the implications of the recent measurement of the speed of tensors for the phenomenology of general families of gravity models for dark energy.

*Keywords*: Dark energy, gravitational waves, large-scale structure of the Universe.

## 1. Introduction

The physics behind the late-time acceleration of the Universe remains elusive. Although the ΛCDM model provides a good and simple phenomenological paradigm for its description, its fundamental understanding suffers due to the current paradigm to explain the nature of the cosmological constant.[1–3]

A description of the accelerating Universe might be embedded within an infrared modification of the standard gravitational paradigm of General Relativity (GR). This idea has sparked the construction of theories which modify the effective gravitational degrees of freedom at large scales, and are usually labelled as dark energy and/or modified gravity models (for detailed expositions, see e.g., Refs. 4, 5). Typical examples are the general scalar-tensor (Horndeski and beyond as well as the so–called DHOST theories), vector-tensor (Einstein-Aether, generalised Proca) and massive/bi-metric theories of gravity. These are the kind of models that will concern us in the discussion to follow.

The current major task of research in cosmology is the investigation of possible such departures from the standard framework of GR. From an observational standpoint, the currently unknown detailed physics of the dark sector make this particularly challenging, due to the unobservability of the *individual* dark components

under pure gravity probes. Here we will explain how *the gravitational slip* parameter is a powerful model independent discriminator between large classes of gravity models in cosmology, and discuss its intimate relation to the properties of gravitational waves (GWs),[6,7] that provides a phenomenological bridge between the physics of GWs and the large scale structure of the Universe. In light of the recent measurement of the speed of GWs, a reverse engineering allows to predict the consequences for large classes of gravity models at large scales.

This summary paper is based on our previous original works which appeared in Refs. 8–12, which we refer to for a full list of references.

## 2. The gravitational slip and model independence

[a]Large scale inhomogeneities are sourced by scalar fluctuations of the metric around the homogeneous and isotropic FLRW spacetime. We assume that scalar metric fluctuations are described according to $ds^2 = -(1+2\Psi(\mathbf{x},t))dt^2 + a(t)^2(1-2\Phi(\mathbf{x},t))d\mathbf{x}^2$. At the linear level, the anisotropy constraint reads as

$$\Phi - \Psi = \sigma(t)\Pi(t,k). \tag{1}$$

Here $\Pi$ is a functional of background quantities and linear perturbation variables (time and scale dependent), while $\sigma(t)$ depends on background quantities only[b]. The gravitational slip parameter $\eta$ is a direct measure of scalar (linear) anisotropic stress and is defined as

$$\eta \equiv \frac{\Phi}{\Psi}. \tag{2}$$

Anisotropic stress therefore sources a gravitational slip, i.e $\eta \neq 1$. At late times, the free streaming of neutrinos makes a negligible contribution to the anisotropic pressure part of the total energy-momentum in the Universe. Instead, its only source in the presence of perfect fluid matter is a possible modification of gravity. For minimally coupled scalar field theories (quintessence, k–essence) or $\Lambda CDM$, it is $\eta = 1$, while $\eta \neq 1$ in non-minimally coupled models such as $f(R)$/Brans–Dicke. Obviously this discussion needs to be made on firm grounds – the distinction between different models will be made precise in section 3 when we will introduce our working definition of modified gravity.

We will now show how $\eta$ can be reconstructed in a model-independent manner, closely following the original work of Refs 8 and 9. Let us start by assuming that galaxies move on geodesics, a valid assumption as long as non-linearities associated with e.g spacetime effects or galaxy-galaxy interactions can be neglected. In addition, it uniquely fixes the conformal frame, an issue implicit in theories with

[a]This section closely follows the original work presented in Refs. 8 and 9.
[b]It is not hard to see that, for any model the anisotropy constraint can be always brought into this convenient form.

different conformal representations (the so–called Jordan/Einstein frame). The resulting geodesic equation reads as

$$\left(a^2\theta_{\rm gal}\right)' = a^2 H k^2 \Psi\,. \tag{3}$$

Therefore, the observable galactic velocity field $\theta_{\rm gal}$ can be simply seen as a measurement of the gravitational potential $\Psi$ at different redshifts and scales.

Weak lensing observations provide a measurement of the lensing potential defined through

$$k^2\Phi_{\rm lens} \equiv k^2(\Psi+\Phi) \equiv -\frac{3(1+z)^3}{2E^2}L\,, \tag{4}$$

where $L \equiv \Omega_{\rm m0}GY(1+\eta)\delta_{\rm m,0}$. Therefore, tomographic weak lensing observations provide a measurement of the linear combination of $\Phi$ and $\Psi$. Now, combining equations (3) and (4) we can derive a model-independent relation for the gravitational slip solely in terms of observable quantities as[8]

$$\eta = \Phi/\Psi = \frac{3(1+z)^3}{2E^2\left(\frac{R'}{R}+2+\frac{E'}{E}\right)}\frac{L}{R} - 1\,, \tag{5}$$

where we introduced the velocity-field observable $R \equiv -\theta_{\rm gal}/H(z)$, and the background evolution $E(z) \equiv H(z)/H_0$, while $L$ was defined after (4).

## 3. Modified gravity and gravitational waves

The distinction between dark energy and modified gravity is sometimes blurry. For a meaningful and unambiguous discussion on how to discriminate between $\Lambda$CDM/dark energy and modified gravity models, we need to have a consistent definition of what we mean by dark energy and modified gravity in a given context. Here, following Ref. 10 we will define a modification of gravity as any theory that changes the propagation of the dynamical degrees of freedom of GR, i.e the gravitational waves (GWs). Assuming that GWs are far away from their source, we write

$$h_{ij}'' + \big(2+\nu(t)\big)Hh_{ij}' + c_{\rm T}^2(t)k^2h_{ij} + a^2\mu^2h_{ij} = a^2\Gamma(t)\gamma_{ij}(t)\,, \tag{6}$$

where the field $h_{ij}$ is the spin-two fluctuation of the metric. FLRW symmetry ensures that, general extensions of GR can modify the propagation of GWs only through one of the following parts: the friction ($\nu(t)$), the propagation speed ($c_{\rm T}^2$), mass ($\mu^2$) and source term ($\Gamma\gamma_{ij}$). Let us now introduce the models that we will be considering, which we conveniently divide into models introducing a new dynamical field of spin-0 (scalar-tensor), spin-1 (vector-tensor) and a spin-2 (massive/bigravity) respectively:

*Scalar-tensor theories:* These start with Brans-Dicke gravity and its generalisations, i.e Horndeski,[13] Beyond Horndeski and DHOST theories.[14–16] The presence of a non-minimal coupling between curvature and the scalar field will induce a running of the effective Planck mass which in turn modifies the friction term in (6) with

$\nu \equiv H^{-1} d \ln M(t)^2/dt$. The existence of a non-trivial kinetic mixing between the scalar and the metric alters the light-cone structure of GWs with respect to that of photons, leading to $c_T^2 \neq 1$. All other modifications in (6) equal zero for this class of models.

*Vector-tensor theories:* This class of theories includes Einstein-Aether (EA),[17] which is related to the low-energy limit of Horava-Lifsitz gravity.[18] The extension of the old (massive) Proca theory is described by the generalised Proca theories,[19,20] corresponding to the general covariant theory of a massive vector on a curved background. All of them lead to $c_T^2 \neq 1$, related to the non-trivial derivative interactions between the dynamical vector field and the metric.

*(Massive)Bi-gravity theories:* This family of theories describes the dynamics of two, non-minimally interacting coupled spin-two fields.[21] The non-minimal character of the interactions inevitably gives a mass to the standard (GR's) graviton, $\mu^2 \neq 0$. What is more, the second graviton sources the evolution of the standard one through the term on the right-hand side of (6), while all other terms are standard.

## 4. The link between gravitational slip and gravitational waves

### 4.1. *Non-standard propagation of gravitational waves implies a gravitational slip*

Let us assume that gravity is modified, according to its definition in Section 3. This means that the propagation of GWs will be different to GR in one way or the other according to (6). In Ref. 10 it was shown that a direct link exists between the propagation of GWs at any scale in the Universe and the existence of gravitational slip in the presence of perfect fluid matter at large scales: *For general extensions of GR introducing an extra spin-0, spin-1 and spin-2 two field respectively, the theory-space parameters that enter the coefficient of anisotropic stress, are exactly those that modify the propagation of GWs at any scale.*

In view of the anisotropy and the GW propagation equation, (1) and (6) respectively, this translates to the theory-space parameters entering $\sigma$ to be the same modifying the propagation of GWs. This link establishes a phenomenological bridge between two apparent disconnected regimes, connecting the physics of large-scale structures in the Universe with the propagation of GWs at any scale.

## 5. Dark energy phenomenology after GW170817

[c]Recently, the speed of GWs was measured from an observation of a merging neutron star and an electromagnetic counterpart, yielding the extremely strong constraint $|c_T/c - 1| \leq 10^{-15}$.[6] The observation has essentially ruled out all gravitational interactions which change the light cone structure of GWs – these are typically

[c]This section closely follows the results presented in Ref. 12.

terms which mix kinetically the scalar with the metric, beyond the simple conformal coupling (Brans–Dicke/$f(R)$). In light of the previously discussed link between GWs and the large-scale structure of the Universe, this new constraint can be translated to phenomenological predictions at large scales. Below we discuss the implications for the theory space of different families of models following the results and notation of the original work.[12]

*Scalar-tensor theories:* For Horndeski theories, the surviving theory space is described by

$$\mathcal{L} = \frac{f(\phi)}{2}R + K(X,\phi) - G(X,\phi)\Box\phi. \tag{7}$$

Notably, the only non-minimal coupling between scalar and curvature allowed is of the conformal type. The second term in (7) encompasses the k–essence/quintessence theory, while the third one the so–called kinetic gravity braiding.[22] At the linear level of scalar perturbations, the theory (7) is described by three functions of time, namely the so–called kineticity ($\alpha_K(t)$), braiding ($\alpha_B(t)$) and Planck mass rate ($\alpha_M(t)$). The first one measures the amount of fluctuations of the scalar field, the second the braiding between scalar and metric fluctuations, while the third the rate of change of the evolving Planck mass. In the quasi-static limit, it turns out that for the effective Newton's constant for the theory (7) reads as

$$Y = 1 + \frac{(\kappa+\alpha_M)^2}{2N}\,, \tag{8}$$

with $Y(t,k) \equiv -2k^2M_*^2\Psi/(a^2\rho_m\delta_m)$. Here, $\kappa \equiv \alpha_M + \alpha_B$ is sourced only through the third operator in (7) and is zero otherwise, since $\alpha_M = -\alpha_B$ for Brans-Dicke/$f(R)$ and $\alpha_M = 0 = \alpha_B$ in minimally-coupled models. $N$ is associated with the sound speed of the scalar and is required to be positive. For the gravitational slip and lensing parameter one finds that,

$$\eta - 1 = -\frac{2\alpha_M(\kappa+\alpha_M)}{2N+(\kappa+\alpha_M)^2}, \qquad \Sigma \equiv \frac{Y(\eta+1)}{2}. \tag{9}$$

From these relations it is straightforward to conclude for the *updated phenomenology* of scalar-tensor theories at large scales: The strength of clustering can be only made stronger than or equal to that in GR, that is, $Y \geq 1$. The lensing is the same as in GR ($\Sigma = 1$) as soon as the third operator in (7) (braiding term) is absent ($\alpha_B = -\alpha_M$ or $\alpha_B = 0 = \alpha_M$) – this is to be expected, as conformally- or minimally-coupled models do not affect null geodesics. However, as soon as the braiding term is included it is $\Sigma \neq 1$. As regards the slip parameter $\eta$, that can be on either side of its GR value, i.e $\eta < 1$ or $\eta \geq 1$.

*Vector theories:* Let us start with Einstein-Aether theories. The theory introduces three constant parameters $\beta_i$ associated with each operator in the action. The requirement of $c_T^2 = 1$ imposes that $\beta_1 = -\beta_3$, and at the same time eliminates the vector's anisotropic stress contribution, fixing $\eta = 1$. For the effective Newton's

coupling, it is $Y = (1+3\beta_2)/(1-\beta_1)$. Given that stability requires $\beta_2, \beta_1 > 0$, then $Y \geq 1$, as was the case in Horndeski models.

On the other hand, generalised Proca theories are characterised by six free functions at the level of the action, and similar to Horndeski theory, these combine to form a set of time-dependent functions that control scalar linear perturbations. The terms in the action that affect the GW propagation are those that kinetically mix the vector with the metric – It turns out that, for the associated free functions of these operators, $G_4 = \text{const}$ and $G_5 = 0$.[23,24] For this case the gravitational slip parameter becomes always equal to unity $\eta = 1$, while for the effective Newton's coupling (within the quasi–static approximation) we find that,

$$Y = 1 + \frac{-w_3 w_2^2}{N} \geq 1, \tag{10}$$

where we used the notation of Ref. 25 for the background functions $w_i(t)$. We further defined the quantity $N \equiv 2\mu_2/\phi + w_3 w_2^2$, which is related to the sound speed of the new degree of freedom, and the functions $w_2, w_3, \mu_2$ are defined in Ref. 25. Investigation of the explicit expression for $w_3$, along with the requirement of absence of ghost instabilities implies that $w_3 < 0$ and on similar grounds, the stability of scalar fluctuations requires that $N > 0$. From these, it follows for this case too that, $Y \geq 1$, that is, the clustering of matter can be made either equal or stronger compared to GR for these models ($Y \geq 1$), similar to the previous models.

As we discussed in Section 3, *massive/bi-gravity theories* predict that GWs propagate with $c_{\rm T}^2 = 1$, hence the recent measurement has no implications for their theory space.

*Consistency conditions:* Based on the above, and working within the small-scale limit of the quasi–static approximation (i.e $k \to \infty$), we can extract two new consistency conditions for *scalar–tensor theories* at large scales[d]:

1. $\eta < 1$ and $\Sigma = 1$: An imprint of a conformally coupled scalar field (Branks-Dicke/$f(R)$).

2. $\eta > 1$ and/or $\Sigma \neq 1$: An imprint of the presence of a kinetic braiding term in the action, in addition to the conformal coupling to curvature.

For *vector models*, an important corollary is the characteristic combination $\eta = 1$ and $Y \geq 1$.

It is interesting to remark that future direct observations of GWs can probe the running rate of the Planck mass in the surviving scalar-tensor sector as was argued in Refs. 27, 28, 29.

[d]For minimally-coupled scalar-tensor models it is easy to see that $\eta = 1$ and $Y > 1$. Notice that here, we do not consider the possibility of special configurations such as the scenario of No-Slip gravity of Ref. 26.

Table 1. Phenomenological implications for the gravitational slip and lensing parameters $\eta$ and $\Sigma$ respectively, after the recent measurement of the speed of GWs (see Section 5).[12] The first two rows describe the surviving theory space of Horndeski models, while the second and third one the Einstein–Aether and generalised Proca vector theories respectively. In all models, it now turns out that for the effective Newton's coupling at large scales it is $Y \geq 1$, i.e, clustering of matter is equal to or stronger than in GR.

| **Model** | $\eta \equiv \Phi/\Psi$ | $\Sigma \equiv (1/2)(\eta+1)Y$ | $Y$ |
|---|---|---|---|
| $M_p^2 R + K(\phi, X)$ | 1 | 1 | $Y \geq 1$ |
| $f(\phi)R + K(\phi, X)$ | $\leq 1$ | 1 | $Y \geq 1$ |
| $f(\phi)R + K(\phi, X) + G(X, \phi)\Box\phi$ | $< 1$ or $\geq 1$ | $\neq 1$ | $Y \geq 1$ |
| Einstein-Aether | $= 1$ | $\neq 1$ | $Y \geq 1$ |
| Generalised Proca | $= 1$ | $\neq 1$ | $Y \geq 1$ |

## 6. Summary

In this short paper we summarised key results from our previous works on the significance and the construction of model independent tests of gravity at cosmological scales, their intimate relation with the properties of GWs and the most recent phenomenological implications of GW observations for dark energy models. The recent measurement of the speed of GWs placed surprisingly stringent constraints on the theory space of gravity models, and allowed for robust cosmological predictions that can be accurately tested with the future Euclid satellite mission.[30] The new predictions and consistency conditions for the gravitational slip, weak lensing and effective gravity strength parameter summarised in Section 5, provide a challenge for the surviving models that will be tested with future surveys.

# Linking multipole vectors and pseudo entropies for CMB analysis

Marvin Pinkwart[1*], Peter Schupp[1] and Dominik J. Schwarz[2]

[1] *Department of Physics and Earth Sciences, Jacobs University, 28759 Bremen, Germany*
[2] *Fakultät für Physik, Universität Bielefeld, 33501 Bielefeld, Germany*
[*] *E-mail: m.pinkwart@jacobs-university.de*

Multipole vectors and pseudo entropies provide powerful tools for a numerically fast and vivid investigation of possible statistically anisotropic, resp. non-Gaussian signs in CMB temperature fluctuations. After reviewing and linking these two conceptions we compare their application to data analysis using the Planck 2015 NILC full sky map.

*Keywords*: Cosmic Microwave background; data analysis; entropy.

## 1. Motivation

Over the past 50 years the cosmic microwave background (CMB) has become the main source of information about the early universe. It displays a nearly isotropic black body with an order $10^{-3}$ dipole modulation due to peculiar motion and order $10^{-5}$ anisotropies which depict energy density fluctuations on the last scattering surface (LSS). Motivated by the simplest inflationary scenarios and linear perturbation theory these anisotropies are commonly assumed to be statistically isotropic and Gaussian, which means that if one decomposes the relative temperature fluctuations on the celestial sphere into spherical harmonics

$$\delta T(\theta,\phi) = \sum_{l=1}^{\infty} \sum_{m=-l}^{l} a_{lm} Y_{lm}(\theta,\phi), \tag{1}$$

the joint distribution of the spherical harmonic coefficients $a_{lm}$ for a given multipole number $l$ should be isotropic

$$p(\hat{R}\{a_{lm}\}) = p(\{a_{lm}\}), \tag{2}$$

where the rotation acts on the $a_{lm}$ via Wigner symbols, and Gaussian

$$p(\{a_{lm}\}) = \mathcal{N} \exp\left(-\frac{1}{2} \sum_{mm'} a^*_{lm'} \mathcal{D}_{l,mm'} a_{lm}\right). \tag{3}$$

Since the one-point function of the $a_{lm}$ vanishes, Gaussianity implies that all information about $\delta T$ is encoded in the two-point functions $\langle a_{lm} a_{lm'} \rangle = \mathcal{D}^{-1}_{l,mm'}$ and statistical isotropy further reduces the degrees of freedom to one per multipole number by diagonalizing the covariance $\mathcal{D}^{-1}_{l,mm'} = C_l \delta_{mm'}$. This yields the power spectrum which is commonly used as the main source of information about the CMB. Hence, the two basic assumptions reduce the real degrees of freedom per multipole from $2l + 1$ to one. If one or both of the assumptions are relaxed, one needs to find additional data compressing measures which are easier and can be interpreted more directly and vividly than the $a_{lm}$. In this contribution we describe and link two approaches to find such measures which are furthermore complementary to

the power spectrum in information content. The first approach concerns multipole vectors whose use is motivated by large scale anisotropy anomalies that have been found recently and the second approach introduces pseudo entropy measures on the space of spin states associated to temperature fluctuation fields which provide a non brute-force method to investigate non-Gaussianities and are motivated by the analogy to statistical mechanics where the large number of microscopic degrees of freedom is essentially captured by a few macroscopic quantities such as entropy.

## 2. Multipole vectors and pseudo entropies

Multipole vectors (MPVs) have been introduced to CMB data analysis in Ref. 1. and were used to identify one of the three basic "atoms" of large scale isotropy anomalies. It was found that the quadrupole and octupole are correlated, that the octupole is unusually planar and that both quadrupole and octupole are unusually orthogonal to the Ecliptic Plane and aligned with the Solar Dipole, see the review in Ref. 2. Contrary to the behavior of spherical harmonic coefficients, MPVs rotate rigidly with the celestial sphere and therefore put themselves forward as the correct basic constituents of measures of statistical anisotropy. Let $\vec{e} = (e^1, e^2, e^3)^T = \vec{e}(\theta, \phi)$ be a unit vector, then the basic idea is to observe that the $l$-multipole-part of $\delta T$ is a homogeneous polynomial of degree $l$ and to decompose it according to

$$(\delta T)_l\,(\vec{e}(\theta,\phi)) = A^{(l)}\left[v_{i_1}^{(l,1)}\cdots v_{i_l}^{(l,l)}\right]\left[e^{i_1}\cdots e^{i_l}\right] = B^{(l)}\prod_{i=1}^{l}\vec{e}\cdot\vec{v}^{(l,i)} + F^{(l)}(\theta,\phi), \quad (4)$$

where $A^{(l)}$ and $B^{(l)}$ are real constants, $F^{(l)}$ is a polynomial of defree $l-2$ and Einstein's summation convention was used.[3] The $\vec{v}^{(i,l)}$ are the MPVs and contain all information content of the temperature map up to a constant amplitude. Since the power spectrum is contained within this amplitude, the information content of the MPVs lies in the complement of the space of $C_l$-information. Hence, MPVs provide an interesting tool to test if this subspace is non-empty, i.e. if the temperature map is statistically anisotropic. In fact, as shown in Ref. 4 the statistical behavior of MPVs is the same for the larger class of all completely random sets of $a_{lm}$, i.e. $p(\{a_{lm}\}) = f(\sum_m |a_{lm}|^2)$, which contains the standard ΛCDM case but also some isotropic non-Gaussian maps. Note, that the $l$-multipole part of $\delta T$ can also be viewed as a normalized spin-$l$ state

$$|\delta T\rangle_l = \sum_m \widetilde{a}_{lm}|lm\rangle \quad (5)$$

up to an amplitude which contains the information about $C_l$, where the $a_{lm}$ have been normalized to $\widetilde{a}_{lm}$. Then the contraction of Bloch coherent states with such a temperature state and stereographic projection yield a complex polynomial

$${}_l\langle\Omega|\delta T\rangle_l \sim \sum_m \sqrt{\binom{2l}{l+m}}\widetilde{a}_{lm}z^{l+m} \sim \prod_{i=1}^{l}(z-z^{(l,i)})\left(z+\frac{1}{(z^{(l,i)})^*}\right), \quad (6)$$

whose $2l$ zeros are the stereographic projections $z^{(l,i)}$ of the MPVs $\vec{v}^{(l,i)}$ and their antipodes.[5] Bloch coherent states are given by the rotation of the highest spin state $|\Omega\rangle_l = \hat{R}(\Omega)|l,l\rangle$ by angles $\Omega = (\theta, \phi)$. For a detailed review on MPV constructions see Ref. 6. Now one can define the most classical quantum entropy which is named Wehrl entropy

$$S_l^{\mathrm{W}} = S^{\mathrm{W}}(|\delta T\rangle_l) = -\frac{(2l+1)}{4\pi}\int \mathrm{d}\Omega\, |{}_l\langle\Omega|\delta T\rangle_l|^2 \log\left(|{}_l\langle\Omega|\delta T\rangle_l|^2\right), \tag{7}$$

and which is used for CMB data analysis as a measure of randomness of temperature fluctuations.[7] The disadvantage of the Wehrl entropy is its numerically expensive form and hence one seeks measures that approximate the Wehrl entropy reasonably well but are much easier to compute. Since the temperature map describes a pure state, the usual von Neumann entropy is trivial. The basic idea to overcome this problem is to apply a quantum channel $\Phi$, which respects isotropy, to the pure temperature state $\rho_l = |\delta T\rangle_l\langle\delta T|$ to obtain a mixed density $\rho_l^{\Phi}$ and afterwards apply the von Neumann entropy to get a mixed pseudo entropy

$$S_l^{\Phi}(\delta T) = -\mathrm{Tr}\left(\rho_l^{\Phi}\log(\rho_l^{\Phi})\right). \tag{8}$$

The term "pseudo" shall indicate that the resulting quantity loses some properties entropies usually possess. From now on we drop this adjunct. In Ref. 8 we introduced two convenient choices of rotationally symmetric quantum channels:

- The $j$-projection entropy uses the mixed density

$$\rho_l^{\mathrm{proj},(j)} = \Phi^{\mathrm{proj},(j)}(\rho_l) = \frac{2l+1}{2(l+j)+1}\hat{P}_{l+j}\left(\rho_l \otimes 1_j\right)\hat{P}_{l+j}, \tag{9}$$

  where $\hat{P}_{l+j}$ denotes the projection to the $[l+j]$-subspace of $[l]\otimes[j]$. It converges to $S_l^{\mathrm{W}} + \log\left(\frac{2(l+j)+1}{2l+1}\right)$ for $j\to\infty$, but not uniformly. The additional term does not depend on the data, but just on the numbers $l$ and $j$ and henceforth in data analysis this term does not need to be taken into account. Therefore one may say that in the realm of data analysis the projection entropy converges to the Wehrl entropy.
- The angular entropy uses the mixed density

$$\rho_l^{\mathrm{ang}} = \Phi^{\mathrm{ang}}(\rho_l) = \frac{1}{l(l+1)}\sum_{i=1}^{3}\hat{L}_i\rho_l\hat{L}_i^{\dagger}, \tag{10}$$

  where the $L_i$ are the angular momentum operators acting on spin space. For $l=2$ it measures the repulsion of MPVs and shows the exact same behavior as the Wehrl entropy once an overall shift and dilation in absolute value has been accounted for. Let $\epsilon$ be the squared chordal distance between the two MPVs on

a sphere of radius 1/2, then the angular and Wehrl entropy can be expressed as

$$S_2^{\mathrm{ang}}(\epsilon) = -\frac{c(\epsilon)}{2}\left((1-\epsilon)^2\log(1-\epsilon)^2 + \epsilon^2\log\left(\epsilon^2\right)\right) - \log\left(\frac{c(\epsilon)}{2}\right) \tag{11}$$

$$S_2^{\mathrm{W}}(\epsilon) = c(\epsilon) - \log(c(\epsilon)) + \frac{32}{15} - \log(6), \tag{12}$$

where $c(\epsilon) := (1-(1-\epsilon))^{-1}$. Motivated by this result, the convergence of the projection to the Wehrl entropy and the numerically similar behavior, we propose that the similarity of Wehrl and angular entropy as well as the interpretation as a measure of repulsion between MPVs should be valid on all scales, at least approximately. Since repulsive behavior of zeros of random polynomials is connected to the degree of Gaussianity of the polynomial, we consider the angular entropy as a simple measure for deviations from Gaussianity, at least as long the deviation causes an exit from the space of completely random distributions. Furthermore, we showed that the probability distribution of the angular entropy is highly sensitive to "small" deviations from Gaussianity, in the sense that if one replaces $i$ MPVs from a Gaussian map by uniformly distributed unit vectors — which constitutes a deviation from Gaussianity without violating isotropy — the shift in distribution is sizable and the largest portion of shift is obtained from the first replaced vector.

Since all entropy measures use the normalized temperature state, their information content is complementary to the $C_l$, which is also the case for MPVs. Using the latter to build vivid scalar quantities yields additional measures, which we interpret as measures of statistical anisotropy. In Ref. 6 we used the following statistics:

- The internal/inner statistics

$$S^{||}(l) = \frac{2}{l(l-1)}\sum_{i<j}|\vec{v}^{(l,i)}\cdot\vec{v}^{(l,j)}| \tag{13}$$

$$S^{v}(l) = \frac{6}{l(l-1)(l-2)}\sum_{i<j<k}\left|\left(\vec{v}^{(l,i)}\times\vec{v}^{(l,j)}\right)\cdot\vec{v}^{(l,k)}\right| \tag{14}$$

  measure internal alignment and non-planarity of multipoles. In structure and interpretation these statistics share some similarities with the entropy measures.
- The external/outer statistics

$$S^{||}_{\vec{D}}(l) = \frac{2}{l(l-1)}\sum_{i}|\vec{v}^{(l,i)}\cdot\vec{D}| \tag{15}$$

$$S^{v}_{\vec{D}}(l) = \frac{6}{l(l-1)(l-2)}\sum_{i<j<k}\left|\left(\vec{v}^{(l,i)}\times\vec{v}^{(l,j)}\right)\cdot\vec{D}\right|, \tag{16}$$

  where $\vec{D}$ denotes some given outer physically motivated direction, measure outer directional or planary influences on the data.

## 3. Application to data analysis

Both methods have been applied to Planck 2015 and Planck 2018 full sky maps in order to compare them to statistically isotropic and Gaussian random maps and investigate if any signs of possible violations appear on multipole numbers up to 50 (MPVs), resp. 1000 (entropies).[6,8] In Fig. 1 we compare $S^{\text{ang}}$ (8)(10), -$S^{||}$(13), and $S^{||}_{\vec{D}}$ (15) with the Solar Dipole as a given physical direction $\vec{D}$ using the NILC 2015 full sky map. We use the negative of $S^{||}$ because it allows for an interpretation as a measure of non-alignment which is related to the interpretation of $S^{\text{ang}}$ as a measure of repulsion. One observes that the general behavior of both $S^{\text{ang}}$ and $S^{||}$ as a function of $l$ approximately agrees while unlikely multipoles are much more pronounced in $S^{\text{ang}}$. $S^{||}_{\vec{D}}$ clearly deviates from the others and the clustering of low-likelihood multipoles at $l \in [2, 5]$ reproduces the corresponding atom of CMB anomalies. Note that for the sake of clarity $1/3\sigma$-boundaries are not shown due to their different relative distances among the statistics, but note that $1\sigma \neq \frac{1}{2}(2\sigma)$.

Eventually we summarize further results that were obtained in Refs. 6, 8. With the MPV statistics the behavior of three full sky maps shows up to be similar even without applying masks, and no global anisotropies could be identified on $l \in [2, 50]$. After masking, the behavior of SEVEM approaches that of the other maps. The direction that is visible in the data most is the Solar Dipole, which appears in the large scale anomalies and via a clustering of $1\sigma$ (anti-)alignments around $l = 20$. Using the entropies the findings on masking, non-masked SEVEM, similarity between the other maps and overall normal behavior agree with those obtained with MPV statistics, but the entropy shows above $2/3\sigma$ unusual values at $l = 5/28$, which are curious because their values are higher than expected. It is unclear which kind of physical temperature map can result in too high entropies. The large-scale anomalies are visible when applying the range angular entropy, which takes into account ranges and possible correlations of multipoles. A comparison between 2015

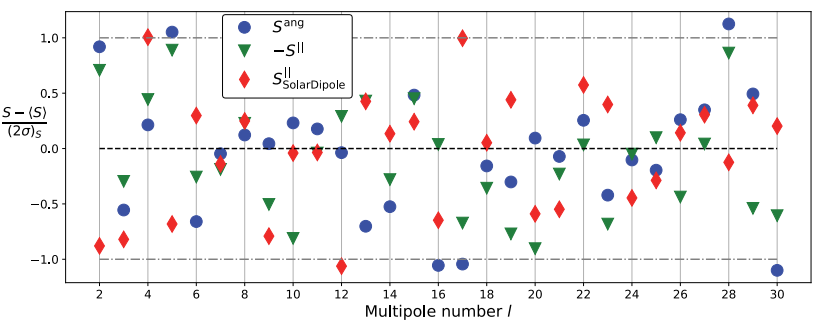

Fig. 1. Comparison of MPV statistics and angular entropy via the deviation of NILC 2015 full sky data from isotropic, Gaussian expectation in units of $2\sigma$-deviation calculated with $10^4$ (entropy) and $10^3$ (MPVs) ensembles on the range $l \in [2, 30]$.

and 2018 data revealed that the change in NILC and SMICA is negligible while unmasked SEVEM has been enhanced. The angular entropy can also be used on very small angular scales with moderate computational expense.

## Conclusions

MPV statistics yield vivid measures for identifying possible statistical anisotropies, possibly induced by physical influences measured via effects of outer directions. On the other hand our entropy methods yield fast measures for non-Gaussianity which allow for investigation down to small angular scales $l \geq 1000$. Both methods are mathematically related, see Eqs. (6), (11) and (12), and yield information content that is complementary to that of $C_l$. Note that in the future effects of inhomogeneous noise and masking should be taken into account more thoroughly. Our methods need full sky data but using e.g. spherical cap harmonics or other local methods one could make more sense of the statistics when applying a mask. An interesting future task would also be to redo the analysis using full focal plane simulations. Finally an efficient measure for unlikeliness when picking out ranges of random size needs to be worked out.

# Preliminary analysis of the optical system of the LSPE-STRIP instrument

Sabrina Realini* and Cristian Franceschet

*Physics Department, Universitá degli Studi di Milano,*
*Via Celoria 16, Milano, Italy*
**E-mail: sabrina.realini@unimi.it*

Maura Sandri and Fabrizio Villa

*INAF OAS Bologna,*
*Via Gobetti 101, Bologna, Italy*

We present a preliminary analysis of the optical system of the STRIP instrument of the Large Scale Polarization (LSPE) experiment, which aims at polarization measurements of the Cosmic Microwave Background on large angular scales. STRIP will observe approximately 25% of the Northern sky from the Observatorio del Teide in Tenerife, using an array of forty-nine coherent polarimeters at 43 GHz (Q-band), coupled to a 1.5 m fully rotating crossed-Dragone telescope. An additional frequency channel with six-elements at 95 GHz (W-band) will be exploited as an atmospheric monitor.

Non-idealities in the optical system may introduce limitations in achieving high precision measurements, if not well understood and controlled. For this reason, we studied the optical design of STRIP, its characteristics in terms of performance on angular resolution, sidelobes, main beam symmetry, polarization purity and feedhorns orientation, by means of electromagnetic simulations.

*Keywords*: CMB polarization, ground-based telescope, microwave optical simulations.

## 1. Introduction

The characterization of the polarized signal of the Cosmic Microwave Background (CMB) is, nowadays, one of the most important branches of observational cosmology. A direct measurement of the slight trace left by primordial gravitational waves on the CMB polarization pattern (the so called B-modes) would shed light on the first seconds of our universe.

The amplitude of the B-mode component is parametrized by the tensor-to-scalar ratio $r$ and, to date, only an upper bound at $r < 0.07$ at 95% C.L. has been set by the joint BICEP2/Keck Array and Planck analysis.[1]

Besides a strict control of the instrumental noise and systematic effects, a deep knowledge of astrophysical foregrounds is a key element for polarization analysis. In fact, both synchrotron and thermal dust emissions are partially linearly polarized. Since there is no region of the sky, at any frequency, where Galactic foreground contamination lies below a B-mode signal, it is important for all future experiments to monitor the foreground emissions with several frequency channels.

In this context, we find the STRIP instrument of the "Large Scale Polarization Explorer" (LSPE), which is the Italian Space Agency's upcoming experiment for the observation of the CMB polarization on large angular scales.

LSPE[2] combines ground-based and balloon-borne observations and aims at improving the limit on the tensor-to-scalar ratio down to $r = 0.03$ at 99.7% confidence level. A second target is to produce wide maps of foreground polarization generated in our Galaxy by synchrotron and interstellar dust emissions in a range of frequencies between 40 and 250 GHz, observing a 25% fraction of the sky in the Northern hemisphere.

## 2. The STRIP Instrument

STRIP is the ground-based instrument of the LSPE experiment that will observe the sky for two years from the "Observatorio del Teide" in Tenerife, starting in early 2020.[3] STRIP will scan the sky with a continuous azimuthal spin at 1 r.p.m., while maintaining the telescope boresight at a fixed elevation angle (approximately 20° from the Zenith at Tenerife latitude).

STRIP consists of an array of forty-nine coherent polarimeters, arranged in seven modules, operating in a 18% frequency band centered at 43 GHz (Q-band) and six polarimeters operating in a frequency band centered at 95 GHz (W-band) for atmosphere monitoring. Receivers are cooled down to 20 K in a cryostat placed in the focal surface of a dual reflector telescope, with a 1.5 m primary mirror.

The STRIP goal sensitivity on Stokes parameters is $\delta Q(U)_{deg} \leq 1.2\,\mu$K for the Q-band and $\delta Q(U)_{deg} \leq 4.5\,\mu$K for the W-band. Each Q-band receiver includes a circular corrugated feedhorn, a polarizer, an orthomode transducer (OMT) and a polarimeter module, which enables the detection of the Q and U Stokes parameters.

The W-band channel consist of a corrugated feedhorn and a septum polarizer, matched to a correlation polarimeter module. This channel will be used especially to track the amount of water vapor, which is the primary cause of atmospheric opacity. Characterizing the Tenerife observing site at W-band, i.e., near the foregrounds minimum, is of high interest also for potential future CMB experiments covering the Northern hemisphere.

## 3. The STRIP Optics

### 3.1. *The telescope*

The STRIP dual-reflector telescope is based on a Dragonian cross-fed design, with a projected aperture of 1.5 m. The crossed Dragone design is characterized by a parabolic primary mirror and hyperbolic secondary arranged to provide a large field of view and to aberrations at the center of the field. Moreover, the Dragonian configuration is the best in terms of polarization purity and symmetry over a wide focal region.[4]

The primary mirror of the STRIP telescope has an offset parabolic shape, with a 1500 mm aperture. The secondary mirror is an offset concave hyperboloid, with a 1719.76 mm × 1658.7 mm wide elliptical rim. The telescope provides an angular resolution of $\sim 20'$ in the Q-band and $\sim 10'$ in the W-band. The entire dual-reflector system has an equivalent focal length of 2700 mm, resulting in a F#$\sim$ 1.8.

The whole array of feedhorns is placed in the focal region of the telescope, ensuring no obstruction of the field of view. All feedhorns modules have been placed according to the telescope focal surface (see Fig. 1) and oriented towards the main reflector center, so that an optimum spillover is obtained while guaranteeing low level of cross–polarization contamination.

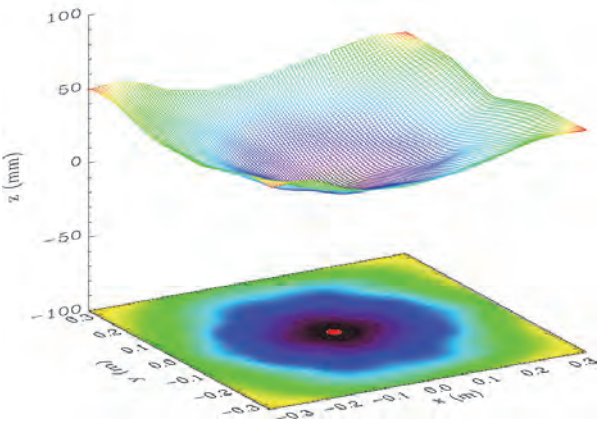

Fig. 1. Focal surface of the STRIP dual-reflector telescope.

### 3.2. *Mount and shielding structures*

The telescope is surrounded by a comoving baffle made of seven aluminum plates in order to reduce the contamination due to the sidelobes. This optical assembly is hold by a mount, which allows the STRIP optics and receivers to point at any direction in the sky. The telescope mount, already built for the CLOVER experiment[5], is a three-axes system that can fully rotate in azimuth and reach elevations from 0° to 89.5°. The telescope elevation angle will be fixed at approximately 20°.

### 3.3. *Electromagnetic model*

The STRIP optics have been modeled with the software GRASP[a]. The model includes the two nominal reflectors, forty-nine Q-band feedhorns and six W-band feedhorns, and the shielding structures, which redistribute the power that is radiated by the feedhorns and is not reflected by the telescope (see Fig. 2).

Main beams and sidelobes have been simulated and analyzed separately, because of the different sampling in the $\theta$ and $\phi$ coordinates and the different simulation

[a]The GRASP software is developed by TICRA (Copenhagen, DK) for analysing general reflector antennas.

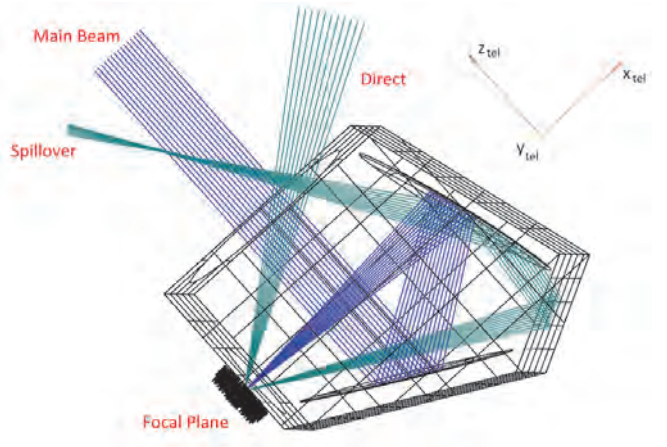

Fig. 2. Telescope and shielding structure model with the ray-tracing of some MrGTD contributions in the symmetry plane.

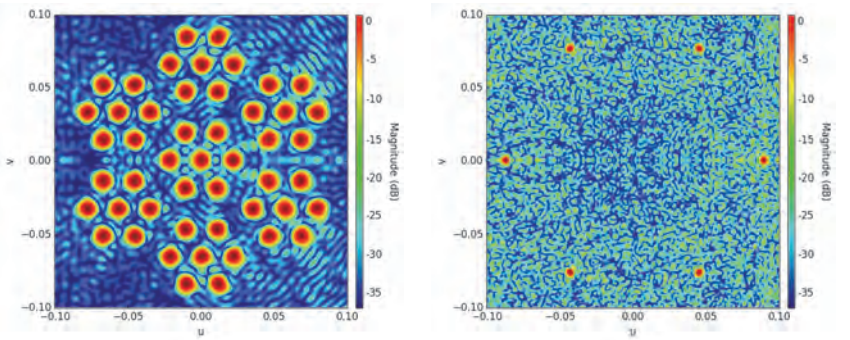
technique. Main beams have been simulated using the Physical Optics (PO) method, which computes the induced currents on the reflecting surfaces in order to obtain the total field. This method is the most accurate for predicting beams; however, in the sidelobes region, the PO integrand oscillates and a finer integration grid is required, leading to an increasing computation time. For this reason, the sidelobes have been computed using the Multi-Reflector Geometrical Theory of Diffraction (MrGTD), which represents a suitable method for predicting the full-sky radiation pattern of complex mm-wavelength optical systems, because it computes the scattered field from the reflectors performing a backward ray-tracing.

## 4. Performance Analysis

The radiation pattern of the feedhorns in the STRIP optics have been simulated in their main beam coordinate system at 43 and 95 GHz, exciting each feedhorn individually with a linearly polarized signal. Fig. 3(a) shows the footprint of the forty-nine beams at 43 GHz in the sky, while Fig. 3(b) shows the footprint of the six beams at 95 GHz.

Given the telescope configuration and the feedhorn off-axis location on the focal surface, the main beams are not perfectly Gaussian, so that they cannot be described by a single parameter. For a complete characterization of the main beams, several descriptive parameters have been evaluated: the angular resolution (FWHM), the ellipticity (e), the main beam directivity (D), the cross-polar discrimination factor (XPD) and the spillover. For the Q-band, the angular resolution is around $21'$ and the directivity is around 54.7 dBi for all the Q-band channels, while the XPD ranges



(a) (b)

Fig. 3. Q-band channel (a) and W-band channel (b) footprints on the sky as seen by an observer looking towards the telescope along its optical axis. The origin of the uv-coordinate system is at the center of the focal plane. The z-axis is along the line-of-sight and points towards the observer.

from 40.8 to 44.5 dB. For the W-band, the angular resolution is around $9.5'$ and the directivity is around 61.4 dBi.

We computed also the sidelobes of the STRIP telescope up to the $3^{rd}$ order of interaction (i.e. reflection or diffraction), for some representative channels. They are unevenly distributed and concentrated mainly in two areas, namely the "direct contribution" and the "spillover" (see Fig. 4). The direct contribution is generated by the rays entering the feedhorns without any interaction with the reflectors; its shape and power level are given by the feedhorn radiation pattern pointing at about 60° from the line of sight of the telescope. The spillover is primarily due to rays reflected by one of the shields and then reflected by the sub-reflector. The radiation patterns of both the Q- and W-band corrugated feedhorns have been measured in an anechoic chamber to check the compliance with the requirements and verify the reliability of the GRASP model.

## 5. Conclusions

In this paper, we presented a preliminary analysis of the optical system of the STRIP instrument of the LSPE experiment. All the main beams have been computed and we retrieved the main descriptive parameters. Concerning the sidelobes, we analyzed only four representative channels, which revealed that particular attention should be paid to multiple reflections inside the shielding structure.

The analysis will be repeated evaluating the response in the bandwidth, because accurate predictions of the telescope response are essential for an in-depth knowledge of the whole instrument response and for the development of the data reduction pipeline, where also instrumental systematic effects are taken into account.

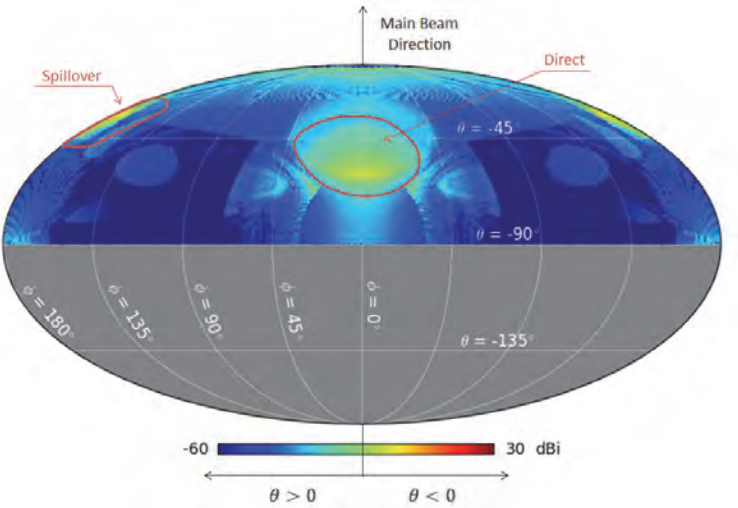


Fig. 4. Far sidelobes at 43 GHz for the feedhorn placed in the telescope focus. The main beam points to the top of the map ($\theta = 0°$) and peaks at 54.76 dBi. The direct contribution is due to the feedhorn sidelobe and peaks at about -5 dBi, while the spillover is due to a double reflection inside the shielding structure and peaks at about -0.8 dBi.

One of the main goals of modern cosmology is to probe inflationary theories by looking on the imprint of primordial gravitational waves in the cosmic microwave background (CMB) polarization field. Future CMB experiments face the great challenge to search for this primordial B-mode signal. However, the CMB sky is also filled with secondary B-modes, including CMB lensing and astrophysical foregrounds. Extracting the CMB B-mode polarization from astrophysical contaminations is a primordial task towards detection of the primordial signal. We use the analytical method of blind separation (ABS) proposed by Zhang, P., et al. (2019) to reconstruct the CMB B-mode power spectrum in the presence of foregrounds and white noise considering a full sky analysis for $r = 0$.

*Keywords*: CMB, foregrounds, statistics.

## 1. Introduction

The temperature anisotropies of the cosmic microwave background (CMB) radiation have been extensively addressed in the literature during the past three decades, being well characterized by various experiments such as WMAP [1, 2] and Planck satellites [3]). It is well known that these surveys detect not only the CMB signal itself, but a mixture of different emissions, including astrophysical foregrounds. One of the challenges in analyzing the CMB data has been the component separation, a fundamental step towards the efficient recovery of the CMB power spectra, thus the estimation of the cosmological parameters. Ongoing experiments targeting the polarized signal already face the difficulties of extracting the $E$-mode [4, 5] and specially the $B$-mode [6] polarization field from foregrounds.

Focusing on the CMB $B$-mode field that can probe inflation on large angular scales, we use the analytical method of Blind Separation (ABS) developed recently by [7] to extract the CMB simulated signal from foregrounds considering a multi-frequency future experiment. Contrary to other "blind" methods, such as the internal linear combination (ILC) [8–15] or the the Spectral Matching Independent Component Analysis (SMICA) [16–19], the ABS do not involve heavy computation. Moreover, it consists of the measured cross band power between different frequency bands, which is derived analytically in order to avoid multiple parameter fitting. Moreover, the ABS method was already successfully tested against

simulated temperature Planck maps [20]. Here, we start the study of the ABS performance on the CMB polarized signal.

## 2. The CMB polarization field

The linearly polarized CMB field is described by $Q$ and $U$ (Stokes parameters) which can be combined into a spin-(2) and spin-(-2) fields, such as $P_{\pm}(\hat{n}) = Q(\hat{n}) \pm iU(\hat{n})$. For full sky, these spin fields can be expanded over spin-weighted harmonic functions basis [21]:

$$P_{\pm}(\hat{n}) = \sum_{\ell m} a_{\pm 2,\ell m}\ {}_{\pm 2}Y_{\ell m}(\hat{n}). \tag{1}$$

The polarization field can also be written as the $E$ and $B$ components, which are defined in terms of the coefficients $a_{\pm 2,\ell m}$ in the harmonic space as

$$E_{\ell m} \equiv -\frac{1}{2}[a_{2,\ell m} + a_{-2,\ell m}], \qquad B_{\ell m} \equiv -\frac{1}{2i}[a_{2,\ell m} - a_{-2,\ell m}]. \tag{2}$$

The above definition allows $E(\hat{n})$ and $B(\hat{n})$ polarization sky maps to be written in terms of spherical harmonics,

$$E(\hat{n}) \equiv \sum_{\ell m} E_{\ell m} Y_{\ell m}(\hat{n}), \qquad B(\hat{n}) \equiv \sum_{\ell m} B_{\ell m} Y_{\ell m}(\hat{n}). \tag{3}$$

The power spectra being

$$C_{\ell}^{EE} \equiv \frac{1}{2\ell+1} \sum_{m} \langle E_{\ell m} E_{\ell m}^{*} \rangle, \qquad C_{\ell}^{BB} \equiv \frac{1}{2\ell+1} \sum_{m} \langle B_{\ell m} B_{\ell m}^{*} \rangle. \tag{4}$$

The brackets indicate the average over all realizations. In this work, we will consider only the $B$-mode field and our ability to recover the $B$-mode power spectrum from a multi-frequency future CMB experiment.

## 3. The ABS method

The ABS method analytically and blindly recovers the CMB power spectra from a contaminated map, relying on the measured cross band power between different frequency bands. The data in the multipole bin $\ell$ can be written as

$$\mathcal{D}_{ij}^{\rm obs}(\ell) = f_i f_j \mathcal{D}^{\rm cmb}(\ell) + \mathcal{D}_{ij}^{\rm fore}(\ell) + \delta\mathcal{D}_{ij}^{\rm noise}(\ell). \tag{5}$$

Here, $\mathcal{D}_{ij}^{\rm obs}(\ell)$ represents the cross band power spectrum of the B-mode power spectra at the $i$- and $j$-th frequency channels, where $i, j = 1, 2 \cdots N_f$ and $N_f$ is the total number of frequency channels.The three main contributions to the signal are $\mathcal{D}_{ij}^{\rm fore}$, which expresses the cross band power matrix of the foregrounds, $\mathcal{D}^{\rm cmb}$ being

the CMB signal and $\mathcal{D}_{ij}^{\rm noise}(\ell)$, which stands for the noise contribution to the total B-mode power spectrum. $f_i = 1$ for all channels in the units of thermodynamic temperature.

The CMB power spectrum can then be analytically derived such as [7]

$$\mathcal{D}^{\rm cmb} = \left( \sum_{\mu=1}^{M+1} G_\mu^2 \lambda_\mu^{-1} \right)^{-1} , \tag{6}$$

for $M < N_f$, where $M \equiv rank(\mathcal{D}_{ij}^{\rm fore})$, which depends on the number of independent foreground components. The order of $\mathcal{D}_{ij}^{\rm obs}(\ell)$ is $N_f$. In the above equation, $G_\mu = \mathbf{f} \cdot \mathbf{E}^\mu$ and $\mathbf{f} = (f_1, \ldots, f_{N_f})^T$. The $\mu$-th eigenvector and the associated eigenvalue of $\mathcal{D}_{ij}^{\rm obs}(\ell)$ are represented by $\mathbf{E}^\mu$ and $\lambda_\mu$, respectively. The eigenvectors are normalized as $\mathbf{E}^\mu \cdot \mathbf{E}^\nu = \delta_{\mu\nu}$.

Taking the instrumental noise into account, we modify Eq. 6 such as

$$\hat{\mathcal{D}}^{\rm cmb} = \left( \sum^{\tilde{\lambda}_\mu \geq \lambda_{\rm cut}} \tilde{G}_\mu^2 \tilde{\lambda}_\mu^{-1} \right)^{-1} - \mathcal{S} \, . \qquad \tilde{\mathcal{D}}_{ij}^{\rm obs} \equiv \frac{\mathcal{D}_{ij}^{\rm obs}}{\sqrt{\sigma_{\mathcal{D},i}^{\rm noise} \sigma_{\mathcal{D},j}^{\rm noise}}} + \tilde{f}_i \tilde{f}_j \mathcal{S} \, ,$$

$$\tilde{f}_i \equiv \frac{f_i}{\sqrt{\sigma_{\mathcal{D},i}^{\rm noise}}} \, , \quad \tilde{G}_\mu \equiv \tilde{\mathbf{f}} \cdot \tilde{\mathbf{E}}^\mu \, . \tag{7}$$

The matrix $\tilde{\mathcal{D}}_{ij}^{\rm obs}$ has $\tilde{\mathbf{E}}^\mu$ and $\tilde{\lambda}_\mu$ as the $\mu$-th eigenvector and corresponding eigenvalue, respectively. To avoid unphysical eigenmodes a threshold corresponding to $\tilde{\lambda}_{\rm cut}$ in Eq. 7 is taken into account, since the instrumental noise can lead to noise dominated eigenmodes with eigenvalues of $|\tilde{\lambda}_\mu| \lesssim 1/2$ in $\tilde{\mathcal{D}}_{ij}^{\rm obs}$ (see the details at [7, 20]). Moreover, the free shift parameter $\mathcal{S}$ is responsible for stabilizing the numerical calculations, specially in the case of the CMB B-mode power spectrum due to its small amplitude together with a high instrumental noise. In the next Section, we apply the ABS method to our polarized simulations.

## 4. Our simulations and results

We consider a future-like experiment with 10 frequency bands described in Table 1. The polarized maps are generated for these bands using the LensPix software [22, 23] with resolution of $N_{\rm side} = 1024$. The predicted CMB $B$-mode power spectrum was obtained by running the public available code CAMB [24], considering the best fit parameters from the standard cosmological model [25] for $r = 0$.

We added to the CMB $Q$ and $U$ maps two polarized foregrounds adopting the nominal `PySM` model [26] as the fiducial foreground model: thermal dust and synchrotron. Finally, a Gaussian instrumental noise, uncorrelated from pixel to pixel and from channel to channel, is also considered. In order to properly test the ABS method in the presence of noise, we generated 50 independent noise maps for each frequency band, being the CMB $B$-mode power spectrum recovered by averaging

Table 1. The considered experimental setup

| Band center (GHz) | Beam FWHM (arcmin) | noise level ($\mu K_{CMB}$- arcmin) |
|---|---|---|
| 030 | 28.3 | 12.4 |
| 043 | 22.2 | 7.9 |
| 075 | 10.7 | 4.2 |
| 090 | 9.5 | 2.8 |
| 108 | 7.9 | 2.3 |
| 129 | 7.4 | 2.1 |
| 155 | 6.2 | 1.8 |
| 223 | 3.6 | 4.5 |
| 268 | 3.2 | 3.1 |
| 321 | 2.6 | 4.2 |

over these sky maps. The associated statistical errors are obtained from its dispersion. It is important to point out that the CMB signal and the foreground components are fixed for all realizations. The results are shown in Figure 1 for $l_{max} = 1050$.

Finally, in order to visualize the difference between the recovered and the "true" $B$-mode power spectrum, we also show in Fig. 1 the relative error, $\hat{\mathcal{D}}_\ell^{\rm cmb}/\mathcal{D}_\ell^{\rm real} - 1$, in the percentage level. For full sky, the recovery of the $B$-mode power spectrum using the ABS method is in agreement with the "true" one for all multipole range within 20%, even though the 1-$\sigma$ confidence level for the reconstructed $B$-mode power spectrum is quite large at low-$\ell$ region.

## 5. Conclusions

We used the ABS methodology to estimate the CMB $B$-mode power spectrum considering a full sky approach. The ABS estimator was applied to simulated mutifrequency maps at 10 different frequency bands centered at 030, 043, 075, 090, 108, 129, 155, 223, 268 and 321 GHz mimicking a possible future CMB experiment. As for foregrounds, we added thermal dust and synchrotron, in addition to the Gaussian uncorrelated noise.

The results for the ABS method for recovering the CMB $B$-mode power spectrum in the presence of foregrounds are promising. We found that for the full range of considered multipoles the ABS is able to perform robustly, being the $B$-mode power spectrum recovered within 20% compared with the input spectrum. Moreover, considering ground based experiments, which are the near future surveys designed to measure the $B$-mode signal, a partial sky analysis must be taken into account. Such analysis is in preparation [27].

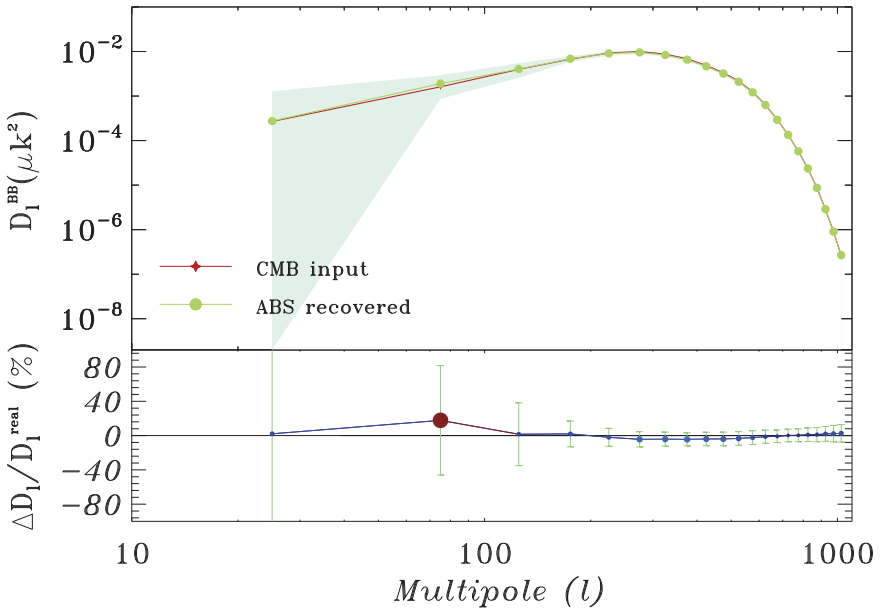

Fig. 1. Upper pane: The CMB binned $B$-mode power spectrum ($\Delta l = 50$) estimated from the ABS approach from a future experiment specified in Table 1 (green curve), considering $r = 0$ and smoothed to a Gaussian beam with FWHM=28.3′. The red curve corresponds to the CMB $B$-mode power spectrum from the sky realization without noise or foregrounds ("true" spectrum). The associated 1-$\sigma$ statistical error are also shown in the shadow region, based on 50 independent realizations of the instrumental noise. Lower panels: In comparison with the true power spectrum, the relative error, $\hat{\mathcal{D}}_\ell^{\rm cmb}/\mathcal{D}_\ell^{\rm real} - 1$ in the percentage level. The symbol colors and sizes illustrate deviations from 0% in respect to the "true" spectrum.

Cosmic strings in the early universe have received revived interest in recent years. In this work we derive these structures as topological defects from singular distributions of the quintessence field of dark energy. Emphasis is placed on the topological charge of tangled cosmic strings, which originates from the Hopf mapping degree and is a Chern-Simons type action possessing strong inherent tie to knot topology. It is shown that the HOMFLYPT (Jones) polynomial can be constructed in terms of this charge, serving as a topological invariant much stronger than the traditional Gauss linking numbers in characterizing string topology. This method induces applications in two aspects. One is to search a tool to measure the cascade of decreasing topological complexity and that of decreasing energy/entropy. The other is arousing a promising mathematical approach for the study of physical breaking-reconnection processes of tangled cosmic strings.

## 1. Complexity and cosmic strings

Cosmic strings as one dimensional relics might have been produced in the early universe, which lead to galaxies and primordial supermassive black holes. Interestingly, tangled cosmic strings compacitificated in a region (contexture) could collapse, causing cold/hot spots in CMB.[1] Dynamical simulations show that tangled string structures whose components tend to move to each other and then reconnect at cross sites quickly become simpler ones to carry less energy/entropy. It is hard to analyze this topology-changing process from a pure dynamical point of view; fortunately, similar process has been investigated via topological complexity in classical fluids. By means of analogy with the knotted fluid structures, we intend to study the evolution of tangled cosmic strings via topological complexity.

Let us start with a superconducting cosmic string (SCS) model with two massive complex scalars, $\phi$ and $\sigma$,

$$S=\int d^4x\left[\left|\widetilde{D}_\mu\phi\right|^2+\left|D_\mu\sigma\right|^2-\frac{1}{4}\widetilde{F}^{\mu\nu}\widetilde{F}_{\mu\nu}-\frac{1}{4}F^{\mu\nu}F_{\mu\nu}+V\left(\phi,\sigma\right)\right], \tag{1}$$

where $V\left(\phi,\sigma\right)=\frac{1}{4}\lambda_\phi\left(\left|\phi\right|^2-\eta_\phi^2\right)^2+\frac{1}{4}\lambda_\sigma\left(\left|\sigma\right|^2-\eta_\sigma^2\right)^2+\beta\left|\phi\right|^2\left|\sigma\right|^2$. This model breaks the $\phi$-related $U(1)$ symmetry in the ground state and keeps the $\sigma$-related one yielding current-carrying SCSs with orientations. With fine-tuning of the Higgs sector, currents are held stable in the cores of the SCSs which can be treated as line defects when observed from far away.

The equation of motion derived from (1) gives a distribution of the fundamental field $\phi$ on the base manifold. Introducing a covariant derivative $D_\mu^{\mathrm{ind}}\phi=\partial_\mu\phi-iA_\mu$,

which indeed corresponds to the parallel field condition in general relativity,[2,3] we obtain a $U(1)$ gauge potential induced by the $\phi$-distribution on the manifold. This $A_\mu$, through the $\phi$-distribution, is able to reflect the topology of the tangled SCSs. Then, based on $A_\mu$ a low-energy classical Yang-Mills model can be proposed to present stable knotted soliton structures in three dimensions, where a topological charge $Q$ is introduced to characterize the tangledness of the system,[4]

$$Q = \int_\Omega A \wedge F, \tag{2}$$

where the field strength is defined as $F = dA$. This $Q$ is recognized to be an integral of an abelian Chern-Simons (CS) type 3-form; traditionally, it can be delivered by topological numbers as $Q(\mathcal{L}) = \sum_{k=1}^{N} W_k^2 SL(\gamma_k) + \sum_{k,l=1(k<l)}^{N} W_k W_l Lk(\gamma_k, \gamma_l)$, where $\mathcal{L}$ denotes the link, $\mathcal{L} = \bigoplus_k \gamma_k$. $W_k$ is the topological charge (i.e., winding number) carried by the closed string $\gamma_k$. The $SL(\gamma_k)$ is the self-linking number of a knot $\gamma_k$, and $Lk(\gamma_k, \gamma_l)$ the Gauss linking number between two link components $\gamma_k$ and $\gamma_l$.[5] This $Q$ was used to study knotted cosmic strings in references.[6]

(a) (b)

Fig. 1. Different topological configurations have the same self-linking number 0.

(a) (b) (c)

Fig. 2. Different topological configurations have the same linking number 0.

However, the (self-)linking numbers are unfortunately weak invariants which fail to distinguish some typical knots/links such as in Figs. 1 and 2. In the following we will introduce more powerful tools of knot theory to characterize topology of SCS structures. Our starting point will still be the CS 3-form $Q$, which is able to generate various kinds of knot topological invariants thanks to the quantum CS topological field theory, such as the Kauffman bracket, Jones and HOMFLYPT polynomials, the Vassiliev finite type invariants via the Kontsevich integral, Khovanov homology, and so on.

## 2. HOMFLYPT polynomial for SCSs

SCSs have a chance to obtain released twist during evolutions, although the latter is not easy to be demonstrated mathematically. The Călugăreanu-White theorem states that writhing and twisting both have independent contributions to string topology, hence we intend to construct the two-variable HOMFLYPT polynomial to catch the topological information of writhes and twists in SCSs.

*Writhe contribution*: Integrating off two dimensions from the triple integral (2), the CS charge $Q$ becomes $Q(\mathcal{L}) = \sum_k W_k \oint_{\gamma_k} A_i dx^i$, where for simplicity one usually takes $W_k = 1$. According to Ref. 7, we propose to consider the exponential form $\exp(Q(\mathcal{L})) = \exp\left(\oint_{\mathcal{L}} A_i dx^i\right)$; in the following a bracket symbol is used, $\langle \mathcal{L} \rangle \equiv e^{Q(\mathcal{L})}$. Obviously, $\langle \bigcirc \rangle = 1$.

Fig. 3. The different states of four almost-the-same knots/links which differ only at one particular crossing site: (a) $L_+$, over-crossing; (b) $L_-$, under-crossing; (c) non-crossings: (*left*) $L_0$, left-right open; (*right*) $L_\infty$, up-down open.

First, let us consider un-oriented strings. Preparing a path-dependent quantity $\alpha$, defined by $\alpha \equiv \langle \gamma_+ \rangle$ and $\alpha^{-1} \equiv \langle \gamma_- \rangle$ with $\gamma_+ =$  and $\gamma_- =$  , we can follow the routine of knot theory to examine the basic states of Fig. 3.

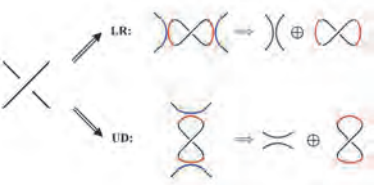

Fig. 4. Two channels for the over-crossing $L_+$: left-right (LR) and up-down (UD) splittings.

Second, based on an ergodic statistical hypothesis, a crossing site decomposes into two equivalent channels with the aid of two pairs of added imaginary strands which cancel each other. For instance, the over-crossing state $L_+$ in Fig. 4 has the splitting $\langle L_+ \rangle = \langle L_+ - \text{LR} \rangle + \langle L_+ - \text{UD} \rangle$, where $\langle L_+ - \text{LR} \rangle = e^{\oint_{L_0 \oplus \gamma_+}} = \alpha e^{\oint_{L_0}}$ and $\langle L_+ - \text{UD} \rangle = e^{\oint_{L_\infty \oplus \gamma_-}} = \alpha^{-1} e^{\oint_{L_\infty}}$. Performing a similar procedure for $L_-$ one obtains $\left\langle \times \right\rangle = \alpha \left\langle )( \right\rangle + \alpha^{-1} \left\langle \asymp \right\rangle$ and $\left\langle \times \right\rangle = \alpha^{-1} \left\langle )( \right\rangle + \alpha \left\langle \asymp \right\rangle$. Then, endowing the components of $\mathcal{L}$ with orientations, and introducing a R-polynomial $R[\mathcal{L}] = \alpha^w \langle \mathcal{L} \rangle$, with $w$ denoting the writhe of $\mathcal{L}$, we achieve

$$R\left(\times\right) - R\left(\times\right) = zR\left()(\right), \tag{3}$$

where $z = \alpha^2 - \alpha^{-2}$ stands for the writhe contribution. This presents one of the skein relations (i.e., the definition formulae) of the R-polynomial.

Fig. 5. Dehn surgery. (a) A cosmic string with intrinsic twist can be regarded as a twisted ribbon. (b) A $2\pi$-twist is added on a torus.

Fig. 6. A twisted ribbon can be decomposed into the sum of an untwisted ribbon, a trivial annulus and a positive twisting operation.

*Twist contribution*: In the context of physical knots, the Dehn surgery is considered as an idealized technique to treat insertion/deletion of intrinsic twists of knots, as showed in Figs. 5 and 6. The twisted string is mathematically identical to the sum of an untwisted ribbon, a trivial annulus and a positive twisting operation,[3,8] *i.e.*, $\exp\left(\oint \right) = a\exp\left(\oint \right)\exp\left(\oint_{\bigcirc}\right)$, where $a = \exp\left(\oint_{\text{positive twisting operation}}\right)$. Introducing the so-called HOMFLYPT polynomial $P(a,z) = a^{-w}R(a,z)$, with $a^{-w}$ being a compensation factor,

**Comment.** : $w\left[\ \right] = +1,\quad w\left[\ \right] = -1,\quad w\left[\ \right] = w\left[\ \right] = w\left[\ \right] = 0.$

we arrive at the HOMFLYPT skein relations of $P(\mathcal{L})$:

$$(1)\ P\left(\bigcirc\right) = 1, \qquad (2)\ aP\left(\times\right) - a^{-1}P\left(\times\right) = zP\left(\ \right). \tag{4}$$

Furthermore, if setting $z = \tau^{1/2} - \tau^{-1/2}$ and $a = \tau^{-1}$, (4) degenerates to the skein relations of the Jones polynomial:[8]

$$(1)\ V\left(\bigcirc\right) = 1,\quad (2)\ \tau^{-1}V\left(\times\right) - \tau V\left(\times\right) = (\tau^{-\frac{1}{2}} - \tau^{\frac{1}{2}})V\left(\ \right). \tag{5}$$

## 3. Example and conclusion

*Example*: The recurrence relation of torus knots/links, $T(2,n)$, is computed:[9] $P_{T(2,n)} = \left[\frac{k^{n-2}-(-k)^{-(n-2)}}{a^{n-3}(k+k^{-1})^{-1}}\right]P_{T(2,3)} + \left[\frac{k^{n-3}-(-k)^{-(n-3)}}{a^{n-3}(k+k^{-1})^{-1}}\right]P_{T(2,2)}$, where $P_{T(2,3)} = 2a^{-2} + a^{-2}z^2 - a^{-4}$ and $P_{T(2,2)} = a^{-1}z + (a^{-1} - a^{-3})z^{-1}$ with $z = k - k^{-1}$. Direct computation of the HOMFLYPT values of $T(2,n)$ allows us to associate a sequence of decreasing numerical values to a cascade of states with decreasing topological complexity, as shown in Figs. 7 and 8.

*Conclusion*: In this paper a new knot theoretical tool, the HOMFLYPT polynomial, has been introduced into the study of cosmic string topology. It can be used to characterize the complexity of SCSs. Typical examples of application are also provided. We hope this method could be useful for investigating topological non-conservative processes such as reconnections.

**E-mail: colin.maclaurin@uqconnect.edu.au*

I investigate the relativistic mechanics of an extended "cable" in an arbitrary static, spherically symmetric spacetime. Such hypothetical bodies have been proposed as tests of energy and thermodynamics: by lowering objects toward a black hole, scooping up Hawking radiation, or mining energy from the expansion of the universe. I review existing work on stationary cables, which demonstrates an interesting "redshift" of tension, and extend to a case of rigid motion. By using a partly restrained cable to turn a turbine, the energy harvested is up to the equivalent of the cable's rest mass, concurring with the quasistatic case. Still, the total Killing energy of the system is conserved.

## 1. Introduction

Hypothetical ropes/strings/cables/tethers in curved spacetime have been applied as test scenarios for energy, thermodynamics, and mechanics: hence are related to major open research questions. The cable considered here obeys ordinary energy conditions for macroscopic matter, and is conceived as engineered rather than naturally occurring. These properties are distinct from other strings in theoretical physics including Nambu-Goto relativistic strings, cosmic strings, and quantum strings such as in superstring theory.

Penrose proposed lowering a mass towards a black hole to extract energy.[1] Bekenstein considered lowering a hot object towards a black hole, to convert heat into work and violate the second law of thermodynamics, inspired by a talk of Geroch.[2] However Gibbons was the first to analyse the cable itself, including its tension.[3] Unruh & Wald suggested a resolution to Geroch's thermodynamic paradox, now in the context of Hawking radiation, and showed a "redshift" of tension along the cable.[4] Redmount used Weyl's axisymmetric solution to analyse distortions of Schwarzschild spacetime by two masses suspended on ropes.[5]

Others considered cables in Friedmann-Lemaître-Robertson-Walker spacetime, to test the dynamics of an expanding universe. Davies showed the futility of scooping up Hawking radiation from the de Sitter horizon.[6] Harrison proposed latching a rope onto distant receding bodies, to mine mechanical energy from the expansion.[7] Others also considered a "tethered galaxy",[8] or a network of strings reminiscent of Szekeres' gravitational compass. There are plenty of other sources, even omitting the cosmic string and string theory literature.

## 2. Newtonian cables

To show the concept is perfectly reasonable, consider a spool of cable tied to a tree branch at height $L$ above ground. Set up a steady state where a segment always stretches from winch to ground, and moves downwards at constant speed $\beta$. Then

under Galilean gravitational acceleration $g$ and linear mass density $\mu$, a constant force $\mu g L$ is exerted downwards. This gives a power $\mu\beta g L$ which can be harnessed at the winch, at the expense of gravitational potential energy.

Next consider a Newtonian "de Sitter" cosmology: an empty universe with cosmological constant $\Lambda$. Suppose the winch is anchored at the coordinate origin. Poisson's law $\vec{\nabla}^2\Phi + \Lambda = 4\pi G\rho$ has solution $\Phi = -\Lambda(x^2+y^2+z^2)/6$ in this case, where $\rho = 0$ since we ignore the cable's own gravitational field. The force on a static cable particle of mass $m$ at location $(x, y, z)$ is $\vec{f} = -m\,\vec{\nabla}\Phi = (x, y, z)m\Lambda/3$. The total force at the winch is hence $-\Lambda\mu L^2/6$ for a cable of length $L$. By allowing the cable to recede, work is gained, but the cable is gradually lost to space.

## 3. Stationary cable

This section reviews results of Gibbons and others, with some additions.[3,5,9] Consider an arbitrary spacetime containing a cable with linear mass density $\mu(\mathbf{x})$ and tension $T(\mathbf{x})$. With no sideways rigidity, the cable's stress-energy tensor is $\mathbf{T} = \tilde{\mu}\mathbf{u}\otimes\mathbf{u} + \tilde{T}\mathbf{q}\otimes\mathbf{q}$. Here $\mathbf{u}$ is the 4-velocity field of cable particles, $\mathbf{q}$ is a unit spatial vector field pointing along the cable, and $\tilde{\mu} := \mu/A$ and $\tilde{T} := T/A$ are scaled by the cross-sectional area.

Conservation of stress-energy implies the vector $\operatorname{div}\mathbf{T}$ vanishes, which when contracted with $\mathbf{u}$ and $\mathbf{q}$ leads to $d\tilde{\mu}/d\tau = -\tilde{\mu}\operatorname{div}\mathbf{u} + \tilde{T}\dot{\mathbf{q}}\cdot\mathbf{u}$ and $d\tilde{T}/dL = -\tilde{T}\operatorname{div}\mathbf{q} - \tilde{\mu}\mathbf{q}\cdot\dot{\mathbf{u}}$ respectively. Here $L$ is the proper-frame length along the cable, $\dot{\mathbf{u}} := \nabla_{\mathbf{u}}\mathbf{u}$ is 4-acceleration, $\dot{\mathbf{q}} := \nabla_{\mathbf{q}}\mathbf{q}$, and a dot between vectors implies the metric inner product. However stress-energy need not be conserved, for instance if the cable's gravitational field is ignored so $\mathbf{T}$ is not the source term in the Einstein field equations. Still, $\mathbf{u}\cdot\operatorname{div}\mathbf{T} = 0$ is guaranteed.[10]

Now suppose the spacetime contains a timelike Killing vector field $\boldsymbol{\xi}$, and that the cable particles are stationary. Hence $\mathbf{u} = \boldsymbol{\xi}/V$, where $V := \sqrt{-\boldsymbol{\xi}\cdot\boldsymbol{\xi}}$ is the redshift factor. In this case stress-energy conservation is guaranteed. It follows $d\tilde{\mu}/d\tau = 0$, and if $\mu$ is also constant over space then the tension varies as

$$\boxed{T = W\frac{V_{\text{end}}}{V} + \mu\Big(1 - \frac{V_{\text{end}}}{V}\Big)} \tag{1}$$

where $W$ is a weight (mass times magnitude of proper acceleration, if a point mass) hanging at the end. This exhibits a curious effect: the tension is "redshifted" by transmission along the cable, due to gravitational time-dilation. This is most evident for a massless cable $\mu \equiv 0$,[4] a limiting case of which is familiar in surface gravity as the "force at infinity" to support a unit mass particle at a horizon.[11] The cases $W = \mu$, or a cable ending at the horizon with $W = 0$, both yield a constant tension $T \equiv \mu$.[5,12] Alternatively, one can extend conservation of energy arguments used by Einstein and Bondi for redshift of photons, to justify redshift of force.

## 4. Moving cable

This section describes the kinematics and dynamics of a moving cable. For further explanation see §7, §9, and §11 of preliminary work.[13]

### 4.1. *Apparatus and background spacetime*

Consider a static, spherically symmetric spacetime with general metric

$$ds^2 = -e^{2\alpha(r)}dt^2 + e^{2\zeta(r)}dr^2 + r^2(d\theta^2 \sin^2\theta\, d\phi^2). \tag{2}$$

Static observers form a useful reference or comparison, these have 4-velocity

$$u^\mu_{\text{static}} = \big(e^{-\alpha}, 0, 0, 0\big), \tag{3}$$

where the $r$-dependence is omitted for brevity. The 4-acceleration is $a^\mu = (0, \alpha' e^{-2\zeta}, 0, 0)$ with magnitude $|\alpha'|e^{-2\zeta}$, and is directed towards increasing $r$ if $\alpha' > 0$ and vice versa. A dash will always indicate derivative with respect to $r$. The gravitational redshift factor, determined as usual by static observers, is $\sqrt{-\partial_t \cdot \partial_t} = e^\alpha$.

Assume the cable is hanging "downwards" in an equilibrium state, so as a whole the 4-velocity field is unchanged by translation in $\partial_t$. As in Section 2, set a winch or spool at the "top" $r = r_0$ say, attached to a turbine which allows only a fixed angular velocity. At the winch location, we assume $e^{\alpha(r_0)} = 1$, which interprets the winch as free of gravitational redshift (otherwise one could introduce an extra constant, or rescale the $t$-coordinate via $\bar{t} := e^{\alpha(r_0)}t$). Suppose the cable is cut repeatedly, so its end is fixed at $\approx r_{\text{end}}$, which simplifies the calculations. (One could imagine a cutting robot tethered to a static "service cable".)

### 4.2. *Kinematics*

Parametrise radial 4-velocities using the speed $\beta(r)$ relative to a local static observer:

$$u^\mu = \gamma\big(e^{-\alpha}, \beta e^{-\zeta}, 0, 0\big), \tag{4}$$

where $\gamma(r) := (1-\beta^2)^{-1/2}$ is the corresponding Lorentz factor, and we allow $\beta < 0$ via $\operatorname{sgn}(\beta) := \operatorname{sgn}(dr/d\tau)$. The cable's stress-energy is not conserved in general, as mentioned previously, but particle number

$$^{(1)}\nabla_i(nu^i) = 0 \tag{5}$$

is conserved. Here $n(r)$ is the number density, and the "(1)" indicates divergence in the radial direction only, which is a sum over $i = 0, 1$, in our coordinates. This evaluates to the first-order ODE $(n\beta\gamma)' + (n\beta\gamma)\alpha' = 0$, with solution

$$n\beta\gamma = Ce^{-\alpha} \tag{6}$$

for some constant $C$, ignoring trivial cases. In a local static frame, the number flux vector $n\mathbf{u}$ has components $n\gamma(1, \beta, 0, 0)$, hence $n\beta\gamma$ is interpreted as the local

number flux density in the radial direction, so $C \equiv n\beta\gamma e^{\alpha}$ is the redshift-corrected value — that is, the number flux density determined at the winch.

An equation of state gives an additional constraint. Instead of relativistic elasticity, for simplicity we assume Born-rigidity, meaning the expansion tensor is zero (constant proper-frame distance between neighbouring particles) in the radial direction. While Born-rigidity is not possible as an *implicit* property of a physical material, we treat it as a toy model, with discretion.[a]

Zero divergence $\nabla_i u^i = 0$, $i = 0, 1$, simplifies to $(\beta\gamma)' + (\beta\gamma)\alpha' = 0$ with solution

$$\beta\gamma = Ke^{-\alpha} \tag{7}$$

for some constant $K$. $\beta\gamma$ is the "proper speed" relative to the local static observer, hence $K$ is interpreted as the redshift-corrected proper speed; we treat $K \in (-\infty, \infty)$ as provided. From Equation 6, $n = C/K$, and it follows the density $\mu$ is constant. Also,

$$\gamma = \sqrt{1 + K^2 e^{-2\alpha}} \qquad\qquad \beta = K/\sqrt{K^2 + e^{2\alpha}}, \tag{8}$$

which follows from Equation 7. The cable 4-velocity is hence

$$u^{\mu} = e^{-\alpha}(\sqrt{1 + K^2 e^{-2\alpha}}, Ke^{-\zeta}, 0, 0). \tag{9}$$

Brotas gives similar results for Schwarzschild spacetime.[14] The 3-velocity $\vec{u}$ relative to the local static frame is $(K/\sqrt{K^2 + e^{2\alpha}}, 0, 0)$, from the decomposition $\mathbf{u} = \gamma(1, \vec{u})$ in a static frame, with $\beta = \|\vec{u}\|$ as expected. While it may seem *a priori* that rigid kinematics are trivial, various authors including Harrison do not correctly treat the frame dependence of length, i.e. "length-contraction". Now given the above motion, a cable particle has 4-acceleration $\mathbf{a} := \nabla_{\mathbf{u}}\mathbf{u}$ with magnitude

$$a = \sqrt{\mathbf{a} \cdot \mathbf{a}} = \frac{|\alpha'|e^{-\zeta}}{\sqrt{1 + K^2 e^{-2\alpha}}} \tag{10}$$

directed in the $\mathrm{sgn}(\alpha')$ direction of the $r$-axis. Physically, this acceleration is due to the support of the cable above.

### 4.3. *Dynamics, energy, and power*

The surplus of energy entering and exiting the system due to the cable's motion gives the power harvested. Consider firstly various energy fluxes measured locally in a static frame at given $r$:

- mass flux: $\mu\beta_r\gamma_r \equiv \mu K e^{-\alpha_r}$, locally at $r$
- kinetic energy flux: $\mu\beta_r\gamma_r(\gamma_r - 1) \equiv \mu K(\gamma_r - 1)e^{-\alpha_r}$, locally
- mass plus kinetic flux: $\mu\beta_r\gamma_r^2 \equiv \mu K\gamma_r e^{-\alpha_r}$, locally

[a] Physical intuition is applied here. For instance we derive tension and power, but not the speed of travelling waves. Similarly, our usage of "tension" is not necessarily compatible with Lorentz transformation of the stress-energy tensor between frames, but should be self-consistent.

In particular at the winch, the passing cable has mass flux $\mu K$ and kinetic energy flux $\mu K(\sqrt{1+K^2}-1)$, with sum $\mu K\sqrt{1+K^2}$. These are the energy rates entering the system. Now for a given power in a static frame at some $r$, transmitted to a static frame at $r_1$, the received power is redshifted by $e^{\alpha_r-\alpha_1}$ twice. (Imagine transmission via photons, then both the number rate and individual wavelengths are affected.)

Subtract the total flux at the start and end of the cable, to determine the overall power as transmitted to the winch frame. This calculation invokes time symmetry. However the incoming kinetic energy must also be provided,[b] hence at the winch:

$$\boxed{\mu K\big(1-\sqrt{K^2+e^{2\alpha_{\text{end}}}}\big).} \tag{11}$$

The winch end, with redshift 1, is included implicitly. The term in parentheses is the energy profit per mass, which for a slow cable ending near a Killing horizon ($e^\alpha \approx 0$) approaches 1, or 100% conversion of $E=mc^2$! If the technology exists to recover the outgoing kinetic energy, the power profit increases to $\mu K(1-e^{\alpha_{\text{end}}})$.

We check using an alternate derivation from forces. The 4-force on a particle is best defined as $\mathbf{f} := \nabla_{\mathbf{u}}\mathbf{p}$, where $\mathbf{p} := m\mathbf{u}$ is the 4-momentum. It follows $\mathbf{f} = dm/d\tau\,\mathbf{u} + m\mathbf{a}$, but $dm/d\tau = 0$ in our case, a "pure force".[15] In an arbitrary orthonormal frame, $\mathbf{f}$ has components $\gamma(\dot{E},\vec{f})$ where $\vec{f}$ is 3-force and $\dot{E}$ is the rate of local energy change in this frame. In a local static frame, $\mathbf{f}$ has components

$$f^\mu = \gamma\Big(\frac{m\beta^2\alpha' e^{\alpha-\zeta}}{K}, \frac{m\alpha' e^{-\zeta}}{\gamma}, 0, 0\Big), \tag{12}$$

which satisfy $\dot{E} = \vec{f}\cdot\vec{u} + \gamma^{-2}dm/d\tau$ as expected.[15] The 3-force is unchanged under boosts in the radial direction. Now a coordinate interval $dr$ contains a mass $\mu\gamma e^\zeta dr$ of cable, according to a *static* frame. This is because a static observer measures a proper length $e^\zeta dr$ with its ruler, and so a greater interval $\gamma e^\zeta dr$ of cable fits, according to the cable's length-contracted rulers in this frame.[16] Replacing $m$ in $\dot{E}$ with this mass density, the power contributed from this cable element is $\mu\beta\alpha' dr$, which is redshifted twice to the winch. This integrates to $\mu K\sqrt{K^2+e^{2\alpha}}$, which concurs with Equation 11 after evaluating it at the cable ends and subtracting the initial kinetic energy rate. This is the total power gained. The reason for focusing on static frames is that they respect time symmetry, hence measure *sustainable* rates.

The 3-force contributed locally from an interval $dr$ is $\mu\alpha' dr$. After redshifting once to a given $r_1$, then integrating over all cable below $r_1$, the tension at $r_1$ is

$$\boxed{\mu\big(1-e^{\alpha_{\text{end}}-\alpha_1}\big)} \tag{13}$$

[b] In practice the cable tension would cause this motion. However in our accounting system, all work done by the cable is harvested, hence the incoming kinetic energy must be considered separately. Also the incoming rest mass is treated as *gratis* or expendable, in order to achieve any profit.

in the static frame or cable frame, and is independent of $K$. At the winch the tension is $\mu(1 - e^{\alpha_{\text{end}}})$. For a cable ending near a Killing horizon, the winch tension is $\approx \mu$, which saturates various energy conditions, and $T/\mu \approx 1$ is the Planck force.

## 5. Conclusions and future work

A cable in curved spacetime illustrates interesting relativistic effects including "redshift" of tension. In an idealised scenario, usable energy equivalent to 100% of a cable's rest mass can be extracted; I have extended calculations to a moving cable. The overall Killing energy is conserved. There are many ways this research could be extended. Instead of ignoring backaction, string-like exact solutions could be analysed. Other possible avenues are quantum effects, elasticity, more general motions, application to quasilocal energies, and thermodynamics.

Cosmic topological defects possibly formed during phase transitions in the very early universe and are theoretically well-motivated. Cosmic strings (CSs) would leave distinct imprints on CMB fluctuations. We apply certain topological and geometrical measures in a multi-scale edge-detection algorithm to CMB maps with contributions from CS network to assess the capability of the CS footprints. On the noiseless sky maps with an angular resolution of $0.9'$, we show that our pipeline is capable of detecting CSs with $G\mu$ as low as $G\mu > 4.3 \times 10^{-10}$. We also explore two powerful tree-based machine learning algorithms to perform feature importance analysis. This analysis would improve future CS searches to focus on the most significant and informative features. Our machine-learning algorithm can detect CSs with $G\mu > 2.1 \times 10^{-10}$ at $3\sigma$ level, for a noise-less experiment and angular resolution of $0.9'$.

*Keywords*: Cosmic background radiation; early Universe; large-scale structure; data analysis.

## 1. Introduction

The line-like version of topological defects called cosmic strings (CSs) are theoretically expected to be produced in the early Universe (see [23, 22] and references therein). A lot of effort has been put into developing powerful statistical tools for cosmic string network detection and putting tight upper and lower bounds on the CS tension, parameterized by $G\mu$, where $G$ and $\mu$ represent Newton's constant and the string's tension, respectively. Mathematical description of the string tension is intimately related to the energy of the phase transition epoch as $\frac{G\mu}{c^2} = \mathcal{O}(\varpi^2/M^2_{\rm Planck})$, with the symmetry breaking energy scale, $\varpi$. The CS network can leave imprints on the CMB temperature and polarization anisotropies through different mechanisms such as ordinary and integrated Sachs-Wolfe effect [8] and lensing. The Gott-Kaiser-Stebbins effect produces line-like discontinuities on the CMB temperature anisotropies of the form: $\frac{\delta T}{T} \sim 8\pi G\mu v_s$ [8, 21]. Here $v_s$ is the transverse velocity of the string. CMB-based approaches to search for CS have been conducted to wide range of constraint on the $G\mu$. This range covers the lower value form $G\mu \gtrsim 6.3{\times}10^{-11}$ for noise-less maps [5] to upper limits of $G\mu < 8.8{\times}10^{-7}$ [1, 23, 22].

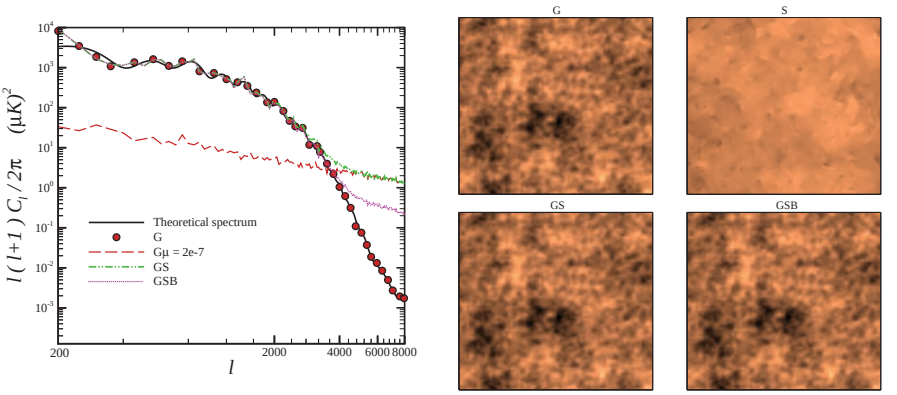

Fig. 1. Left panel: The CMB power spectrum for different components. Right panel includes the Gaussian CMB, CS-induced anisotropies, the combination of the Gaussian and string, smeared by the beam named by G, S, GS and GSB maps, respectively [23].

Here, we propose a multi-scale edge-detection algorithm to search for the CS network on the CMB anisotropies. We also develop machine-learning (ML)-based algorithms for a systematic search of CSs. ML algorithms are ideally capable to exploit all available information in the data and extract the most relevant features for CS detection.

## 2. Simulation the components

Our pipeline for simulation of mock CMB map consists of three components: (1) the Gaussian inflation-induced contribution denoted by $G$, as well as the secondary lensing signal, (2) the CS contribution, $G\mu \times S$, where $S$ represents the normalized simulated template for the string signal and $G\mu$ sets its amplitude, and (3) the experimental noise indicated by $N$. The full simulated map $T(x, y)$, with $x$ and $y$ representing pixel coordinates, would then be

$$T(x, y) = B\,[G(x, y) + G\mu \times S(x, y)] + N(x, y) \tag{1}$$

where $B$ characterizes the beam function [23]. For the CS-induced CMB anisotropies, we use high-resolution flat-sky CMB maps obtained from numerical simulations of Nambu-Goto string networks [3, 18]. They are also produced by stacking maps from various redshifts [3, 18, 17]. Our simulated 100 square maps of side $\Theta = 7.2^\circ$ are well in the flat sky limit, with $1024 \times 1024$ pixels with the resolution of $R = 0.42'$ before convolution with an experimental beam. Figure 1 shows the power spectrum of various components together the corresponding real space fluctuations.

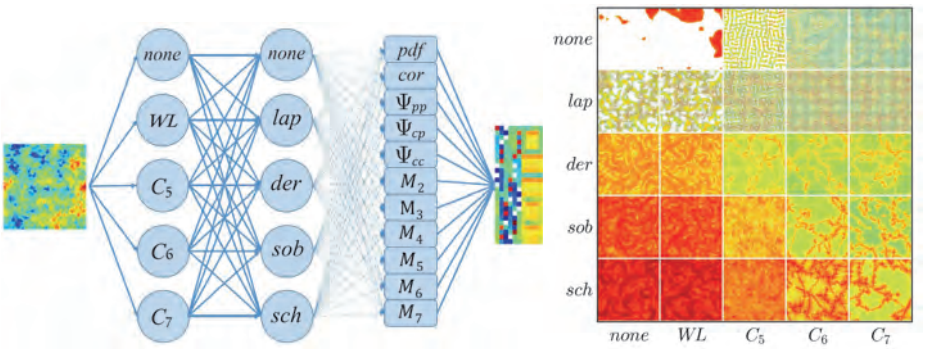

Fig. 2. Left panel: A schematic view of the feature vector generation. For a CMB map including a 275-dimensional feature vector, here presented as a $25 \times 11$ array (right side). Right panel: All of the 25 outputs of the image processing layers of the algorithm applied to a map with $G\mu = 1.0 \times 10^{-7}$. The color scale is logarithmic. These are then passed to the 11 statistical measures, yielding the full set of 275 features[22].

## 3. Image processing based methods

Our goal in this work is to evaluate the performance of various sequences of image-processing and statistical tools in the detection of the trace of possible CS networks on CMB maps. Our proposed pipeline comprises two major steps: (1) Processing CMB maps using multi-scaling method accompanying applying filters and (2) Using various statistical analysis of CMB map to quantify the detectability of CSs signature on the filtered maps from the first step.

### 3.1. *Multi-scale image processing*

We apply several image-processors with the aim to isolate or/and enhance the CSs imprint on CMB maps. The two pillars of this step are a multi-scaling analysis through curvelet-decomposition of the input maps and the generation of filtered maps through extended Canny algorithm. Curvelet decomposition and extended Canny algorithm are used to enhance the string detectability as indicated in Figure 2.

### 3.2. *Statistical measures*

In order to quantify the statistical measures, we start with probabilistic framework. The 2D CMB stochastic field is represented by a map $T \in \mathrm{L}^2(\mathbb{R}^2)$ (Eq. (1)). We also denote a vector variable, $\mathcal{A}$, at each spatial location on the CMB map as:

$$\{\mathcal{A}\} \equiv \{\delta_T, \eta_x, \eta_y, \xi_{xx}, \xi_{yy}, \xi_{xy}\}$$

where $\delta_T \equiv T$ (temperature fluctuation) for the CMB map. We define $\eta_x \equiv \partial\delta_T/\partial x$, $\eta_y \equiv \partial\delta_T/\partial y$ and $\xi_{xy} \equiv \partial^2\delta_T/\partial x\partial y$. The characteristic function of $\mathcal{A}$, is defined

by:

$$\mathcal{Z}(\lambda) = \int_{-\infty}^{+\infty} \mathrm{d}^6 \mathcal{A} \mathcal{P}(\mathcal{A}) e^{\boldsymbol{i}\lambda.\mathcal{A}}, \tag{2}$$

where $\lambda$ is an array with the same dimension as $\mathcal{A}$. Expansion form of $\mathcal{Z}$ becomes [11]:

$$\mathcal{Z}(\lambda) = \exp\left( -\frac{1}{2}\lambda^T.\mathcal{C}.\lambda + \left[ \sum_{j=3}^{\infty} \frac{\boldsymbol{i}^j}{j!} \left( \sum_{\mu_1}^{N} \sum_{\mu_2}^{N} ... \sum_{\mu_j}^{N} \mathcal{K}^{(j)}_{\mu_1,\mu_2,...,\mu_j} \lambda_{\mu_1}\lambda_{\mu_2}...\lambda_{\mu_j} \right) \right] \right). \tag{3}$$

where $\mathcal{K}^{(n)}_{\mu_1,\mu_2,...,\mu_n} \equiv \langle \mathcal{A}_{\mu_1}\mathcal{A}_{\mu_2}...\mathcal{A}_{\mu_n} \rangle_{\mathrm{c}}$ are the *connected* cumulants. Here $\mathcal{C} \equiv \langle \mathcal{A} \otimes \mathcal{A} \rangle$ represents the covariance matrix of $\mathcal{A}$ at each spatial point. Using the temperature power spectrum of CMB, the various spectral parameters read as:

$$\sigma_m^2 = \sum_{\ell} \frac{(2\ell+1)}{4\pi} \left[\ell(\ell+1)\right]^m C_\ell^{TT} W_\ell^2. \tag{4}$$

The smoothing kernel associated with beam transfer function is $W_\ell = \exp\left(-\theta^2_{\mathrm{beam}}\ell(\ell+1)/2\right)$ and $\theta_{\mathrm{beam}} = \theta_{\mathrm{FWHM}}/\sqrt{8\ln(2)}$ [4, 6, 7]. Also $C_\ell^{TT}$ is CMB temperature power spectrum.

Now, we have robust approaches in hand to deduce statistical measures applied on CMB map. Here we only notice to geometrical measures and for the rest part refer to [23, 22].

### 3.2.1. *The n-point joint PDF*

The joint probability density function (JPDF) can be calculated from the inverse Fourier Transform of the corresponding characteristic function according to:

$$\mathcal{P}(\mathcal{A}) = \frac{1}{(2\pi)^6} \int_{-\infty}^{+\infty} \mathrm{d}^6\lambda \mathcal{Z}(\lambda) e^{-\boldsymbol{i}\lambda.\mathcal{A}}. \tag{5}$$

Inserting Eq. (3) in Eq. (5) gives

$$\mathcal{P}(\mathcal{A}) = \exp\left[ \sum_{j=3}^{\infty} \frac{(-1)^j}{j!} \left( \sum_{\mu_1=1}^{6} ... \sum_{\mu_j=1}^{6} \mathcal{K}^{(j)}_{\mu_1,\mu_2,...,\mu_j} \frac{\partial^j}{\partial\mathcal{A}_{\mu_1}...\partial\mathcal{A}_{\mu_j}} \right) \right] \mathcal{P}_{\mathrm{G}}(\mathcal{A}), \tag{6}$$

where

$$\mathcal{P}_{\mathrm{G}}(\mathcal{A}) = \frac{1}{\sqrt{(2\pi)^6|\mathcal{C}|}}\, e^{-\frac{1}{2}(\mathcal{A}^T.\mathcal{C}^{-1}.\mathcal{A})}. \tag{7}$$

The probability density function for the CMB temperature induced by CS network deviates from Gaussian distribution depending on the value of $G\mu$ [16].

3.2.2. *The weighted TPCF*

The weighted two-point correlation function (TPCF) which is defined as $\mathcal{C}_{TT} = \langle \delta_T(\mathbf{r}_1)\delta_T(\mathbf{r}_2)\rangle$ is another statistical measure used for searching the footprint of CS. Here $\mathbf{r}_1$ and $\mathbf{r}_2$ represent the coordinates of the points.

3.2.3. *The unweighted TPCF*

The unweighted TPCF of a certain feature is referred to the its excess probability. Here, we compare the clustering of the local maxima and up-crossing of CMB maps for Gaussian-only fluctuations with those affected by the CS network as well. The excess probability of finding two different features represented by symbols, $\oplus$ and $\otimes$ is $\Psi_{\oplus-\otimes}$ separated by distance $r = |\mathbf{r}_1 - \mathbf{r}_2|$, at thresholds $\vartheta_1 \equiv \alpha_1/\sigma_0$ and $\vartheta_2 \equiv \alpha_2/\sigma_0$ is defined as:

$$\Psi_{\oplus-\otimes}(r;\vartheta_1,\vartheta_2) = \frac{\langle n_{\oplus}(\mathbf{r}_1,\vartheta_1) n_{\otimes}(\mathbf{r}_2,\vartheta_2)\rangle}{\bar{n}_{\oplus}(\vartheta_1)\bar{n}_{\otimes}(\vartheta_2)} - 1. \tag{8}$$

The mathematical description of local maxima number density, $\bar{n}_{\rm pk}(\vartheta)$, reads:

$$\bar{n}_{\rm pk}(\vartheta) = \langle \delta_{\rm d}(\delta_T - \vartheta\sigma_0)\delta_{\rm d}(\eta)\,|\det(\xi)|\rangle\,. \tag{9}$$

The second derivative tensor of the CMB field ($\xi_{ij}$) should be *negative definite* at peak position. Its analytical expression for a 2D homogenous Gaussian field was calculated in [2, 4]. While the mean number of up-crossings of a 2D CMB field $\delta_T$ at a given threshold $\vartheta$ for an arbitrary 1D slice denoted by $\diamond$ is given by [15, 20, 19, 10, 12, 11, 14, 13]:

$$\bar{n}^{\diamond}_{\rm up}(\vartheta) = \langle \delta_{\rm d}(\delta_T - \vartheta\sigma_0)\Theta(\eta^{\diamond})\,|\eta^{\diamond}|\rangle\,, \tag{10}$$

where $\Theta(\eta)$ is the unit step function and $|\eta^{\diamond}|$ is the absolute value of the first derivative of temperature fluctuations in direction $\diamond$ [11]. One can choose any direction $\diamond$ on the statistically isotropic CMB map, without loss of generality. To reduce the boundary effect as much as possible in computing excess probability, $\tilde{\Psi}_{\oplus-\otimes}(r;\vartheta)$, following estimator has been proposed [9]:

$$\tilde{\Psi}_{\oplus-\otimes}(r;\vartheta) = \left[\frac{D_{\oplus}D_{\otimes}(r,\vartheta)}{R_{\oplus}R_{\otimes}(r,\vartheta)}\right]\frac{N_{R_{\oplus}}N_{R_{\otimes}}}{N_{D_{\oplus}}N_{D_{\otimes}}} - 1. \tag{11}$$

Here, $RR(r,\vartheta)$ and $DD(r,\vartheta)$ are the number of feature pairs in random and data catalogs, respectively, separated by distance $r$ from each other. Similarly, $N_D$ and $N_R$ are the total number of feature in data and random catalogs, respectively.

We utilize above statistical measures for the third layer to make feature vector (see Figure 2). Therefore, we compare the results with null hypothesis. On noiseless sky maps with an angular resolution of $0.9'$, we show that our pipeline detects CSs with $G\mu$ as low as $G\mu \gtrsim 4.3\times10^{-10}$. At the same resolution, but with a noise level typical to a CMB-S4 phase II experiment, the detection threshold would increase to $G\mu \gtrsim 1.2\times10^{-7}$ [23].

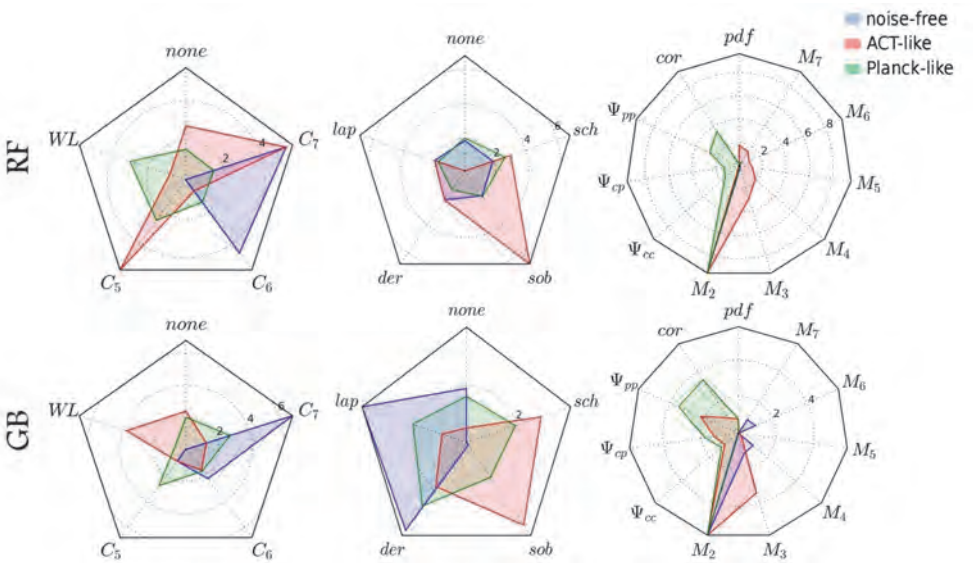

Fig. 3. Feature importance report: the average number of times each pre-processing tool appeared among the top ten features, for each layer of the pre-processor, for the RF (top) and GB (bottom) learner [22].

## 4. Machine-learning approach

The purpose is to develop a detection strategy through optimally exploiting the available information accessible to the multi-scale pipeline presented by Vafaei et al. [23]. We use two tree-based supervised classifiers: random forest (RF) and gradient boosting (GB) [22]. The information in the maps is compressed into feature vectors before being passed to the learning units. The feature vectors contain various statistical measures of the processed CMB maps that boost cosmic string detectability (see Figure 2). Our proposed classifiers, after training, give results similar to or better than claimed detectability levels from other methods for string tension. Our results confirm that the minimum detectable $G\mu$ for a noise-free experiment is $2.1 \times 10^{-10}$. This bound is, to the best of our knowledge, below the claimed detectability levels by other methods on noise-less maps. The minimum detectable tension in this work for a CMB-S4-like (II) experiment, $G\mu \gtrsim 3.0 \times 10^{-8}$, is a major improvement over the claimed detectability level by the above multi-scale pipeline, $G\mu \gtrsim 1.2 \times 10^{-7}$. For a Planck-like case, the minimum detectable $G\mu$ is $5 \times 10^{-7}$, comparable to the current upper bounds from Planck data [1]. Figure 3 compares the feature importance of the most significant features in each of the three pre-processing layers for noise-free, ACT-like and Planck-like cases, and for the two tree-based algorithms considered in this work, namely RF and GB. Among the 275 features, we choose the ten most significant ones by comparing the number of their occurrences as the splitting feature in all trees of a MLM. The plot shows the

number of occurrences, averaged over all MLMs, of the pre-processing tools among these top ten features, separated by their parent layer, i.e., decomposers, filters and statistical measures. Final remark is that, the scale of curvelet components should be matched to the effective resolution of experiments in the presence of experimental noise, larger-scale curvelet components are the more important decomposers. For filters it is difficult to make a definite recommendation, while the second moment is the most important statistical measure in the classification process.

## 5. Conclusion

In this review, we introduced multiscaling approach followed by some excursion and critical sets in order to explore the footprint of CSs network superimposed on the CMB simulation maps. Particularly, we focused on this question: What is the minimum value of CS's tension which could be recognized in the CMB map? In order to answer this question, at first we proposed a pipeline and accordingly, the minimum detectable value in noiseless CMB map is $G\mu > 4.3\times10^{-10}$ while applying more advanced searching method, namely machine learning approach, enables us to find CS with $G\mu > 2.1 \times 10^{-10}$. In this algorithm, we are also able to evaluate the significance of each pre-processors in detecting algorithm for different CMB observational strategies.

Topological defects formed in the early stages of our universe can play a crucial role in understanding anisotropic deviations of the Friedmann Lemaître Robertson Walker model we observe today. These defects are the result of phase transitions associated with spontaneous symmetry breaking in gauge theories at the grand unification energy scale. The most interesting defects are cosmic strings, vortex-like structures in the famous gauged U(1) abelian Higgs model with a "Mexican-hat" potential. Other defects, such as domain walls and monopoles are probably ruled out, because they should dominate otherwise the energy density of our universe. This local gauge model is the basis of the standard model of particle physics, where the Higgs-mechanism provides elementary particles with mass. It cannot be a coincidence that this model also explains the theory of superconductivity. The decay of the high multiplicity ($n$) super-conducting vortex into a lattice of $n$ vortices of unit magnetic flux is energetically favourable and is experimentally confirmed. It explains the famous Meissner effect. This process could play an essential role by the entanglement of cosmic strings just after the symmetry breaking. The stability of the lattice depends critically on the parameters of the model, especially when gravity comes into play. The questions is how the imprint of the cosmic strings could be observed at present time. Up to now, no evidence is found. The recently found alignment of the spinning axes of quasars in large quasar groups on Mpc scales, could be a first indication of the existence of these cosmic strings. The temporarily broken axial symmetry will leave an imprint of a preferred azimuthal-angle on the lattice. This effect is only viable when a scaling factor is introduced. This can be realized in a warped five dimensional model. The warp factor plays the role of a dilaton field on an equal footing with the Higgs field. The resulting field equations can be obtained from a conformal invariant model. Conformal invariance, the missing symmetry in general relativity, will then spontaneously be broken, just as the Higgs field. The dilaton field, or equivalently, the warp factor, could also contribute to the expansion of the universe as it can act as a dark energy term coming from the bulk spacetime. It makes the cosmic string temporarily super-massive. This process could solve the cosmological constant and hierarchy problem. It is conjectured that the dilaton field has a dual meaning. At very early times, when the dilaton field approaches zero, it describes the small-distance limit of the model, while at later times it is a warp (or scale) factor that determines the dynamical evolution of the universe. When more data of quasars of high redshift will become available, one could prove that the alignment emerged after the symmetry breaking scale and must have a cosmological origin. The effect of the warp factor on the second-order perturbations could also be an indication of the existence of large extra dimensions.

## 1. Introduction

The standard model (SM) of the electroweak and strong interactions is a successful framework in which one studies elementary particles and includes the principles of quantum mechanics (QM). On the other hand, general relativity (GR) is also a very impressive theory constructed by theoretical physicists. It describes large scale structures in our universe and one can construct solutions which are related to real physical objects, for example the Kerr solution, the end stage of a collapsing spinning star. A legitimate question is if there are other axially symmetric solutions in GR. It came as a big surprise that there exist vortex-like solutions in Einstein's theory. These vortex solutions occur as topological defects at the symmetry breaking scale in the Einstein-abelian U(1) scalar-gauge model, where the gauge field is coupled to a complex charged scalar field [1,2]. The solution shows a surprising resemblance with type II superconductivity of the Ginzburg-Landau (GL) theory, where the electro-magnetic(EM) gauge invariance is broken and the well-known Meissner effect occurs [3]. One says that the phase symmetry is spontaneously broken and the EM field acquires a length scale, which introduces a penetration depth of the gauge field $A_\mu$ in the superconductor and a coherence length of $\Phi$. In the relativistic case one says that the photon acquires mass. Because we have three space dimensions, these solutions of the GL theory behave like magnetic flux vortices (or Nielsen-Olesen (NO) strings [2]) extended to tubes and carry a quantized magnetic flux $2\pi n$, with $n$ an integer, the topological charge or winding number of the field. It was discovered by Abrikosov [3] that these vortices can form a lattice. These localized vortices (or solitons) in the GL-theory are observed in experiments. The phenomenon of magnetic flux quantization in the theory of superconductivity is characteristic for so-called ordered media. The vortex solution possesses mass, so it will couple to gravity. The resulting self-gravitating cosmic strings (CS) still show all the features of superconductivity, but the stability conditions complicate considerably. The stability of the formed lattices depends critically on the parameters of the model, certainly when gravity comes into play. The force between the gauged vortices depends on the the strength of the self-interaction potential of the Higgs field, the gauge-coupling constant, the energy scale at which the phase transition takes place and the spacetime structure. When the mass of the Higgs field is greater than the mass of the gauge field, vortices will repel each other. So gravity could balance the vortices. The energy of the vortex grows by increasing multiplicity $n$, so configurations with $n > 1$ can be seen as multi-soliton states and it is energetically favourable for these to decay into $n$ well separated $n = 1$ solitons. Vortices with high multiplicity can be formed during the symmetry breaking. The total vortex number $n$ is the sum of multiplicities $n_1, n_2, ..$ of isolated points (zero's of $\Phi$). Our universe, described by a spatially homogeneous and isotropic Friedmann Lemaître Robertson Walker (FLRW) spacetime, shows significant large-scale inhomogeneous structures, for example, the cosmic web of voids with galaxies and clusters in sheets, filaments and knots, the angular distribution in the cosmic microwave background (CMB)

radiation and the recently found alignment of polarization axes of quasars in large quasar groups (LQG's) on Mpc-scales[4,5]. The question is if these complex nonlinear structures of deviation from isotropy and homogeneity have a cosmological origin at a moment in the early stage of the universe. One possibility of this origin could be a CS-network formed by the self-gravitating Einstein-scalar-gauge model. A pleasant fact is that this model has very few parameters and hence more appealing than other models such as inflationary models. It is believed that the mass per unit length of the CS is of the order of the GUT scale, $G\mu \approx 10^{-7}$. Observational bounds, however, predict a negligible contribution of CS's to initial density perturbation from which galaxies and clusters grew. Besides the inconsistencies with the power spectrum of the CMB, radiative effects of the CS embedded in a FLRW spacetime are rapidly damped in any physical regime[6]. Further, the lensing effect of these CS's are not found yet. There is, however, another possibility to detect the presence of CS's. On a warped spacetime, the fields can become temporarily super-massive by the warp factor in the framework of string theory (or M-theory). Naively one expect that gravity will play a subordinate role compared with the other fields. In 4D counterpart models this is true, but not in warped spacetimes. The super-massive CS's can be formed at a symmetry breaking scale much higher than the GUT scale, i.e., $G\mu >> 1$. So their gravitational impact increases considerably, because the CS builds up a huge mass in the bulk space. Here we consider the warped brane world model of Randall-Sundrum (RS)[7,8], with one large extra dimension. The result is that effective 4D Kaluza-Klein (KK) modes are obtained from the perturbative 5D graviton. These KK modes will be massive from the brane viewpoint. The modified Einstein equations on the brane and scalar gauge field equations will now contain contributions from the 5D Weyl tensor[9]. In order to explore these effective field equations, we apply an approximation scheme, i.e., a multiple scale method(MSM). In this method one can handle the decay of the $n$-vortex in a perturbative way. The MSM or high-frequency method is an approved tool to handle nonlinearities and secular terms arising in the partial differential equations (PDE) in GR. When there is a high curvature situation, a linear approximation of the Einstein equations is not suitable[10,11]. Other issue related to our 5D warped spacetime is the behavior at small scales, i.e., when the warp factor or scale factor of the spacetime becomes very small. We conjecture that our warp factor becomes the dilaton field which is needed to make the Lagrangian conformal invariant. Breaking of the conformal symmetry (which will occur when other fields come into play; after all we experience today a huge discrepancy in scales), can be compared with the Brout-Englert-Higgs Mechanism (BEH) in the standard model of particle physics.

## 2. The superconducting string model in warped spacetime

### 2.1. *Outline of the model*

Our model will be based on a warped five-dimensional FLRW spacetime

$$ds^2 = \mathcal{W}(t,r,y)^2\Big[e^{2(\gamma(t,r)-\psi(t,r))}(-dt^2+dr^2)+e^{2\psi(t,r)}dz^2+r^2e^{-2\psi(t,r)}d\varphi^2\Big]+dy^2, \tag{1}$$

with $\mathcal{W}=W_1(t,r)W_2(y)$ is the warp factor. All standard model fields reside on the brane, while gravity can propagate into the bulk. An extended treatment of the warped five-dimensional spacetime and the effective gravitational equations can be found in Shiromizu et al.[9] and Slagter[12]. The 5D Einstein equations are

$${}^{(5)}G_{\mu\nu} = -\Lambda_5\,{}^{(5)}g_{\mu\nu}+\kappa_5^2\delta(y)\Big(-\Lambda_4\,{}^{(4)}g_{\mu\nu}+{}^{(4)}T_{\mu\nu}\Big), \tag{2}$$

with $\kappa_5 = 8\pi^{(5)}G = 8\pi/{}^{(5)}M_{pl}^3$, $\Lambda_4$ the brane tension, ${}^{(4)}g_{\mu\nu} = {}^{(5)}g_{\mu\nu}-n_\mu n_\nu$, and $n^\mu$ the unit normal to the brane. The effective 4D Einstein-Higgs-gauge field equations are

$${}^{(4)}G_{\mu\nu} = -\Lambda_{eff}\,{}^{(4)}g_{\mu\nu}+\kappa_4^2\,{}^{(4)}T_{\mu\nu}+\kappa_5^4\mathcal{S}_{\mu\nu}-\mathcal{E}_{\mu\nu}, \tag{3}$$

$$D^\mu D_\mu\Phi = 2\frac{dV}{d\Phi^*}, \qquad {}^{(4)}\nabla^\mu F_{\nu\mu} = \frac{1}{2}ie\Big(\Phi(D_\nu\Phi)^*-\Phi^*D_\nu\Phi\Big), \tag{4}$$

with $D_\mu\Phi \equiv {}^{(4)}\nabla_\mu\Phi+ieA_\mu\Phi$, ${}^{(4)}\nabla_\mu$ the covariant derivative with respect to ${}^{(4)}g_{\mu\nu}$, $V(\Phi)=\frac{1}{8}\beta(\Phi\Phi^*-\eta^2)^2$ the potential of the Abelian Higgs model and $\eta$ the symmetry breaking scale. $F_{\mu\nu}$ is the Maxwell tensor. The righthand side of the Einstein equations contains a contribution $\mathcal{E}_{\mu\nu}$ from the 5D Weyl tensor and carries information of the gravitational field outside the brane. The quadratic term in the energy-momentum tensor, $\mathcal{S}_{\mu\nu}$, arising from the extrinsic curvature terms in the projected Einstein tensor. ${}^{(4)}T_{\mu\nu}$ represents the matter content on the brane, in our case the scalar and gauge fields[9,12]. These terms are responsible for the effective 4D modes, i.e., KK-modes, of the perturbative 5D graviton. We parameterize the self-gravitating scalar gauge field as

$$\Phi = \eta X(t,r)e^{in\varphi}, \qquad A_\mu = \frac{n}{e}\big[P(t,r)-1\big]\nabla_\mu\varphi, \tag{5}$$

with n the topological charge or winding number of the scalar field. The warp factor can be solved from the 5D Einstein equations:

$$\mathcal{W} = W_2(y)W_1(t,r) = \frac{\pm e^{\sqrt{-\frac{1}{6}\Lambda_5}(y-y_0)}}{\sqrt{\tau r}}\sqrt{\Big(d_1e^{(\sqrt{2\tau})t}-d_2e^{-(\sqrt{2\tau})t}\Big)\Big(d_3e^{(\sqrt{2\tau})r}-d_4e^{-(\sqrt{2\tau})r}\Big)}, \tag{6}$$

On the one hand, the constants $(d_i,\tau)$ will be fixed at late time by the features of the FLRW-model. They will appear in the modified second Friedmann equation. On the other hand, on the very small scale, the warp factor equals the dilaton field in conformal invariant models and these constant will be determined by constraint equations.

### 2.2. *The approximation*

In order to study perturbations in the model, one can apply the multiple-scale approximation, very suited at high curvature situations [10,11]. The method is called a "two-timing" method, because one considers the relevant fields $V_i$ in point $\mathbf{x}$ on a manifold M dependent on different scales $(\mathbf{x}, \xi, \chi, ...)$:

$$V_i = \sum_{n=0}^{\infty} \frac{1}{\omega^n} F_i^{(n)}(\mathbf{x}, \xi, \chi, ...). \tag{7}$$

Here $\omega$ represents a dimensionless parameter, which will be large (the "frequency", $\omega >> 1$). So $\frac{1}{\omega}$ is a small expansion parameter. Further, $\xi = \omega\Theta(\mathbf{x})$, $\chi = \omega\Pi(\mathbf{x}), ...$ and $\Theta, \Pi, ...$ scalar (phase) functions on M. The parameter $\frac{1}{\omega}$ can be the ratio of the characteristic wavelength of the perturbation to the characteristic dimension of the background. On warped spacetimes it could also be the ratio of the extra dimension y to the background dimension or even both. When one substitutes the expansions of the field variables

$$\begin{aligned} g_{\mu\nu} &= \bar{g}_{\mu\nu}(\mathbf{x}) + \frac{1}{\omega} h_{\mu\nu}(\mathbf{x}, \xi) + \frac{1}{\omega^2} k_{\mu\nu}(\mathbf{x}, \xi) + ..., \\ A_\mu &= \bar{A}_\mu(\mathbf{x}) + \frac{1}{\omega} B_\mu(\mathbf{x}, \xi) + \frac{1}{\omega^2} C_\mu(\mathbf{x}, \xi) + ..., \\ \Phi &= \bar{\Phi}(\mathbf{x}) + \frac{1}{\omega} \Psi(\mathbf{x}, \xi) + \frac{1}{\omega^2} \Xi(\mathbf{x}, \xi) + ..., \end{aligned} \tag{8}$$

into the equations, one obtains first order equations in $u = t - r$ for the first and second order perturbations [13,14]. They are of the form

$$\partial_u \dot{\mathbf{U}}_1 = \bar{\mathbf{A}}, \qquad \partial_u \dot{\mathbf{U}}_2 = \bar{D}_1 \dot{\mathbf{U}}_2 + D_2 \dot{\mathbf{U}}_1 + D_3 \tag{9}$$

where $\bar{A}$ and $\bar{D}_1$ depends solely on the background fields, while $D_2, D_3$ depend on the first order perturbations and background fields. The dot represents differentiation with respect to the rapid scale $\xi$. In principle one could push the approximation to higher orders. In this way one obtains a wavelike approximation which is asymptotically finite. To highest order in $\omega$, one obtains the equations $l^\alpha(\ddot{h}_{\alpha\nu} - \frac{1}{2}\bar{g}_{\alpha\nu}\ddot{h}) = 0, l_\alpha l^\alpha \ddot{\Psi} = 0$ and $l^\alpha \ddot{B}_\alpha = 0$, where $l_\alpha \equiv \frac{\partial\Theta}{\partial x^\mu}$ is the wave vector perpendicular to the hyper-surface. These equations deliver constraints on $h, B$ and $C$. In other approximations, they are a priori used as gauge conditions. Moreover, the original symmetry on the gauge field will be broken by the appearance of $B_t$ besides $B_\varphi$.

In our approximation scheme we can gain a lot of insight in the behavior of the clustering of vortices when gravity is present. The equations (Eq. (9)) are hard to solve. However, the energy-momentum tensor components can tell us a lot about the behavior of the model.

### 2.3. *Excitation of the vortices and the quasar link*

In the expansion of Eq. (8) we parameterized the scalar field in subsequent orders as[13,14]

$$\bar{\Phi} = \eta \bar{X}(t,r)e^{in_1\varphi}, \qquad \Psi = Y(t,r,\xi)e^{in_2\varphi}, \qquad \Xi = Z(t,r,\xi)e^{in_3\varphi}. \tag{10}$$

It turns out that the solution to second order is no longer axially symmetric. There appear terms like $\sin(n_2 - n_1)\varphi$ in the field equations. The most interesting information can be found in the energy-momentum tensor components

$${}^4T^{(0)}_{t\varphi} = \bar{X}\bar{P}\dot{Y}n_1 \mathbf{sin}[(n_2 - n_1)\varphi], \tag{11}$$

$${}^4T^{(0)}_{tt} = \dot{Y}^2 + \dot{Y}(\partial_t \bar{X} + \partial_r \bar{X})\mathbf{cos}[(n_2 - n_1)\varphi] + \frac{e^{2\bar{\psi}}}{\bar{W}_1^2 r^2 e}\Big(e\dot{B}^2 + n_1 \dot{B}(\partial_r \bar{P} + \partial_t \bar{P})\Big), \tag{12}$$

While ${}^4\bar{T}_{t\varphi} = 0$, we conclude from Eq. (12) that the axial symmetry is broken already to first order. The energy ${}^4T^{(0)}_{tt}$ contribution to first order contains the warp factor in the denominator. So the energy depends crucially on the age of the universe. Terms in the energy can dominate at early times and are negligible at late times in the evolution of the universe. In the second order contributions there appear terms like $\cos(n_3 - n_1)\varphi$. The azimuthal-angle dependency are expressed in trigonometrical functions with extrema which differ $mod(\frac{\pi}{k})$. After the excitation of the vortex with multiplicity n, it will decay into n vortices of unit flux in a regular lattice (figure 1).

There is another characterization of the winding number. It is the total vortex number, i.e., the number of points in the plane with multiplicity taken into count where $\Phi = 0$. The zero's of $\Phi$ are then a set of n isolated points $z_i, i = 0..n$ in $\mathbb{C}$ such that $\Phi(z, z^*) \sim c_j(z - z_j)^{n_j}$ with $n_j$ the multiplicity of $z_j$ and $n = \sum_{z_j} n_j$.

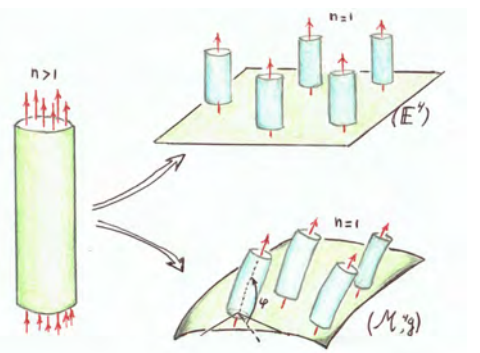

Fig. 1. Excitation and decay of a high multiplicity vortex into correlated vortices of unit flux $n = 1$. Top: the Abrikosov lattice in Euclidean space. Bottom: correlated vortices with preferred azimuthal angle $\varphi$ in curved spacetime after the symmetry breaking.

This n-vortex solution represents a finite energy configuration with n flux quanta, provided $\Phi$ and $A$ satisfy the boundary conditions

$$\lim_{r\to 0} X = 0, \quad \lim_{r\to 0} P = 1, \quad \lim_{r\to\infty} X = 1, \quad \lim_{r\to\infty} P = 0. \tag{13}$$

The collection of n vortices of unit flux is energetically more appealing than a n-flux vortex. The energy density is peaked around the zero's of $\Phi$. Hence they can be identified by the location of the vortices. In general, one must solve the time-dependent GL equations in order to get insight in the stability issues. In this case there is a gradient flow, which makes the analysis very complicated. The PDE's are badly nonlinear and one relies often on numerical simulation. The temporarily broken axial symmetry will be the onset of emission of electro-magnetic and gravitational waves. From Eq. (11) we see that the angular momentum will fade away when $n_2$ approaches $n_1$ and the axial symmetry is restored. The first and second order perturbations of the scalar and gauge fields in higher winding number decay into NO strings of n=1. In order to understand the azimuthal-angle ($\varphi$) preference, one must consider the terms of ${}^4T_{\varphi\varphi}$, for example

$${}^4T^{(0)}_{\varphi\varphi} = e^{-2\gamma} r^2 \dot{Y}(\partial_t \bar{X} - \partial_r \bar{X})\mathbf{cos}[(n_2 - n_1)\varphi] + \frac{n_1 e^{2\bar{\psi}-2\bar{\gamma}}}{\bar{W}_1^2 e}\dot{B}(\partial_r \bar{P} - \partial_t \bar{P}), \tag{14}$$

$T_{\varphi\varphi}$ plays an important role in the interaction of the strings. Positive terms in the expression indicate "pressure" in the direction of the Killing vector field $(\frac{\partial}{\partial\varphi})^i$ (and negative "tension"). The result is that the interaction contribution can change sign dynamically (dependent of the warp factor). This Killing vector must be normalized such that, along a closed integral curve, the parameter $\varphi$ varies van 0 to $2\pi$ with $\varphi = 0$ and $\varphi = 2\pi$ identified. This will provide boundary conditions for the metric fields close to the axis of the string, such as $\partial_r(r^2 e^{-2\psi})(0) = 1$. We observe in the expressions of ${}^4T^{(0)}_{\varphi\varphi}$ and ${}^4T^{(0)}_{t\varphi}$ that when $sin(n_2 - n_1)\varphi$ becomes zero, $cos(n_2 - n_1)\varphi$ has its maximum. So there is an emergent imprint of a preferred azimuthal angle $\varphi$ on the lattice of vortices when the ground state is reached ($n = 1$). This effect can also be seen in the ${}^4T^{(0)}_{zz}$ component which is not equal to $-{}^4T^{(0)}_{tt}$ as is the case in static models. The second order contribution ${}^4T^{(1)}_{\varphi\varphi}$ contains terms like $cos(n_3 - n_1)\varphi$ and produces a complicated extremum[14]. The recently observed alignment of the spinning axes of quasars in LQG's on Mpc-scales can be explained by our model. The observations were carried out at the European Southern Observatory, Paranal with the Very Large Telescope equipped with the FORS2 instrument. There was a confirmation of the alignment for radio galaxies by the Giant Metrewave Radio Telescope in the ELAIS-N1 field. This curious effect cannot be the result of statistical fluctuations[16]. The origin must be found in the early universe just after the symmetry breaking, as described in our model. Specially, the two preferred orientations perpendicular to each other in quasar groups of less richness could be the second order effect in our model by the appearance of the trigonometrical terms with periodicity difference of $\frac{\pi}{2}$. The correlated $n = 1$ vortices with preferred

azimuthal angle, emerged on a correlation length smaller than the horizon on that moment and took place at the Ginzburg temperature $\sim \frac{1}{\beta\eta}$. These correlated regions will survive to later times, because at this moment the gravity contribution from the 5D bulk comes into play. The warp factor will have different contributions to the field equations for different times. The mass per unit length will contain the warp factor. Just after the symmetry breaking, the vortex will acquire a huge mass $G\mu > 1$ and will initiate the perturbations of high-frequency and justifies our high-frequency approximation. This is the reason that the regions with $(n = 1, \varphi = \varphi_0)$ will stick together and are observed in LQG's with aligned polarization axes [4,5]. The most striking observation is the alignment of the spin axes of the quasars parallel to the major axes of their host LQG, while the spin axes can also become perpendicular to the the LQG major axes when the richness decreases. This can be explained in our model as second order effect: the higher multiplicity terms like $\cos(n_3 - n_1)\varphi$ enters the energy-momentum tensor component ${}^4T^{(1)}_{\varphi\varphi}$ and is out phase with the term $\cos(n_2 - n_1)\varphi$. In figure 2 we sketched a global distribution of the polarization axes as found by the observations. Some specific features of this alignment which must be confirmed by more observations on quasars and radio sources at high redshift. Alignment at high redshifts would confirm that the mechanism took place indeed in the early universe.

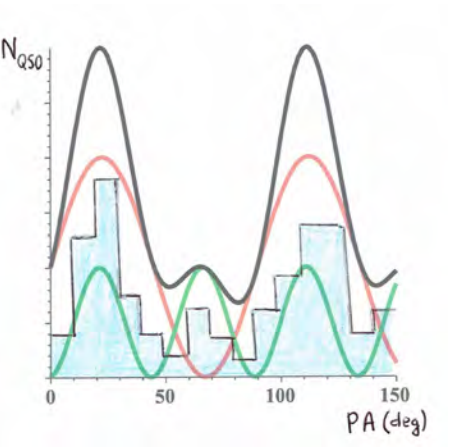

Fig. 2. Possible fit of the theoretical predicted curve (black) on the distribution of a number of observed polarization angles. This curve can be the sum of the first (red) and second (green) contribution.

### 2.4. *Breaking of the axial symmetry from a different viewpoint*

Self-gravitating objects in equilibrium exhibit a striking analogue with the mathematical model of the Maclaurin-Jacobi sequences and its bifurcation points [17]. Bifurcation points that are of particular interest to us here are those marking the

onset secular instability, i.e., the dynamical breaking of axially symmetry (or better formulated: the spacetime possesses 2 in stead of 3 Killing vectors). This means the appearance of an off-diagonal metric function. In our model it is the transition from the Weyl metric (after the substitution $t \to iz, z \to it$) to the Papapetrou metric, expressed by the appearance of the $T_{t\varphi}$ components in first and second order. It is remarkable that this symmetry breaking can be compared with the second order phase transition in type II superconductivity[18–20], which is the basis of our model (see also Slagter[14] for more details). An initial axially symmetric configuration, as is the case in our perturbative model, can dynamically spontaneously be broken, where equatorial eccentricity plays the role of order-parameter. The equatorial eccentricity $\varepsilon \equiv \frac{b}{a}$, with b and a the two equatorial axes, can be expressed through the azimuthal-angle $\varphi(t)$. The particular orientation of the ellipsoid in the frame $(r, \varphi, z)$ expressed through $\varphi_0 \equiv \varphi(t_0)$, will be at $t > t_0$ determined by the transformation $\varphi \to \varphi_0 - Jt$, where $J$ is the rotation frequency (circulation or "angular momentum") of the coordinate system. The angle $\varphi_0$ is fixed arbitrarily at the onset of symmetry breaking. This arbitrariness of $\varphi_0$, i.e., the orientation of the ellipsoid at $t = t_0$ can be compared with the massless Goldstone-boson modes of the spontaneously broken symmetry of continuous groups. The phase transition take place on the same time scale that the vorticity is destroyed by dissipative mechanism and $J$ is lost. The end point is a lower energy state that belongs to the Jacobi or Dedekind sequence of equilibrium ellipsoids[21]. In the original paper of Chandrasekhar and Lebovitz[18], in the Newtonian case, the deformations of the axisymmetric configuration by an infinitesimal non-axisymmetric deformation is described in terms of a Lagrangian displacement $\varsigma^a(r, z, \varphi) = \bar{\varsigma}^a(r, z)e^{in\varphi}$, with $n$ an integer. However, the real part of the $e^{in\varphi}$ must be put in by hand, in contrast to our result: it appears in a perturbative way as a first and second order effect. The temporarily broken axial symmetry will be the onset of emission of electro-magnetic and gravitational waves, while the string relaxes to the NO configuration. It is a consequence of the coupled system of PDE's that a high-frequency scalar field can create through an electro-magnetic field, a high frequency gravitational field and conversely. It is the appearance of the term $sin(n_2 - n_1)\varphi$ in the first order term ${}^4T^{(0)}_{t\varphi}$ (Eq.(11)) and explained in section 2c, which triggers this angular momentum and the axially symmetry will be restored when $n_2$ becomes equal to $n_1$ again. The second order contribution ${}^4T^{(1)}_{tt}$ shows terms like $\dot{B}^2 h_{44}$, indicating the interaction between the high-frequency EM and gravitational waves. It contains the warp factor in the denominator. In the early stages of the universe $W_1$ is still small and the term is significant. As time increases, it will fade away.

## 3. Conclusion

By considering an axially symmetric warped five-dimensional warped spacetime, were the standard model fields are confined to the brane, we find in a nonlinear approximation, an emergent azimuthal-angle dependency of Nielsen-Olesen vortices

just after the symmetry breaking at GUT scale. Using a approximation scheme, the azimuthal-angle dependency appears in the first and second order field equations as trigonometrical functions $\sin(n_i - n_j)\varphi$ and $\sin(n_i - n_j)\varphi(i > j)$, with $n_i$ the multiplicities of subsequent perturbation terms of the scalar field. Vortices with high multiplicity decay into a lattice with entangled Abrikosov vortices. The stability of this lattice of correlated flux $n = 1$ vortices with preferred azimuthal-angle is guaranteed by the contribution from the bulk spacetime by means of the warp factor: the cosmic string becomes super-massive for some time during the evolution. These so-called super-massive cosmic strings arise in a natural way in string theory or M-theory., i.e., brane-world models and are produced when the universe underwent phase transitions at energies much higher than the GUT scale, $G\mu > 1$. The imprint on the effective 4D brane spacetime can be caused by wavelike disturbances triggered by the huge mass of the cosmic strings in the bulk. One conjectures that these disturbances could act as an effective dark energy field. Another possible effect can be the formation of massive KK-modes as the imprint of the 5D gravitational field on the 4D brane.

We used the azimuthal-angle correlation for the explanation of the recently observed alignment of polarization axes of quasars in large quasar groups. The detailed behavior of this alignment can be explained with our model. The two different orientations perpendicular to each other in quasars groups of less richness could be a second order effect in our model.

When gravity is coupled to standard model fields and one demands the validity on all distance scales, one runs into problems. These are: the dark energy problem, the cosmological constant problem, the hierarchy problem and the problem how probe the small distance structure of our spacetime. Conformal invariance could be the solution for at least some of these problems. It could be the missing symmetry of nature. In our model, by identifying the warp factor as a dilaton field, one will not encounter singular behavior when the dilaton field becomes very small. At present time, the warp-like manifestation of the dilaton field describes the exponential expansion of our universe. Moreover, the exceptional smallness of the cosmological constant, $\Lambda \sim 10^{-120}$ compared to the calculated vacuum energy could be explained in the warped 5D spacetime by the warp factor. More data of high-redshift quasars will be needed in order to test the second order effect predicted in our model.

# Linking dark energy and a Kaluza–Klein treatment of a graviton via the deceleration parameter $Q(z)$ by quintessence?

Andrew Walcott Beckwith

*Physics Department, Chongqing University, Chongqing 401331, People's Republic of China*
*E-mail: Rwill9955b@gmail.com; abeckwith@uh.edu*
*english.cqu.edu.cn*

We examine a dark-energy equation of state. [1] From there, we link early-universe graviton production by varying the DE equation from $-1$ to 1 with a Kaluza–Klein treatment of reacceleration and comment on how modification of gravitational $\frac{1}{r}$ potentials and the reacceleration of the universe also bridge between the first and second parts of this document, in terms DE physics and gravitons, as well as changing $Q(z)$ reacceleration behavior. We close with a suggestion on redoing initial contributions to DE.

*Keywords*: Massive Gravitons, Entropy, Kaluza Klein, Dark Matter, Dark Energy PACS: 98.80.-k, 98.80.Cq, 89.70 CF.

## 1. DE Equation of State, as a Starting Point

*If we quantize the gravitational field as an effective field, we find that it too comes in set quanta, called gravitons.* In short, we argue that to come up with a graviton-based DE model with reacceleration of the universe, and to have it coincide with the modification of the $1/r$ potential, we are really developing a program to find if gravity can be quantized. What we have done is also to specify a relic black hole genesis for early-universe gravitons, which complements the picture of turbulence in the electroweak era. This, in turn, is relatable to the question of if micro black holes could contribute to cosmology. [2] We are trying to reconcile $-1 \leq \omega$ from the DE equation of state with the idea of graviton production from the early states of the universe to the present era, where we have acceleration of the universe. What motivates this presentation as we will try reconcile relic conditions for GW / graviton production. [3,4] The models seem irreconcilable and we do have a huge problem. A possible reconciliation [1 p. 114] suggests an examination of the DE equation of state for reacceleration of the universe, $\widetilde{m} > 1$:

$$\omega = \frac{\dot{\phi}^2 - 2V(\phi)}{\dot{\phi}^2 + 2V(\phi)} \approx \frac{\dot{\phi}^2 - 2V_0 \exp\left(-\sqrt{\frac{2}{\widetilde{m}}}\frac{\phi}{m_{\text{Planck}}}\right)}{\dot{\phi}^2 + 2V_0 \exp\left(-\sqrt{\frac{2}{\widetilde{m}}}\frac{\phi}{m_{\text{Planck}}}\right)}. \tag{1}$$

Again, this looks like a very hard problem, but in a nutshell, we need make the following identification, which may allow for us to make a concrete bridge between formalisms which otherwise look unlinkable. There is there a way to link $\phi$ of Eq. (1) with $\varphi_k$ of Eq. (3) below so as to come up with an acceptable form of $\phi$ that would satisfy the following equation. Here we need for acceleration of universe $\widetilde{m} > 1$.

$$V(\phi) = V_0 \exp\left(-\sqrt{\frac{2}{\widetilde{m}}}\frac{\phi}{m_{\text{Planck}}}\right). \tag{2}$$

Then, we should try to link $\phi$ of Eq. (1) with $\varphi_k$ of Eq. (3).[1,4]

$$\left(\frac{3}{8\pi G}\frac{\kappa}{a^2}+\frac{\kappa^2}{a^2}\varphi_k^2-\frac{16}{3}c_1B^4\right)\approx\frac{-\alpha c_2}{r^\alpha}\equiv\frac{-\alpha c_2}{(Planck\text{–}length)^\alpha}$$
$$\Leftrightarrow\left[\frac{\alpha}{(Planck\text{–}length)^\alpha}\right]\approx\frac{16}{3}\frac{c_1}{c_2}B^4-\frac{\frac{3}{8\pi G}\cdot\frac{\kappa}{a^2}+\frac{k^2}{a^2}\cdot\varphi_k^2}{c_2}. \tag{3}$$

To make this equivalence, we would, after considerable work, be able to link to the scale factor $a$ which shows up in Eq. (1) above. That is, having results in terms of the scale factor, and $\phi$ while making full identification with Eq. (3) above, may be a way to reformulate the linkage with early DE. In addition, such restraints upon scale factor $a$ may also begin to explain some of the scale-factor behavior. Also, the final equation-of-state constraint we have to keep in mind is[1,3,4]

$$-2m_{\text{Planck}}^2\dot{H}=\dot{\phi}^2. \tag{4}$$

We can use this to connect the final and initial parts of expansion of the universe. We will start with, initially going to a Kaluza–Klein (KK) treatment of gravitons.[2,5]

## 2. Reacceleration of the Universe and KK Gravitons with a Nonzero Rest Mass. The KK Treatment

Consider if there is, then, also a small graviton mass:[6,7]

$$m_n=\sqrt{\frac{n^2}{L^2}+(m_{\text{graviton rest mass}}=10^{-65}\text{ g})^2}=\frac{n}{L}+10^{-65}\text{ g}. \tag{5}$$

Note that Rubakov works with KK gravitons, without the tiny mass term for a four-dimensional rest mass included in Eq. (5). To obtain the KK-graviton/DM candidate representation along $RS\,\mathrm{d}S$ Brane world, Rubakov obtains his values for graviton mass and graviton physical states in space–time after using the normalization $\int\frac{\mathrm{d}z}{a(z)}h_m(z)h_{\widetilde{m}}(z)\equiv\delta(m-\widetilde{m})$ and $J_1$, $J_2$, $N_1$, and $N_2$, which are different forms of Bessel functions.[8] His representation of a graviton state is given by Eq. (4). If so, then the wave function for a graviton with a tiny four-dimensional space–time rest mass can be written as[8]

$$h_m(z)=\sqrt{\frac{m}{k}}\frac{J_1\left(\frac{m}{k}\right)N_2\left[\frac{m}{k}\exp(kz)\right]-N_1\left(\frac{m}{k}\right)J_2\left[\frac{m}{k}\exp(kz)\right]}{\sqrt{\left[J_1\left(\frac{m}{k}\right)\right]^2+\left[N_1\left(\frac{m}{k}\right)\right]^2}}. \tag{6}$$

Equation (6) is for KK gravitons having 1 TeV magnitude mass $M_Z\sim k$ (i.e., for mass values at 0.5 TeV to above 1 TeV) on a negative tension RS Brane. It would be useful to relate this KK graviton, which is moving with a speed proportional to $H^{-1}$ with regards to the negative tension Brane with $h\equiv h_m(z\to 0)=const\sqrt{\frac{m}{k}}$ as an initial starting value for the KK graviton mass. If Eq. (5) is for a "massive" graviton with a small four-dimensional graviton rest mass and if $h\equiv h_m(z\to 0)=const\sqrt{\frac{m}{k}}$ represents an initial state, then one may relate the mass of the KK graviton moving at high speed with its initial rest mass. This rest mass of a graviton

is $m_{\text{graviton}}(\text{4D GR}) \sim 10^{-48}$ eV, opposed to $M_X \sim M_{\text{KK}} \sim 0.5 \times 10^9$ eV. Whatever the range of the graviton mass, it may be a way to make sense of what was presented for a graviton mass using CMBR measurements of $M_{\text{KK}} \sim 10^{-20}$ eV.[9] Also, Eq. (6) will be the starting point used for a KK tower version. So[10]

$$\dot{a}^2 = \left\{ \left[ \frac{\widetilde{\kappa}^2}{3} \left( \rho + \frac{\rho^2}{2\lambda} \right) \right] a^2 + \frac{\Lambda a^2}{3} + \frac{m}{a^2} - K \right\}. \tag{7}$$

Maartens[10] also gives a second Friedman equation.

$$\dot{H}^2 = \left\{ - \left[ \frac{\widetilde{\kappa}^2}{2} \cdot (p + \rho) \cdot \left( 1 + \frac{\rho^2}{\lambda} \right) \right] + \frac{\Lambda \cdot a^2}{3} - 2\frac{m}{a^4} + \frac{K}{a^2} \right\}. \tag{8}$$

Also, an observer is in the low-redshift regime for cosmology, for which $\rho \approx -P$ and one obtains exact equality, $\rho = -P$ for redshift, $z$, between zero and five. The net effect will be to obtain, based on Eq. (7), assuming $\Lambda = 0 = K$ and using $a \equiv \frac{a_0 = 1}{1+z}$ to get a deceleration parameter,

$$q = -\frac{\ddot{a}a}{\dot{a}^2} = -1 + \frac{2}{1 + \widetilde{\kappa}^2 \left( \frac{\rho}{m} \right) \cdot (1+z)^4 \cdot \left( 1 + \frac{\rho}{2\lambda} \right)} \approx -1 + \frac{2}{2 + \delta(z)}. \tag{9}$$

These set values allow a graviton-based substitute for DE. $\Lambda = 0 = K$ plus a small rest mass for a graviton in four dimensions allows for "massive gravitons" that behave the same as DE. Setting $\Lambda = 0 = K$, with a modified behavior for the density expression, for a Friedman equation with small four-dimensional graviton mass replaces dark energy by a small four-dimensional rest mass for a graviton.

## 3. How a Small Graviton Mass Reaccelerates the Universe

Revising Alves et al.,[11] Beckwith[6,7] used a higher-dimensional Brane-world model with KK graviton towers, per Maartens,[10] and a Brane-world energy density $\rho$ in the Friedman equation similar to Alves et al.[11] for a nonzero graviton:[6,7]

$$\rho = \rho_0 \cdot (1+z)^3 - \left[ \frac{m_{\text{g}} \cdot (c=1)^6}{8\pi G(\hbar = 1)^2} \right] \cdot \left[ \frac{1}{14 \cdot (1+z)^3} + \frac{2}{5 \cdot (1+z)^2} - \frac{1}{2} \right]. \tag{10}$$

At $z \approx 4$, a billion years ago, acceleration of the universe increased, as shown in Fig. 1.[6,7] Figure 1 is, if confirmed, a good verification of the Ng hypothesis,[12] and would be a starting point to investigate the role of gravitons in cosmology. Buonnano[13] assumes a much lower range of initial frequencies for relic GW. Beckwith[6,7] obtained a reacceleration of the universe as given in Fig. 1. The contribution of a low rest mass for four-dimensional gravitons, as given in Eq. (10) leads to reacceleration of the expansion of the universe a billion years ago. That is, for a redshift slightly smaller than .5. We will state what is needed to explain, in part, Fig. 1.

## 4. Reconciling Graviton Impact and Graviton Generation

The key is to consider the following, namely Eq. (4), Eq. (9), and if $\rho_{\text{DE}} = \rho$.[1,4]

$$3m_{\text{Planck}}^2 H^2 = \rho_{\text{DE}} = \rho = 3m_{\text{Planck}}^2 \left\{ \left[ \frac{\widetilde{\kappa}^2}{3} \left( \rho + \frac{\rho^2}{2\lambda} \right) \right] + \frac{\Lambda}{3a^2} + \frac{m}{a^4} - \frac{K}{a^2} \right\}. \tag{11}$$

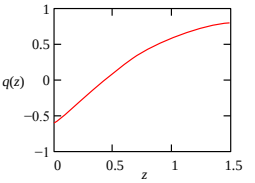

Fig. 1. Reacceleration of the universe.[6] Note that $q(z) < 0$ if $z < .423$.

Leading to

$$\left[\frac{\alpha}{(Planck\text{–}length)^{\alpha}}\right] \approx \frac{16}{3}\frac{c_1}{c_2}B^4 - \frac{\frac{3}{8\pi G}\cdot\frac{\kappa}{a^2} + \frac{k^2}{a^2}\cdot\varphi_k^2}{c_2}, \tag{12}$$

and also satisfying $V \cong \frac{c_2}{r^{\alpha}}$ for deignated $r$ values, $-1 \leq \omega \leq 1$ for the DE equation of state,

$$\omega = \frac{\dot{\phi}^2 - 2V(\phi)}{\dot{\phi}^2 + 2V(\phi)} \approx \frac{\dot{\phi}^2 - 2V_0\exp\left(-\sqrt{\frac{2}{\widetilde{m}}}\frac{\phi}{m_{\text{Planck}}}\right)}{\dot{\phi}^2 + 2V_0\exp\left(-\sqrt{\frac{2}{\widetilde{m}}}\frac{\phi}{m_{\text{Planck}}}\right)}, \tag{13}$$

and

$$V_0\exp\left(-\sqrt{\frac{2}{\widetilde{m}}}\frac{\phi}{m_{\text{Planck}}}\right) \leftrightarrow V \cong \frac{c_2}{r^{\alpha}}. \tag{14}$$

We would have restricted versions of $\alpha$ with this identification. The idea would be if say early gravitons are released by this mechanism,[3] we could eventually come up with a polynomial reconstruction for an inflaton, $\phi$ which would be commensurate with both Eq. (12) and a description of say early universe black holes (micro sized) shedding relic gravitons.[3]

## 5. Conclusions

*To put it mildly, we are bridging between the initial and second physics realms as to graviton physics and cosmology.* This in turn means keeping in mind the following.[2] The diagram[14] gives the relation between GW frequency and GW energy density for different cosmological models. And link Beckwith with Li et al.[1,3,4] and see how they compare with LIGO.[14] That is, we refer you to the figure[14] showing the relation between GW frequency and GW energy density for different cosmological models. Then, we should try to reconcile if is there a way to link $\phi$ of Eq. (1) with $\varphi_k$ of Eq. (3) and Eq. (15)

$$V_0\exp\left(-\sqrt{\frac{2}{\widetilde{m}}}\frac{\phi}{m_{\text{Planck}}}\right) \leftrightarrow V \cong \frac{c_2}{r^{\alpha}}. \tag{15}$$

By using $-1 \leq \omega \leq 1$ of Eq. (1) with the physics of the situation outlined in Eq. (15) and finding $\phi$ of Eq. (15) with $\varphi_k$ of Eq. (3), we hope to eventually reach o final

theory of the evolution of DE and, in doing so, explain the state of gravitons released by initial micro black holes,[3,4] with the physics given in Fig. 1, which represents gravitons as a form of DE, reaccelerating the universe from one billion years ago.

## 6. Now for a Very Important Final Insight from Ng, Using the Idea of Holographic Foam Cosmology

We examine two formulas[15 p. 77] for a cosmic density function, and entropy defined in Eq. (16), with $R_{\rm H}$ being a Hubble radius, $l_{\rm Planck}$ being a Planck radius, and entropy $\approx (R_{\rm H} l_{\rm Planck})^2 \stackrel{?}{\to} n$ (graviton count)

$$\rho_{\rm Cosmic} = \frac{3}{8\pi}(R_{\rm H} l_{\rm Planck})^{-2} \approx \left(\frac{H}{l_{\rm Planck}}\right)^2 . \tag{16}$$

If $\rho_{\rm Cosmic} \propto \rho_{\rm DE} \approx \rho$, can $R_{\rm H}$ be defined rigourously?

As of today, we have the Hubble volume approximately equal to $10^{31}$ cubic light years, approximately the cube of the radius, of Eq. (16), but how this Hubble radius evolves may have much to do with the evolution of dark energy. This is an important detail to work out. Furthermore, in line with Eq. (16), we have another line of inquiry to pursue:[15] If $\rho_{\rm DE} \approx \rho$ and

$$\rho \approx \frac{\hbar k_{\rm Planck}^4}{16\pi^2} \approx \frac{\hbar\left[k_{\rm Planck}^4 = \left(\frac{2\pi}{\Lambda}\right)^4\right]}{16\pi^2} \approx 10^{123}\rho_{\rm observed}, \tag{17}$$

reset $\Lambda$ to $\Lambda_{\rm initial} = 10^{\frac{123}{4}}\Lambda$, so that

$$\rho \approx \frac{\hbar k_{\rm Planck}^4}{16\pi^2} \approx \frac{\hbar\left[k_{\rm Planck}^4 = \left(\frac{2\pi}{\Lambda_{\rm initial}}\right)^4\right]}{16\pi^2} \approx \rho_{\rm observed}. \tag{18}$$

Key to this would be, perhaps, putting Eq. (17) initially into Eq. (16), If this is feasible or not needs to be explored. It could though be part of a new gravitons–DE tapestry. A possible issue is, do we have, after formation of DE density, some sort of invariance of this dark-energy density value, say after the electroweak era?

# A five-dimensional approach to dark matter and dark energy

Michael B. Gerrard* and Timothy J. Sumner

*Physics Department, Imperial College London, London, UK*

**E-mail: gerrardmb@icloud.com*

*www.imperial.ac.uk*

A naive five-dimensional model simultaneously explains dark energy and the flat rotation curves of galaxies and enhanced gravitational lensing usually attributed to dark matter. An additional (fifth) dimension is invoked which corresponds to the radius of curvature of four-dimensional space-time and does not represent a degree of freedom of motion. The universe so modeled has two modes of expansion: that of three-dimensional space and that of the fifth dimension itself, where the latter has the characteristics partly of space and partly of time. The boundary between four-dimensional space-time and the fifth dimension is modeled by contours along which energy is conserved. The model is able to reproduce: (i) the observed relationship between distance modulus and red shift for Type 1a supernovae; (ii) the Tully-Fisher relationship; and (iii) gravitational lensing effects beyond General Relativity for galaxies and clusters of galaxies.

*Keywords*: Dark Energy; Dark Matter; 5 dimensions.

## 1. Introduction

A discrepancy exists between the observed extent of gravitating matter in the universe and that inferred from galaxy rotation curves, galaxy cluster dynamics, gravitational lensing and simulations of evolution of the universe. The existence of abundant unobserved (or dark) matter has been proposed by many cosmologists[1] to account for this discrepancy, although to date dark matter has not been directly detected.[2–4] Observations concerning the luminosity distance of Type 1a supernovae, their red shift and the rate of expected Hubble expansion of the universe have led to the conclusion that the expansion has been accelerating since about six billion years ago. This has led many to propose that dark energy permeates the universe, counteracting the decelerating effect of gravity.[5,6] However, to date, the source of dark energy has not been identified.[7]

It is the purpose of this paper to show that a universe comprised of five rather than four large-scale dimensions and without the assumed presence of dark matter and dark energy, could account for these same observations concerning galaxies, clusters of galaxies and the expansion rate of the universe. The possibility of additional dimensions of space-time has, of course, long been under discussion within theoretical physics.[8–11] However, the distinctive features of the dimension considered in this paper include its large scale and its hybrid character, being partly like space and partly like time.

## 2. A Fifth Large Scale Dimension

We consider a naive model universe in which three-dimensional space, $s(x, y, z)$, is isotropic, closed and expanding. The radius of curvature in this universe is given the symbol, $r$, and dimensions of length and is defined to be orthogonal to the three space dimensions, $s$, and time, $t$. If Newton's Second Law can be extended to five dimensions, then energy propagating (at the speed of light, $c$, through three-dimensional space that is closed and forming the "surface volume" of a four-dimensional hyper-sphere of radius $r$, will experience a virtual acceleration $a_r$ (1) acting in the direction of $r$ increasing. It is assumed to be fundamental that energy is conserved within four-dimensional space-time, notwithstanding that it is embedded within five dimensions.

$$a_r = \frac{c^2}{r}. \tag{1}$$

## 3. Angular Velocity Vectors in 5 Dimensions

An axial vector, $\Omega$, representing angular velocity is aligned normal to the plane of rotation $xy$ of the rotating body it describes. However, the direction of $\Omega$ can lie anywhere in the $zr$ plane, as both dimension $z$ and the additional dimension, $r$, are orthogonal to the $xy$ plane. Consequently, more information is required to define uniquely the orientation of $\Omega$ within a five-dimensional framework.

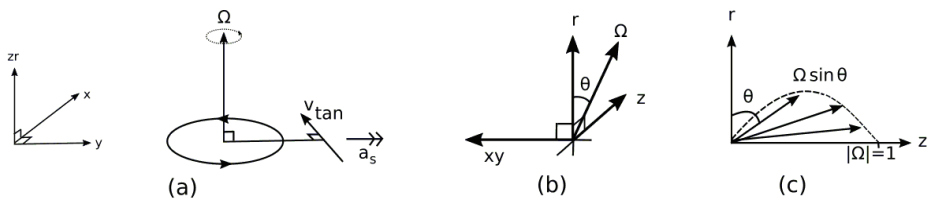

Fig. 1. Axial vector ($\Omega$), its orientation in 5 dimensions and resolved magnitude in 4 dimensions.

This additional information comes from including the influence of the additional acceleration $a_r$ (defined above) on the rotating body, which defines the orientation $\theta$ of the angular velocity vector $\Omega$ in the $zr$ plane (Fig. 1). The centrifugal acceleration, $a'_s$, experienced by the rotating body within a five-dimensional framework is given by (2), where: $\tan\theta = a_s/a_r$; $a_s$ is the four-dimensional centrifugal acceleration of the body; and $v_{tan}$ is the tangential velocity of the body about its centre of rotation. The possibility of forces arising from an additional dimension and perturbing dynamics observed within four dimensions has been previously identified by Wesson.[12]

$$a'_s = \Omega\,(\sin\theta + i\cos\theta)\,v_{tan}. \tag{2}$$

This five-dimensional analysis of rotational motion ultimately leads to the derivation of (3) and so to the Tully-Fisher relationship[13] and predictions of flat rotation curves for certain types of galaxies[14], without the need for dark matter to be assumed, where $M$ is the baryonic mass of the galaxy and $G$ is the gravitational constant. However, consistent with observations, this analysis does not predict any departure from the expected four-dimensional Newtonian behaviour for stars at the fringe of galaxies, as regards their motion normal to their planes of rotation, nor their motion radially from the centre of the galaxy.[15,16]

$$|a_r GM| = v_{tan}^4. \tag{3}$$

Comparing the parameters predicted by this analysis with those reported by Stark[17] and McGaugh[18] places values for $a_r$ in the range $1.2 - 1.9 \times 10^{-10}\,\mathrm{ms}^{-2}$ which is also consistent with values for the MOND constant, $a_0$, reported by Milgrom.[19,20] From (1), the implied range of values for $r$ is $4.7 - 7.5 \times 10^{26}\,\mathrm{m}$. A steady increase in $r$ with cosmological time, described in section 5. implies a steadily reducing value for $a_r$.

## 4. Gravitational Lensing

The principle of energy conversation along contours that define the boundary between four-dimensional space-time, $s, t$ and the fifth dimension, $r$, can be used to generate the Lorentz contraction formula of Special Relativity and the dilation formula of General Relativity, as they apply to the dimension $r$. The latter is shown in (4) where $r_u$ is the value for $r$ remote from gravitational fields.

$$r = r_u \left(1 - \frac{2GM}{sc^2}\right)^{1/2}. \tag{4}$$

In five dimensions, the acceleration, $a$, experienced by a beam of light propagating through a gravitational field (generated by mass $M$) is given by (5), where $g$ is the gravitational acceleration.

$$a = g + \left(\frac{c}{r} \wedge \dot{r}\right). \tag{5}$$

Considering only the real term in (2), the induced angular rate of perturbation of the beam of light, $\dot{\epsilon}$, can be written as in (6), where the relevant gradient $\tan\theta = g/a_r$ and the tangential velocity is the speed of light, $c$.

$$\dot{\epsilon} = \frac{a}{c \sin\theta}. \tag{6}$$

Integration along the path of the beam of light in five dimensions yields the expected expression (7) of General Relativity for the angular deflection, $\Delta\epsilon$, of the beam of light, where $s$ is the impact parameter; however, with an additional term that accounts for enhanced lensing effects at the fringes of galaxies and galaxy clusters.

$$\Delta\epsilon = \frac{4GM}{sc^2 f\,(\sin\theta)}. \tag{7}$$

Whereas for the Sun, $f(\sin\theta) = 1$ as $g >> a_r$ at the impact parameter, for galaxies and clusters of galaxies $g < a_r$ and, correspondingly $f(\sin\theta) < 1$ leading to lensing effects that are beyond GR expectation (7). The distribution of matter within the lensing system determines the local profile of $\sin\theta$ and could, in principle, give rise to a centre of lensing which did not coincide with the centre of mass of the system. This would be relevant to consideration of lensing observed for the bullet cluster and similar systems.[21]

## 5. The Expansion of Space

If matter is assumed on a large scale to be evenly spread across the universe, it is possible to derive from (4) an expression for the background value for $r$, given the symbol $r_b$, of the form $r_b = f(r_u, G, \rho, H_H, c)$ where $\rho$ is the baryonic mass density of the universe (a value of $4.2 \times 10^{-28}\,\mathrm{kgm}^{-3}$ has been used for the current era[22]) and $H_H$ is the Hubble horizon. The derivatives of $r_b$ show how a universe defined in five dimensions (rather than four) has two modes of expansion: the first concerns the expansion of three-dimensional space at a constant value of the fifth-dimensional parameter $r_b$; and the second concerns the expansion of space due to increases in the parameter $r_b$ itself. Accordingly, in five dimensions Hubble's constant can be decomposed into two terms, referred to respectively as $H3$ and $H5$, whose values can be shown to contribute to a Hubble constant of value $68.1\,\mathrm{kms}^{-1}\mathrm{Mpc}^{-1}$,[23,24] as follows: $H3 = 66.5\,\mathrm{kms}^{-1}\mathrm{Mpc}^{-1}$ and $H5 = 1.6\,\mathrm{kms}^{-1}\mathrm{Mpc}^{-1}$. The competing effects of these two modes of expansion can give rise to either an accelerating or decelerating expansion of the universe, within a five-dimensional framework.

Moreover, the conservation of energy at the boundary between four-dimensional space-time and the fifth dimension must necessarily impose an important constraint on the second derivative of $r_b$, shown in (8), and values for these two terms can be independently derived[25] and shown to satisfy

$$\frac{c^2}{r_b} + \ddot{r}_b = 0. \tag{8}$$

The balance between accelerations directed in three-dimensional space and those directed in the fifth dimension determines the gradient of contours $r(s)$ which define the boundary between four-dimensional space-time and the fifth dimension. This condition of balance (or equilibrium) between different accelerations can, alternatively, be thought of as defining a "surface tension" within the contour at the boundary between four-dimensional space-time the fifth dimension, which in $(x, y, z, r)$ dimensions become branes. This approach to the determination of the local curvature of space-time suggests a more than coincidental basis for the rubber sheet analogy of General Relativity.

Finally, we use the five-dimensional model described in this paper to calculate the relationship between distance modulus, $\mu$ and red shift, $z$ for Type 1a SN and compare this with currently available observational data from

(http://supernova.lbl.gov/Union/Union2.html).[26] The results of this fit are shown in Fig 2. The residuals trend indicates that the model slightly over-estimates $\mu$ at lower red shift and, correspondingly, under-estimates it for larger $z$. This kind of residuals trend may be an artefact of the way the data are calibrated for the absorption of light by inter-stellar gas. The relative evolution of the terms $H3$ and $H5$ in the model (see above) predict a point of inflection in the rate of expansion of the universe circa 6 billion years ago, but from an accelerating to a decelerating expansion. That is, the reverse of what has been deduced from fitting the SN data to four-dimensional models.[5,6] The five-dimensional model does not indicate the presence of an unaccounted accelerating expansion of the universe, which has been taken to indicate the presence of dark energy.

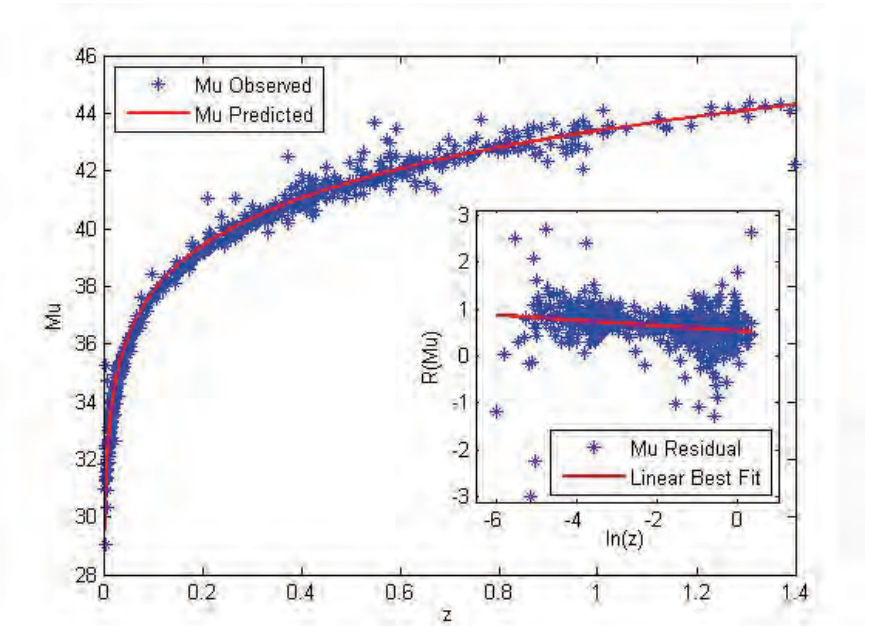

Fig. 2. Type 1a SN luminosity distance modulus ($\mu$) vs red shift, $z$, comparison between observation and five-dimensional model predictions.

## 6. Conclusion

If five-dimensional effects are taken into account, then predictions can be made for orbital dynamics within galaxies, the gravitational lensing of galaxies and galaxy clusters, and the relationship between distance modulus and red shift for Type 1a SN, which are consistent with observations, without the need to introduce dark matter or dark energy. The additional dimension introduced in this analysis has characteristics both of space dimensions (e.g. being a radius of curvature and a

distance parameter within vector algebra) and a time dimension (e.g. being neither a degree of freedom of motion nor being directly observable).

# Non-metric fields in quantum gravity

Kaushik Ghosh*

*Vivekananda College,*
*Kolkata, West Bengal 700091, India*
** E-mail: kaushikhit10@gmail.com*
*www.vckolkata63.org*

In this manuscript, we will discuss the construction of a theory of gravity with nonmetricity and general affine connections. We will consider a simple potential formalism with symmetric affine connections and symmetric Ricci tensor. Corresponding affine connections introduce two massless scalar fields. One of these fields contributes a stress-tensor with opposite sign to the sources of Einstein's equation when we state the equation using the Levi-Civita connections. This means we have a massless scalar field with negative stress-tensor in the familiar Einstein equation. These scalar fields can be useful to explain dark energy and inflation. These fields bring us beyond strict local Minkowski geometries.

*Keywords*: Connections, nonmetricity, scalar fields, negative stress tensor.

## 1. Introduction

In this manuscript, we will try to find if quantum gravity can introduce additional fields besides metric. We will discuss this with reference to the construction of covariant derivative operator in quantum gravity. We have earlier found it is a perceptive alternative to use affine connections more general than metric compatible affine connections in quantum gravity.[1] General affine connections introduce additional fields in the theory that can be useful to explain cosmological observations and can introduce new effects.[2] These fields are non-localized similar to dark energy and inflation. In this article, we have considered a simple case with symmetric Ricci tensor. Corresponding affine connections are symmetric and introduce only two massless scalar fields. One of these gives a stress tensor with opposite sign to the sources of Einstein's equation in the classical theory when we state the equation using the Levi-Civita connections. This means we have a source with negative stress tensor in the familiar Einstein equation. These scalar fields can be possible candidates for dark energy and inflation. These two fields break strict local Minkowski structure of spacetime. Global splitting of spacetime into space and time no longer remains exact in such spaces. This is an important issue in quantum gravity.[3] Finding the particle interpretations and other possible interactions of the above fields are non-trivial problems without local Minkowski structure. However, experiments suggest that such effects are very small in the present universe and the corresponding scalars mentioned above are also small. Their effects can be observed in large scale phenomena like the present cosmic acceleration. This is also consistent with the smallness of the parameters like the cosmological constant required to explain dark energy in some models mentioned at the beginning. The effects of these fields

will be large in the quantum gravity domain. We note that vacuum fluctuations of these fields can also be useful in cosmology.

## 2. General Affine Connections and Scalar Fields

In this section, we will consider applications of the potential formalism of the Palatini theory discussed in to introduce finite on shell non-metricity.[1] General affine connections are given by: $\Gamma^{\alpha}_{\ \mu\nu} + \tilde{C}^{\alpha}_{\ \mu\nu}$, where $\Gamma^{\alpha}_{\ \mu\nu}$ is the Levi-Civita connections and $\tilde{C}^{\alpha}_{\ \mu\nu}$ is symmetric in the lower indices and the sources do not couple with these fields. We consider symmetric Ricci tensors only. This is the most relevant case when we consider semiclassical and classical limits of quantum gravity. This example will introduce two massless scalar fields. One of them will contribute a negative stress tensor to Einstein's equation in the semiclassical or classical theories. We will use the geometrized units in the following where, $G = c = 1$. We have discussed earlier that we can introduce non-metricity by defining the affine connections to be compatible with a symmetric covariant field: $b_{\mu\nu} = g_{\mu\nu} + a_{\mu\nu}$; $a_{\mu\nu} \neq k g_{\mu\nu}$, where $k$ is a constant including zero.[1] Such a set of affine connections give a symmetric Ricci tensor. We now break $a_{\mu\nu}$ into a trace and a traceless part:

$$a_{\mu\nu}(x) = \Phi(x) g_{\mu\nu} + \bar{a}_{\mu\nu}(x); \quad \Phi(x) = \frac{a(x)}{4} \tag{1}$$

Where, $\Phi$ is a scalar field, $a(x)$ is the trace of $a_{\mu\nu}$ and $\bar{a}_{\mu\nu}$ is trace-free. We can express corresponding $\tilde{C}^{\alpha}_{\ \mu\nu}$ in the following way:

$$\tilde{C}^{\alpha}_{\ \mu\nu} = \delta^{\alpha}_{\ (\mu} \nabla'_{\nu)} [ln(1+\Phi)] - \frac{1}{2} g_{\mu\nu} \nabla'^{\alpha} [ln(1+\Phi)] + E^{\alpha}_{\ \mu\nu} \tag{2}$$

The first two terms in the *r.h.s* gives the contribution of the trace part of $b_{\mu\nu}$ given by: $(g_{\mu\nu} + \Phi(x) g_{\mu\nu})$.[4] A further contraction of the third term in the covaraiant indices leads to the following expression for a general $a_{\mu\nu}$:

$$\tilde{C}^{\alpha}_{\ \mu\nu} = \delta^{\alpha}_{\ (\mu} \nabla'_{\nu)} [ln(1+\Phi)] - \frac{1}{2} g_{\mu\nu} \nabla'^{\alpha} [ln(1+\Phi)] + g_{\mu\nu} \nabla'^{\alpha} \Psi + g_{\mu\nu} E^{\alpha} + \bar{E}^{\alpha}_{\ \mu\nu} \tag{3}$$

Where, $E^{\alpha}$ is a vector field which is not a gradient and $\bar{E}^{\alpha}_{\ \mu\nu}$ is traceless in the lower indices. $\Phi$ gives the trace-scalar of $a_{\mu\nu}$. The scalar $\Psi$ is also expected. In the Minkowski space, we have a spin zero boson associated with $\bar{a}_{\mu\nu}$ in addition to a spin one boson and a spin two boson. We will discuss this aspect further below Eq. (14). We now consider the simplest cases of Eq. (3). We first consider the case where the traceless part of $a_{\mu\nu}$ vanish and which introduces a scalar field only:

$$b_{\mu\nu} = g_{\mu\nu} + \Phi(x) g_{\mu\nu} = \chi(x) g_{\mu\nu} \tag{4}$$

We use affine connections that are compatible with $b_{\mu\nu}$ which is conformal to metric. In this case, $\tilde{C}^{\alpha}_{\ \mu\nu}$ and the modified curvature scalar are given by the following expressions:[4]

$$\tilde{C}^{\alpha}_{\ \mu\nu} = \delta^{\alpha}_{\ (\mu}\nabla'_{\nu)}[ln(1+\Phi)] - \frac{1}{2}g_{\mu\nu}\nabla'^{\alpha}[ln(1+\Phi)] \tag{5}$$
$$\mathcal{R} = R' - \frac{3}{2}\frac{1}{(1+\Phi)^2}(\nabla'\Phi)^2$$

Here $(\nabla'\Phi)^2 = (\nabla'_{\ \mu}\Phi)(\nabla'^{\mu}\Phi)$, is the norm of the gradient of $\Phi$ and the primed quantities are evaluated using the Levi-Civita connections. For small $\Phi$ ($<< 1$), we have the following modification of the *r.h.s* of Einstein's equation where covariant derivatives are evaluated using the Levi-Civita connections:[4]

$$\nabla'_{\ \kappa}\nabla'^{\kappa}\chi + \frac{1}{\chi}(\nabla'\chi)^2 = 0 \ \approx \ \nabla'_{\ \kappa}\nabla'^{\kappa}\Phi + (\nabla'\Phi)^2 \tag{6}$$
$$G'_{\ \mu\alpha} = 8\pi P'_{\ \mu\alpha} + \frac{3}{2\chi^2}[(\nabla'_{\ \mu}\chi)(\nabla'_{\ \alpha}\chi) - \frac{1}{2}g_{\mu\alpha}(\nabla'\chi)^2]$$
$$\approx 8\pi P'_{\ \mu\alpha} + \frac{3}{2}[(\nabla'_{\ \mu}\Phi)(\nabla'_{\ \alpha}\Phi) - \frac{1}{2}g_{\mu\alpha}(\nabla'\Phi)^2]$$
$$= 8\pi[P'_{\ \mu\alpha} + \frac{3}{16\pi}P'_{\ \mu\alpha}(\Phi)]$$

Where, we have considered terms upto second order in $\Phi$. $P'_{\ \mu\alpha}$ is the stress tensor of ordinary matter. $P'_{\ \mu\alpha}(\Phi)$ is the stress tensor of an ordinary masless scalar field. Both $\chi$ and $\Phi$ are massless. We find that the scalar field $\Phi$ behaves like a massless scalar field with its stress tensor coming as a source term in Einsrein's equation. This field can be useful to explain inflation. We can modify the metric-affine action by adding potential term for $\chi$ or $\Phi$. To ensure non-metricity, we have the following condition:

$$\nabla_{\mu}g_{\alpha\beta} = -g_{\mu(\alpha}\nabla'_{\beta)}[ln(1+\Phi)] \neq 0 \tag{7}$$

This is a mild condition. In the present case, matter fields do not couple with $\Phi$. The only observable effect of $\Phi$ is to produce a massless scalar field stress tensor in Einstein's equation. We now consider the other case where only $\Psi$ is finite:

$$\tilde{C}^{\alpha}_{\ \mu\nu} = g_{\mu\nu}\nabla'^{\alpha}\Psi \tag{8}$$

We have the following expressions for different quantities:

$$\mathcal{R}_{\mu\alpha} = R'_{\ \mu\alpha} + g_{\mu\alpha}(\nabla'\Psi)^2 - (\nabla'_{\ \mu}\Psi)(\nabla'_{\ \alpha}\Psi) \tag{9}$$
$$\mathcal{R} = R' + 3(\nabla'\Psi)^2$$

We now solve the corresponding extremization problem and obtain the following set of equations:

$$\begin{aligned} \nabla'_{\kappa}\nabla'^{\kappa}\Psi &= 0 \\ G'_{\mu\alpha} &= 8\pi P'_{\mu\alpha} - 3[(\nabla'_{\mu}\Psi)(\nabla'_{\alpha}\Psi) - \frac{1}{2}g_{\mu\alpha}(\nabla'\Psi)^2] \\ &= 8\pi[P'_{\mu\alpha} - \frac{3}{8\pi}P'_{\mu\alpha}(\Psi)] \end{aligned} \tag{10}$$

Where, $P'_{\mu\alpha}$ is the stress-tensor of ordinary sources and $P'_{\mu\alpha}(\Psi)$ is the stress-tensor of the massless scalar field $\Psi$. This stress tensor satisfy all the energy and pressure conditions that the stress-tensor of a massless scalar field satisfies but it comes with an opposite sign in the *r.h.s* of Einstein's equation, when we state the equation using the Levi-Civita connections. Thus, the effect of $\Psi$ introduced to generalize the Levi-Civita connections, is to contribute a negative massless scalar field stress tensor to the sources of the Einstein equation obtained from the Einstein-Hilbert action formalism. This gives us an alternate way to explain effects that dark energy is proposed for. Negative stress-tensor is also important in Hoyle-Narlikar theory of gravity and also in wormhole and warp drive. In this case, we can not generate the cosmological constant with ordinary massless scalar field $\Psi$ for which the energy density is positive definite. We have the following expression for non-metricity:

$$\nabla_{\mu}g_{\alpha\beta} = -2g_{\mu(\alpha}\nabla'_{\beta)}\Psi \tag{11}$$

This expression is similar to the non-metricity obtained for $\Phi$ apart from a factor of 2. We now consider the case when both $(\Psi, \Phi)$ are present. $\tilde{C}^{\alpha}_{\mu\nu}$ is given by the following expression:

$$\tilde{C}^{\alpha}_{\mu\nu} = \delta^{\alpha}_{(\mu}\nabla'_{\nu)}[ln(1+\Phi)] - \frac{1}{2}g_{\mu\nu}\nabla'^{\alpha}[ln(1+\Phi)] + g_{\mu\nu}\nabla'^{\alpha}\Psi \tag{12}$$

We obtain the following expression for the modified curvature scalar:

$$\mathcal{R} = R' - \frac{3}{2}\frac{1}{(1+\Phi)^2}(\nabla'\Phi)^2 + 3(\nabla'\Psi)^2 + \frac{3}{(1+\Phi)}[(\nabla'_{\kappa}\Phi)(\nabla'^{\kappa}\Psi)] \tag{13}$$

We have the following generalization of Einstein's equation:

$$\begin{aligned} \nabla'_{\kappa}\nabla'^{\kappa}\Psi + \frac{1}{2}\frac{1}{(1+\Phi)}\nabla'_{\kappa}\nabla'^{\kappa}\Phi &= 0 \\ \frac{3}{2}\nabla'_{\kappa}\nabla'^{\kappa}\Phi + \frac{1}{(1+\Phi)}(\nabla'\Phi)^2 - (\nabla'_{\kappa}\Psi)(\nabla'^{\kappa}\Phi) &= 0 \\ G'_{\mu\alpha} &= 8\pi[P'_{\mu\alpha} + \frac{3}{16\pi}P'_{\mu\alpha}(\Phi) - \frac{3}{8\pi}P'_{\mu\alpha}(\Psi) - \frac{3}{8\pi}P'_{\mu\alpha}(\Psi,\Phi)] \\ P'_{\mu\alpha}(\Psi,\Phi) &= \frac{1}{(1+\Phi)}[(\nabla'_{(\mu}\Psi)(\nabla'_{\alpha)}\Phi) - \frac{1}{2}g_{\mu\alpha}(\nabla'_{\kappa}\Psi)(\nabla'^{\kappa}\Phi)] \end{aligned} \tag{14}$$

The first two equations are the equations for $\Psi$ and $\Phi$ respectively. We find that coupling of $\Psi$ with $\Phi$ gives another contribution to source stress tensor which can be positive or negative. This is again important for dark energy research.

We now briefly discuss the geometrical significance of $(\Psi, \Phi)$ and corresponding non-metricities given by Eqs. (7,11). We define the the non-metricity tensor by:

$$Q_{\mu\alpha\beta} = -\nabla_\mu g_{\alpha\beta} = g_{\mu(\alpha}\nabla'_{\beta)}[ln(1+\Phi)]; \quad 2g_{\mu(\alpha}\nabla'_{\beta)}\Psi \tag{15}$$

Both $\Psi$ and $\Phi$ can be present in the manifold when non-metricity is required. We can split $Q_{\mu\alpha\beta}$ into a trace $Q_\mu$ and traceless part $\bar{Q}$ in the last two indices:[3]

$$Q_{\mu\alpha\beta} = Q_\mu g_{\alpha\beta} + \bar{Q}_{\mu\alpha\beta} \tag{16}$$

Both trace and traceless parts of $Q_{\mu\alpha\beta}$ are finite for the above cases. Corresponding connections do not preserve the light cone under parallel transport and we no longer have the local Minkowski structure of spacetime.[3] Thus, we can not have exact $(3+1)$ -splitting of the underlying manifold into space and time. We find that departure from local Minkowski geometry can give new fields like dark matter, dark energy and inflation not found ordinarily. A few examples of non-metric affine connections with vanishing $\bar{Q}$, that are local gauge theories for the Weyl group (Poincare group plus dilatation), are discussed in the references given at the footnote 24 of Ref. 3. We can have finite or vanishing torsion in such theories. These theories preserve the light cone under parallel transport and are locally Minkowski due to the reparameterization invariance of geodesics.[4]

The scalar fields $(\Psi, \Phi)$ are purely quantum gravitational in origin. They are kinematically required in quantum gravity. In this domain, $Q_{\mu\alpha\beta}$ can not vanish due to the arguments given in Sect. III. $(\Psi, \Phi)$ are finite every where and hence, they are non-localized similar to dark energy and inflation. They break the local Minkowski structure of spacetime, and are not present in the matter-gravity coupling part of the semiclassical theory of quantum gravity which presently is locally Lorentz invariant quantum field theory in curved spaces. It is unexpected that any significant coupling between $(\Psi, \Phi)$ and ordinary matter like fermions, present in the full quantum theory, will be lost in the semiclassical limit. Thus, we assume that $(\Psi, \Phi)$ can be present without corresponding sources from ordinary matter. They contribute non-trivially to the source stress tensor of Einstein's equation and are possible candidates for dark energy and inflation. Dark energy is non-localized, have negative pressure and is primarily observed by their gravitational effects. These make $\Psi$ a possible candidate for dark energy. $\Phi$ can be a possible candidate for inflation. The amount of dark energy is much higher than ordinary matter and $(\Psi, \Phi)$ need not to have ordinary matter with finite hypermomentum as their sources. A complete theory of quantum gravity will illuminate this issue further. $(\Psi, \Phi)$ are in line with other scalars introduced similarly, like the dilaton.[5] Observed local Lorentz invariance in many experiments indicate that $(\Psi, \Phi)$ are presently very small. This can explain the smallness of parameters like the cosmological constant required to explain present cosmological acceleration in some models. With $(\Psi, \Phi)$ being small

and non-localized, their effects are usually observed in large scale phenomena and are not much significant in small scale astrophysics like that of the Solar system. This is another characteristic aspect of dark energy. Quantum fluctuations in $(\Psi, \Phi)$, including vaccuum fluctuations, can also be useful to explain different cosmological eras. $(\Psi, \Phi)$ will be coupled with each other when we include both of them. This is given by Eq. (14). When required, we can include $E^{\alpha}, \bar{E}^{\alpha}{}_{\mu\nu}, q_{\mu\nu}$ and torsion potentials to explain different cosmological observations. A related problem is to find out possible interactions and particle interpretations of fields that correspond to different representations of the Lorentz group when the local Minkowski structure of spacetime is broken strongly. This will happen in the quantum gravitational domain. This will be important to understand the relations between the complete set of fields including ordinary matter and gauge fields. We can continue to describe gauge theories by potentials. This is consistent with the Palatini formalism, since the potentials are analogous to connections in the geometric theory of gauge fields.

We consider a model based on $p$-form kinetic Lagrangians in the context of dark energy. The Lagrangian of the model is built with kinetic terms of the field strength for each $p$-form coupled to a scalar field $\phi$ through a kinetic function. We assume that this scalar field is responsible for the present accelerated expansion of the Universe. Since we are interested in cosmological applications, we specialize the analysis to a 4-dimensional case, using an anisotropic space-time. By studying the dynamical equations, we investigate the evolution of the dark energy density parameter, the effective equation of state and the shear induced by the anisotropic configuration.

*Keywords*: Dark energy; $p$-forms; dynamical systems.

## 1. Motivation

The predictions coming from the inflationary paradigm 1, 2 had been successfully confirmed with measures of the fluctuations in temperature of the Cosmic Microwave Background (CMB), and probes in the Large Scale Structure (LSS) of the Universe, with a significantly increase of precision during the last decades. In its simple form, based on a single scalar field (the *inflaton*) with a slow-roll potential, inflation predicts a statistical Gaussian distribution function and an isotropic power spectrum. However, some anomalies present in current data, need models beyond the standard slow-roll description in order to be fully addressed. These anomalies are related with statistical anisotropies and signals of parity violation 3.

One simple attempt relies in the inclusion of vector fields (or 1-forms), due to the intrinsic preferred directions they dictate. Models which couples a Maxwell kinetic term and a scalar field as $f(\phi)F^{\mu\nu}F_{\mu\nu}$ with $F_{\mu\nu}$ the field strenght of a vector field $A_\mu$, had been studied in the context of inflation 4, as well as modifications like $\phi F_{\mu\nu}\tilde{F}^{\mu\nu}$ with $\tilde{F}$ the dual of $F$ 5. With the same spirit, the anisotropic spectrum of models including terms as $H_{\mu\nu\sigma}H^{\mu\nu\sigma}$ being $H_{\mu\nu\sigma}$ the corresponding field strength of a 2-form field $B_{\mu\nu}$, had been considered 6.

Besides the applications to cosmic inflation, general $p$-forms had potential interest to explain the current acceleration of the Universe. In particular, anisotropic dark energy coming from a quintessence field $\phi$ coupled to a vector field were studied in Ref. 7. A similar analysis was carried out in Ref. 8, but this time using the field strength of a 2-form coupled to the scalar $\phi$. In both references, possible scenarios

where dark energy domination era is plausible after radiation and matter epochs, were found. We can go further the standard approach of Maxwell-like terms of the $p$-forms and allow for couplings between them, as in Ref. 9, where this construction was made. The aim of this short paper is to begin studying the cosmological consequences of coupled $p$-forms. We will focus in the case of a 4-dimensional space-time and will consider the effect of a combination of a 1-form and a 2-form fields coupled to a kinetic function of the quintessence field.[a]

## 2. *p*-form-scalar model

We will consider the standard Lagrangian for a scalar field composed by its kinetic term and a potential $V(\phi)$ as:

$$\mathcal{L}_\phi = \frac{1}{2}\partial_\mu\phi\partial^\mu\phi + V(\phi). \tag{1}$$

For the $p$-form sector we start with basic definitions. Given a $p$-form $A_{p\,\mu_1,\mu_2\cdots\mu_p}$, its dynamics is introduced by the field strength $F_{p\,\mu_1\mu_2\cdots\mu_{p+1}} \equiv \partial_{[\mu_1}A_{p\,\mu_2\mu_3\cdots\mu_{p+1}]}$. In this simple case, the Lagrangian that we are going to construct will be built out of the appropriate combinations of the field strengths of the $p$-forms, coupled to the scalar field $\phi$ through arbitrary functions $f(\phi)$. In four dimensions, only two terms remain 9, thus the Lagrangian simply reads[b]

$$\mathcal{L}_p(\phi, A_p) = f^2(\phi)\left(\frac{1}{4}F_{1\,\mu_1\mu_2}F_1^{\mu_1\mu_2} + \frac{1}{12}F_{2\,\mu_1\mu_2\mu_3}F_2^{\mu_1\mu_2\mu_3}\right). \tag{2}$$

Assuming standard gravity, the action of our model can be written as

$$S_p = \int \mathrm{d}^4x\sqrt{-g}\left[\frac{M_\mathrm{p}^2}{2}R - \mathcal{L}_\phi - \mathcal{L}_p(\phi, A_p)\right], \tag{3}$$

where $M_\mathrm{p}$ the Planck mass and $R$ the Ricci scalar.

## 3. Background equations

The Einstein equations could be written as

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} = 8\pi G(T^m_{\mu\nu} + T^\phi_{\mu\nu} + T^p_{\mu\nu}), \tag{4}$$

where we split the energy momentum tensor, $T_{\mu\nu}$, in three parts: $T^\phi_{\mu\nu}$, $T^p_{\mu\nu}$ and $T^m_{\mu\nu}$, representing the contributions of the scalar field, the $p$-forms and the standard

[a] In 4 dimensions there is a non-vanishing coupling term between a 1-form and a 2-form, which can support anisotropic inflation 10. We leave the study of these term in the context of dark energy for a forthcoming publication.

[b] The coupling functions $f_i(\phi)$ for each $p$-form are in general different. Here we assume them equal just for simplicity.

matter, respectively.

$$T^{\phi}_{\mu\nu} = \partial_\mu\phi\partial_\nu\phi - \frac{1}{2}g_{\mu\nu}\partial_\sigma\phi\partial^\sigma\phi - g_{\mu\nu}V(\phi), \tag{5}$$

$$T^{p}_{\mu\nu} = f^2\left[F_{1\,\nu\gamma}F_{1\,\mu}^{\ \gamma} + F_2^{\alpha\beta}{}_{\nu}F_{2\,\alpha\beta\mu} - g_{\mu\nu}\left(\frac{1}{4}F_1^2 + \frac{1}{12}F_2^2\right)\right], \tag{6}$$

with the shorthand notation $F_1^2 \equiv F_{1,\mu_1\mu_2}F^{1,\mu_1\mu_2}$ and $F_2^2 \equiv F_{2,\mu_1\mu_2\mu_3}F^{2,\mu_1\mu_2\mu_3}$. For the matter sector we assume a perfect fluid contribution $T^m_{\mu\nu} = \text{diag}\,(\rho_f, p_f, p_f, p_f)$ with $\rho_f$ the energy density and $p_f$ the preassure. Taking into account the Lagrangian of the scalar field $\mathcal{L}_\phi$ given in eq. (1), variation w.r.t. $\phi$ gives

$$\Box\phi - V_{,\phi} + 2ff_{,\phi}\left(F_1^2 + F_2^2\right) = 0, \tag{7}$$

with $f_{,\phi} \equiv \frac{\mathrm{d}f(\phi)}{\mathrm{d}\phi}$. In which follows, we will use the gauge freedom $A_0 = \partial^i A_i = 0$, to choose the vector field along the $x$ direction $A_1 = A_1(t)\mathrm{d}x$, and the 2-form along the plane $y-z$, this is $A_2 = A_2(t)\mathrm{d}y\wedge\mathrm{d}z$ 6. Thus, due to the rotational symmetry of $A_{1\,\mu_1}$ and $A_{2\,\mu_1\mu_2}$ we use a Bianchi I metric:

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + e^{2\alpha(t)}\left[e^{-4\sigma(t)}\mathrm{d}x^2 + e^{2\sigma(t)}(\mathrm{d}y^2 + \mathrm{d}z^2)\right], \tag{8}$$

being $e^\alpha \equiv a$, with $a$ the scale factor, and $\sigma$ the spatial shear. The equation of motion (e.o.m.) for the fields $A_1$ and $A_2$ are

$$\ddot{A}_1 + \left[2\frac{f'}{f}\dot{\phi} + \dot{\alpha} + 4\dot{\sigma}\right]\dot{A}_1 = 0, \qquad \ddot{A}_2 + \left[2\frac{f'}{f}\dot{\phi} - (\dot{\alpha} + 4\dot{\sigma})\right]\dot{A}_2 = 0, \tag{9}$$

the solutions are simply

$$\dot{A}_1 = \tilde{p}_1 f(\phi)^{-2}e^{-\alpha-4\sigma}, \qquad \dot{A}_2 = \tilde{p}_2 f(\phi)^{-2}e^{\alpha+4\sigma}, \tag{10}$$

with $\tilde{p}_1$ and $\tilde{p}_2$ integration constants. If we define the energy densities of the $p$-forms as

$$\rho_1 = \frac{f^2}{2}e^{-2\alpha+4\sigma}\dot{A}_1^2, \qquad \rho_2 = \frac{f^2}{2}e^{-4\alpha-4\sigma}\dot{A}_2^2, \tag{11}$$

the Friedmann equations, coming from eq. (4), and the e.o.m for the scalar field could be written as

$$\dot{\alpha}^2 = \dot{\sigma}^2 + \frac{1}{3M_{\rm pl}^2}\left[\rho_m + \rho_r + \frac{1}{2}\dot{\phi}^2 + V(\phi) + \rho_1 + \rho_2\right], \tag{12}$$

$$\ddot{\alpha} = -3\dot{\alpha}^2 + \frac{1}{M_{\rm pl}^2}\left[\frac{\rho_m}{2} + \frac{\rho_r}{3} + V(\phi) + \frac{1}{3}\rho_1 + \frac{2}{3}\rho_2\right], \tag{13}$$

$$\ddot{\sigma} = -3\dot{\alpha}\dot{\sigma} + \frac{1}{M_{\rm pl}^2}\left[\frac{2}{3}\rho_1 - \frac{2}{3}\rho_2\right], \tag{14}$$

$$\ddot{\phi} = -3\dot{\alpha}\dot{\phi} - V_{,\phi} + 2\frac{f_{,\phi}}{f}(\rho_1 + \rho_2), \tag{15}$$

where we take into account contributions of non-relativistic matter and radiation.

## 4. Cosmological dynamics

Let us introduce the following dimensionless quantities

$$\Sigma \equiv \frac{\dot{\sigma}}{\dot{\alpha}}, \quad X \equiv \frac{\dot{\phi}}{\sqrt{6}M_{\rm pl}H}, \quad Y \equiv \frac{\sqrt{V}}{\sqrt{3}M_{\rm pl}H}, \quad \Omega_m \equiv \frac{\rho_m}{3M_{\rm pl}^2H^2}, \tag{16}$$

$$\Omega_r \equiv \frac{\rho_r}{3M_{\rm pl}^2H^2}, \quad \Omega_1 \equiv \frac{\rho_1}{3M_{\rm pl}^2H^2}, \quad \Omega_2 \equiv \frac{\rho_2}{3M_{\rm pl}^2H^2}, \tag{17}$$

where $H \equiv \dot{\alpha}$. Thus, eq. (12) can be written as $\Omega_m = 1 - \Sigma^2 - \Omega_{DE} - \Omega_r$, where $\Omega_{DE} \equiv X^2 + Y^2 + \Omega_1 + \Omega_2$, is the dark energy density parameter . The effective equation of state (e.o.s.) is defined as $w_{\rm eff} \equiv -1 - \frac{2\dot{H}}{3H^2}$, where the ratio $\frac{\dot{H}}{H^2}$ can be computed from eq. (13) as

$$\frac{\dot{H}}{H^2} = -\frac{1}{2}\left(3 + 3X^2 - 3Y^2 + 3\Sigma^2 + \Omega_1 - \Omega_2 + \Omega_r\right). \tag{18}$$

In addition, we define the dark energy density and pressure as

$$\rho_{\rm DE} = \frac{\dot{\phi}}{2} + V(\phi) + \rho_1 + \rho_2 + 3M_{\rm pl}^2H^2\Sigma^2, \tag{19}$$

$$p_{\rm DE} = \frac{\dot{\phi}}{2} - V(\phi) + \frac{\rho_1}{3} - \frac{\rho_2}{3} + 3M_{\rm pl}^2H^2\Sigma^2. \tag{20}$$

The e.o.s for dark energy becomes

$$w_{\rm DE} \equiv \frac{p_{\rm DE}}{\rho_{\rm DE}} = \frac{3(X^2 - Y^2 + \Sigma^2) + \Omega_1 - \Omega_2}{3(X^2 + Y^2 + \Sigma^2 + \Omega_1 + \Omega_2)}. \tag{21}$$

In order to get a closed system of equations, is necessary to define explicitly the form of the potential $V(\phi)$ and the coupling function $f(\phi)$. We choose them to be of exponential type $V(\phi) \propto e^{-\frac{\lambda\phi}{M_{\rm pl}}}$, $f(\phi) \propto e^{-\frac{\mu\phi}{M_{\rm pl}}}$, where $\lambda$ and $\mu$ are dimensionless constants 7, 8. Thus, by differentiating w.r.t the number of $e$-folds $N \equiv \ln a$ each one of the variables given in eq. (16) and eq. (17) we find

$$\Sigma' = \frac{\Sigma}{2}\left(3X^2 - 3Y^2 + 3\Sigma^2 - 3 + \Omega_1 - \Omega_2 + \Omega_r\right) + 2\Omega_1 - 2\Omega_2, \tag{22}$$

$$X' = \frac{3X}{2}\left(X^2 - Y^2 + \Sigma^2 - 1 + \frac{\Omega_1}{3} - \frac{\Omega_2}{3} + \frac{\Omega_r}{3}\right) - \sqrt{6}\left(\mu(\Omega_1 + \Omega_2) - \frac{\lambda Y^2}{2}\right), \tag{23}$$

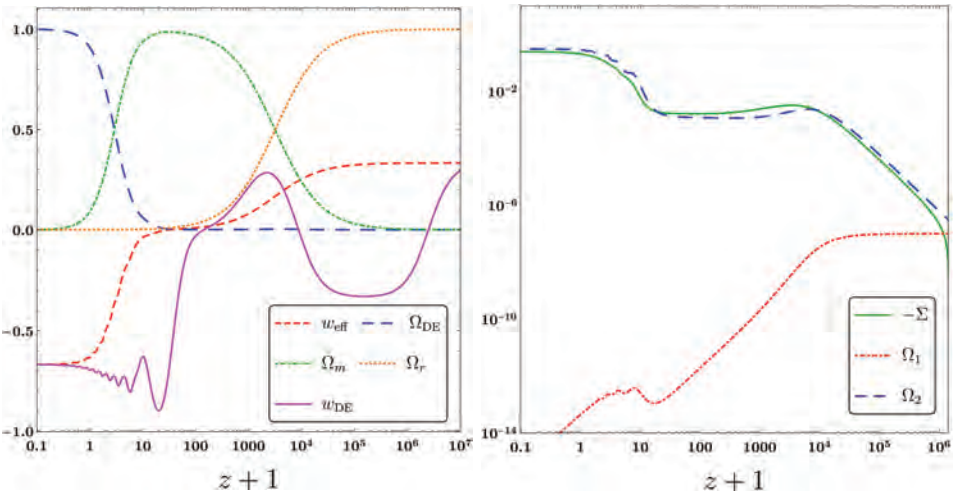
$$Y' = \frac{Y}{2}\left(3X^2 - 3Y^2 + 3\Sigma^2 + 3 + \Omega_1 - \Omega_2 + \Omega_r - \sqrt{6}\lambda X\right), \tag{24}$$

$$\Omega_1' = \Omega_1\left(3X^2 - 3Y^2 + 3\Sigma^2 + 4\Sigma - 1 + 2\sqrt{6}\mu X + \Omega_1 - \Omega_2 + \Omega_r\right), \tag{25}$$

$$\Omega_2' = \Omega_2\left(3X^2 - 3Y^2 + 3\Sigma^2 + 4\Sigma + 1 + 2\sqrt{6}\mu X + \Omega_1 - \Omega_2 + \Omega_r\right), \tag{26}$$

$$\Omega_r' = \Omega_r\left(3X^2 - 3Y^2 + 3\Sigma^2 - 1 + \Omega_1 - \Omega_2 + \Omega_r\right). \tag{27}$$

Instead of the standard analysis of critical points and stability for the previous autonomous system, we decide the make numerical integrations of the equations to obtain a general behavior of the solutions. A complete analysis of this system goes



(a) (b)

Fig. 1. (a) Evolution of $\Omega_{\rm DE}$, $\Omega_r$, $\Omega_m$, $w_{\rm DE}$, and $w_{\rm eff}$ versus $z+1$ for $\lambda = \mu = 10$, with the initial conditions $X = 10^{-13}$, $Y = 10^{-14}$, $\Sigma = 0$, $\Omega_1 = 10^{-7}$, $\Omega_2 = 10^{-10}$, and $\Omega_r = 0.99996$ at the redshift $z = 7.9 \times 10^7$. (b) Evolution of $-\Sigma$, $\Omega_1$ and $\Omega_2$ versus $z+1$ for $\lambda = \mu = 10$ with the same set of initial conditions as figure (a).

beyond this short paper and is left for a forthcoming work. In Fig. 1 we shown the numerical integration of the set of eqs. (22) to (27) where the couplings constants were fixed to be $\lambda = \mu = 10$. Typically, we search for a transition from radiation dominance, to matter dominance, and finllay reach an epoch dominated by dark energy today. In terms of effective equation of state $w_{\rm eff}$ those transitions are of the type $w_{\rm eff} \sim \frac{1}{2} \longrightarrow w_{\rm eff} \sim 0 \longrightarrow w_{\rm eff} \leq -\frac{1}{3}$, as we can see in Fig. 1a, where the sequence is observed in terms of the density parameters. For large redshifts the radiation dominates and start to decrease at an approximate redshift of $z \sim 3000$ to a matter dominated epoch ($\Omega_m \sim 1$), as expected. The evolution of the shear $\Sigma$ and the density parameters $\Omega_1$ and $\Omega_2$ are shown in Fig. 1b. The contribution of the 2-form always dominate over the 1-form, except for the initial condition at high redshift ($\sim 10^7$); the shear increases until a constant value in the present time. In contrast with the case presented in Ref. 8, where only the 2-form is considered, $w_{\rm eff}$ and $w_{\rm DE}$ we will not reach the asymptotic value $\sim -1$. Nevertheless, we check numerically by evolving $w_{\rm DE}$ with different (larger) values of the coupling $\mu$, that this value is realized.

As we anticipated, a complete analysis including the stability of fixed points of the autonomous system, will be presented in a future work, where we also want to elucidate the effect of a non-vanishing coupling between the 1- and 2-form fields.

# Cosmological constant: the possible nature and relationship with quantum gravity and fundamental particle masses

Ho-Ming Mok

*RHU, Hong Kong SAR, China*
*E-mail: a8617104@graduate.hku.hk*

In order to reconcile the quantum mechanics and general relativity, the equivalence principle of quantum gravity is introduced for extending the equivalence principle of general relativity to the observer frames of reference which are in quantum mechanical motions. The equivalence principle of quantum gravity is that the laws of physics must be of such a nature that they apply to systems of reference in any kind of motions, both classical and quantum mechanical. Under such principle, the quantum gravity should be formulated in the quantum space-time-matter space with local conformal symmetry and the mathematical expressions for the cosmological constant as well as the masses of fundamental particles can be found by the theory.

*Keywords*: Cosmological constant, equivalence principle of quantum gravity, Higgs condensate, quantum space-time-matter geometry, local conformal symmetry, Weyl geometry.

## 1. Introduction

It is well known that the two main pillars of modern physics, the general relativity (GR) and quantum mechanics (QM), are fundamentally inconsistent with each other. In order to reconcile the QM and GR, the equivalence principle of quantum gravity is introduced for extending the equivalence principle of GR to the observer frames of reference which are in quantum mechanical motions[1]. The equivalence principle of quantum gravity is that the laws of physics must be of such a nature that they apply to systems of reference in any kind of motions, both classical and quantum mechanical. That means the quantum state of a particle is relative to the observer frame of reference which can also be itself in a quantum mechanical state. Under the principle, the quantum gravity should be formulated in the quantum space-time-matter (QSTM) space with local conformal symmetry. It was also expected that the ultimate theory of quantum gravity would explain the cosmological constant problem[2,3].

## 2. Quantum space-time-matter geometry

In relativity, the space and time are defined by the coordinate system established by measuring-rods and synchronised clocks, which are in classical motions and their measuring results correspond to the points in the 4-dimensional spacetime coordinate system. However, the measuring-rods and clocks themselves are subject to the quantum uncertainty as well as quantum mechanical motions. Therefore, the space-time cannot simply be a 4-dimensional coordinate system with spacetime points but should be associated with the quantum states of measuring-rods and clocks specified

by their state parameters. The quantum state of the measuring-rod and clock, that is the quantum state of the spacetime by definition, can be defined[4] as $|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle$, where $\overrightarrow{x}$ is the classical spacetime vector and $\Delta\overrightarrow{x}$ is the associated uncertainty. As the quantum uncertainties depends upon the energy scales, the modified definition of spacetime should therefore be observation energy scale dependent. The quantum state $|\alpha\rangle$ of a particle can be projected to such quantum spacetime state to become a wavefunction $\phi(\overrightarrow{x}, \Delta\overrightarrow{x})$ as $\phi(\overrightarrow{x}, \Delta\overrightarrow{x}) = \langle \overrightarrow{x}, \Delta\overrightarrow{x}|\alpha\rangle$. Furthermore, the particle quantum state can be observed in another quantum spacetime state $|\overrightarrow{y}, \Delta\overrightarrow{y}\rangle$ which can be expressed in general as linear combination of the eigenstate of $|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle$. The transformation can be expressed as

$$\langle \overrightarrow{y}, \Delta\overrightarrow{y}|\alpha\rangle = \int \langle \overrightarrow{y}, \Delta\overrightarrow{y}|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle \langle \overrightarrow{x}, \Delta\overrightarrow{x}|\alpha\rangle \tag{1}$$

The integration sign denotes the summation or integration of all the possible eignestates of $|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle$. Actually, such notation can be omitted by identifying the operator $|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle\langle\overrightarrow{x}, \Delta\overrightarrow{x}|$ as the internal index of the summation or integration as analogous to the Einstein's convention.

For introducing the geometrical concept to QM and the equivalence priniple of quantum gravity in quantum gravity, the spacetime should be merged with matter together to become the QSTM space with local conformal symmetry under the Weyl like geometry[1,4]. As a consequence, all the physical laws apply not just to the frames of reference in any kind of classical motion as in GR but also the same in the reference frames in quantum mechanical motions as well. It implies that the general physical laws of nature are required to be expressed by equations which hold good for all systems of quantum spacetime states which are covariant under the transformation in Eq (1) and the quantum mechanical motion is relative in nature. The QSTM state $|\Psi\rangle$ is the combination of the quantum state of particle and spacetime as $|\Psi\rangle = |\phi\rangle|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle$. The length of a general small line element $dL$ can be defined in a small region of QSTM space as the inner product of $\delta|\Psi\rangle$ as

$$dL^2 = \delta|\Psi\rangle \cdot \delta|\Psi\rangle = \delta(|\phi\rangle|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle) \cdot \delta(|\phi\rangle|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle) \tag{2}$$

where the inner product can be defined as the usual inner product used for quantum mechanical states and thus $dL^2$ has a real value. Let us also introduce the operator $\widehat{\delta\overrightarrow{x}_{\Delta x}}$, which can extract the spacetime length from the quantum spacetime state, for small changes on spacetime state with the property as

$$\widehat{\delta\overrightarrow{x}_{\Delta x}}\delta|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle = \delta\overrightarrow{x}_{\Delta x}\delta|\overrightarrow{x}, \Delta\overrightarrow{x}\rangle \tag{3}$$

When there is no local mixing between the quantum matter particle state and the quantum spacetime state, another line element $dl$ can be defined in the QSTM

space and when expressing it in generalised coordinates $\xi_m^\mu$ in the QSTM space gives

$$dl^2 = \delta\left|\phi\right\rangle \widehat{\delta\overrightarrow{x}_{\Delta x}}\delta\left|\overrightarrow{x},\Delta\overrightarrow{x}\right\rangle \cdot \delta\left|\phi\right\rangle \widehat{\delta\overrightarrow{x}_{\Delta x}}\delta\left|\overrightarrow{x},\Delta\overrightarrow{x}\right\rangle = G_{\mu\nu}^{mn} d\xi_m^\mu d\xi_n^\nu \tag{4}$$

where $G_{\mu\nu}^{mn}$ is the combined metric of the QSTM space and the extracted spacetime length and the index $\mu$ and $\nu$ are the usual spacetime indexes in GR while $m$ and $n$ are the indexes associated with the quantum spacetime and matter states. Such formulation works well on discrete eigenstates as well as continuous eignestates. Let us define the local conformal operator $\Omega$ on the QSTM state as $\delta\left|\Psi\right\rangle \rightarrow \Omega\delta\left|\Psi\right\rangle$. By using the closest admissible action in Weyl geometry analogous to the Einstein's action for local conformal symmetry[5],

$$S = \int \Re^2 \sqrt{-G} d^p\xi \tag{5}$$

where $\Re$ is the curvature scalar defined for $G_{\mu\nu}^{mn}$ with the QSTM and $p$ is the total number of dimensions of it. It is a generalized action of quantum gravity in the formulation of the QSTM space. The variation of the action under a suitable local conformal transformation with imposing the gauge $\Re \sim 4\Lambda$ for fixing the scale of the QSTM space, where $\Lambda$ is a constant, gives

$$S = \int \left(\widetilde{\Re} - 2\Lambda\right) \sqrt{-G} d^p\xi \tag{6}$$

In the special case that the QSTM space is a flat space and, for simplicity, assuming that the matter field is a scalar field, the Eq (4) can be written as

$$dl^2 = \left\langle \phi^2 \overline{g}\left(\Delta x\right)_{\mu\nu} \right\rangle dx^\mu dx^\nu \tag{7}$$

where $\left\langle \phi^2 \overline{g}\left(\Delta x\right)_{\mu\nu} \right\rangle$ is the quantum probability weighted spacetime metric, which is specified with measurement uncertainty, combined with the matter field. Also, for a flat space, the metric $G_{\mu\nu}^{mn}$ does not vary with $\xi_m$ and the action can then be expressed in terms of $\overline{g}_{\mu\nu}$ and $\phi$ with variation on spacetime as

$$S = \int \left(\phi^2 \overline{R} - 2\Lambda\phi^4 + 6\left(\partial\phi\right)^2\right) \sqrt{-\overline{g}} d^4x \tag{8}$$

Aligning the term $\left(\partial\phi\right)^2$ as the kinetic term of the $\phi$ field gives

$$S' = \int \left(\frac{1}{12}\phi^2 \overline{R} - \frac{1}{6}\Lambda\phi^4 + \frac{1}{2}\left(\partial\phi\right)^2\right) \sqrt{-\overline{g}} d^4x \tag{9}$$

If $\overline{R}$ is a constant, the spontaneous symmetry breaking (SSB) on the $\phi$ field gives the relation $\overline{R}/4\Lambda = \phi_0^2$. Defining the conformal operator $\omega$, which is associated with the change of scale of observation, in the spacetime on the metric and scalar field as $\overline{g}_{\mu\nu} \rightarrow \omega^2 \overline{g}_{\mu\nu}$ and $\phi \rightarrow \omega^{-1}\phi$. The action in Eq (9) is invariant under

such conformal transformation. The quantum gravity therefore possesses a double conformal structures. This point is very cruical as it allows the change scale in one degree of freedom and then compensate by the other to make the physical laws invariant.

## 3. Particle masses and cosmological constant

Considering a shift field $h$ around the minimum of the potential as $\phi = \phi_0$ with an energy scale $\phi_0^2 = 6m'^2$ in the SSB of the action in Eq (9), the equation becomes

$$S = \int \left( \frac{1}{2} m'^2 \overline{R} - 3\Lambda m'^4 - \frac{1}{2} (\partial h)^2 + \frac{1}{2} \overline{R} h^2 + ... \right) \sqrt{-\overline{g}} d^4x \tag{10}$$

Under the change the scale of observation by applying conformal transformation on the spacetime as $\overline{g}_{\mu\nu} \to (m'/M_p)^2 \overline{g}_{\mu\nu}$ and $\phi \to (m'/M_p)^{-1} \phi$, where the mass scale $M_p$ is the reduced Planck mass, the equation can be expressed as

$$S = \int \left( \frac{1}{2} M_p^2 \overline{R'} - 3\Lambda M_p^4 - \frac{1}{2} (\partial h')^2 + \frac{1}{2} \overline{R'} h'^2 + ... \right) \sqrt{-\overline{g'}} d^4x \tag{11}$$

The term $\overline{R'} h'^2$ acts as the mass term of the excitation field $h'$. Since $\overline{R'}$ is the conformal transformation of the term related to the vacuum energy of spacetime in empty space and since $\overline{R}\sqrt{-\overline{g}}$ should be transformed as $\overline{g}$ and therefore $\overline{R'}$ should be equal to $(m'/M_p)^2 \overline{R}$ which is the particle squared mass term. That imply the existence of a particle with mass $(m'/M_p) \overline{R}^{\frac{1}{2}}$. We can change the observer frame of reference for observing such particle due to the double conformal symmetry and this will lead to the change on the broken scale. Recalling that the scale of the QSTM space is fixed by the gauge $\Re \sim 4\Lambda$ and let the factor for the associated scale change is $\Omega^4$, the scale of $\Lambda$ is therefore changed as $\Lambda \to \Omega^4 \Lambda$. The scale change of $\Lambda$ implies that the SSB condition $\overline{R}/4\Lambda = \phi_0^2$ requires to be varied so that the mass value $(m'/M_p) \overline{R}^{\frac{1}{2}}$ in Eq (11) of the said particle will be changed also. As the mass value is determined by the ratio $\overline{R}\sqrt{-\overline{g}}/\phi^2$ and under the change of scale for Eq (11) following the conformal transformation $\omega$ on the spacetime and matter field induce the transformation as

$$\frac{\Omega^4 \overline{R} \sqrt{-\overline{g}}}{\phi^2} \to \frac{\omega^4 \Omega^4 \overline{R} \sqrt{-\overline{g}}}{\phi^2} \tag{12}$$

Therefore, for keeping the mass unchanged through the change of observer frame of reference requires that $\omega = 1/\Omega$. The structure of the QSTM space under broken symmetry can be explored by repeatedly performing the above processes of changing observer frame such that in every changed frame the mass of the particle are still equal to $m'/M_p$, although the $M_p$ varies with the transformed frame of reference. A set of scale factors can be found for the QSTM space scale

$$(\Omega)^{2n} = \left( \frac{m'}{M_p} \right)^2 \Rightarrow \Omega = \left( \frac{m'}{M_p} \right)^{\frac{1}{n}} \tag{13}$$

where $n$ is the number of the said transformation to achieve the mass factor $m'/M_p$ in a frame. Suppose $m'/M_p \sim 10^{-15}$, that is $m' = 2.435TeV$, and since the particle mass $m_i$ is equal to $\Omega_{mi}\overline{R}^{\frac{1}{2}}$, if $\overline{R}^{\frac{1}{2}} = 10TeV$, a set of mass values can be found and compared with the lepton masses data of the Particle Data Group[7] as $m_1 = 10^{-15}\overline{R}^{\frac{1}{2}} = 0.01eV \sim m_\nu$?; $m_2 = 3.16 \times 10^{-8}\overline{R}^{\frac{1}{2}} = 316.23keV \sim m_e$; $m_3 = 10^{-5}\overline{R}^{\frac{1}{2}} = 100MeV \sim m_\mu$; $m_4 = 1.778 \times 10^{-4}\overline{R}^{\frac{1}{2}} = 1.778GeV \sim m_\tau$, where $m_\nu$, $m_e$, $m_\mu$ and $m_\tau$ are respectively the mass of neutrinos, electron, muon and tau lepton. The actual neutrino masses might not necessary be degenerate as the radiative corrections is not considered in the above calculation. The $m_2$ state is of the order of the electron mass and the difference could be due to the radiative correction to the QED vacuum. The $m_3$ state is equal to the muon mass up to about 5 percent and the $m_4$ state is even equal to the tau lepton mass up to only about 0.06 percent. For the mass states with $n > 4$, for instance, the mass value of $m_5$ state is consistent with the dark matter candidate with a mass of 10 GeV as proposed by some researchers[8]. In extending the argument to half-integer value of $n$, $m_{4.5} = 4.64GeV$ and $m_{8.5} = 171.9GeV$. The values are very close to the mass values of bottom and top quarks. That means the half integer values of $n$ may correspond to the quark masses. However, due to the QCD vacuum, the calculated values for the lighter quark masses would have greater discrepancy with the actual current quark masses.

As the Eq. (9) and Eq. (11) is related by the conformal transformation of spacetime and the matter field and the SSB which is determined by the observation scale. In fact, the Eq (9) resembles the following action of the Higgs potential when $\overline{R}$ is a constant in one hand

$$S' = \int \left(\frac{1}{2}\mu^2\phi^2 - \frac{1}{4}\lambda\phi^4 + \frac{1}{2}(\partial\phi)^2\right)\sqrt{-\overline{g}}d^4x \tag{14}$$

On the other hand, it can become the action of gravitational field coupled to matter field after the local conformal transformation and SSB as discussed above. Comparing the coefficients between the Eq (9) and Eq (14) gives $\overline{R}/12 = \mu^2/2$ and $\Lambda/6 = \lambda/4$. Furthermore, by comparing Equation (11) with the gravitational action and eliminating $\Lambda$ in the above equations, we get $3\Lambda M_p^2 = \Lambda_{cc}$ and $\Lambda_{cc} = 4.5\lambda M_p^2$, where $\Lambda_{cc}$ is the cosmological constant. If then applying a conformal transformation on the QSTM space metric to change the observer frame of reference, under the same factor as the one in obtaining the fundamental particle masses with $n = 2$, and since the cosmological constant transforms as the square of the metric, that is conformal factor $\Omega^4$, with respect to the conformal factor of $\Omega^2$ on the metric, we have

$$\Omega = \left(\frac{m'}{M_p}\right)^2 \Rightarrow \Lambda_{cc} = 4.5\lambda\frac{m'^4}{M_p^2}\left(\frac{m'}{M_p}\right)^4 \tag{15}$$

By putting $\lambda = 0.258$ which is based on the 125 GeV Higgs particle mass and 246 GeV electroweak VEV value, we get $\Lambda_{cc} = 6.49 \times 10^{-66}eV^2$. Such calculated

cosmological constant value is in very good agreement with the observation value of $4.33 \times 10^{-66} eV^2$ of Planck CMB probe when connecting to the fundamental particle masses.

## 4. Discussions and conclusions

The theory of quantum gravity is formulated in the QSTM space with local conformal symmetry under the equivalence principle of quantum gravity. The QSTM space possesses a double conformal symmetry geometrical structure. Different exponent $n$ values of the associated conformal factor $\Omega = (m'/M_p)$ gives the fundamental particle mass values and the observed cosmological constant value with very good agreement. It indicates that the fundamental particle masses and the cosmological constant are related in the theory. Furthermore, the above mass formula allows the existence of some mass states that are so far not experimentally observed that might provide new opportunities for discussing the nature of such mass states.

In this work, we study the $F(R)$ gravity with $f$ -essence for the flat and homogeneous Friedman-Robertson-Walker universe. For this model, we have presented the point-like Lagrangian and the corresponding field equations. To describe the dynamics of the universe, we have investigated some cosmological solutions for $K$, $F$ and $h$ functions. It is shown that these solutions describe the late time accelerated expansion of the Universe.

*Keywords*: Cosmology, FRW metric, $F(R)$ gravity, fermion field, scale factor.

## 1. Introduction

To theoretically investigate the accelerated expansion of the Universe, many alternative gravity theories have been proposed. One of these theories is $F(R)$ gravity, where $R$ is a Ricci scalar [1–3]. In this theory, the Einstein-Hilbert action is generalized to action for $F(R)$, i.e. as arbitrary function of $R$. On the other hand, it is known that higher degrees of $R$ in the Einstein-Hilbert action can lead to an inflation effect accelerated expansion in the early stages of the Universe [4]. Each form of $F(R)$ generates a new cosmological model. So it is important that this theory be tested for compliance not only with cosmological, but also with other requirements, such as stability of solutions.

As one of the other modifications in modern cosmological theory, is additional fermions fields (Dirac or spinor fields) are considered, such candidates for inflation or dark energy have been studied in the works [5,6]. Some cosmological model with fermion field in teleparallel gravity studied in works [7,8]. And in the work [9] were study the cosmic expansion from boson and fermion fields. Generalized fermion fields were considered in [10] and known as $f$-essence. In work [11] was considered some cosmological model in $F(T)$ gravity with $f$-essence. Starobinsky model with $f$-essence was considered in work [12].

This paper organizing as following: In Sect. 2 we review $F(R)$ gravity. In Sect. 3 we consider the generalization of $F(R)$ gravity with $f$-essence and derived field equations. In Sect. 4 we apply Noether symmetry to find the form of $F(R)$ gravity, coupling function and potential. The cosmological solutions are investigated in Sect. 5.

The signature of space-time metric used is $(-,+,+,+)$ and units have been chosen so that $8\pi G = c = \hbar = k = 1$.

## 2. $F(R)$ gravity

For four dimensions space-time, the action in $F(R)$ gravity with matter is written as

$$S = \int d^4x\sqrt{-g}\,[F(R) + L_m] \tag{1}$$

were $g = det(g_{ik})$ is the determinant of the metric tensor matrix, $F(R)$ is a differentiable function of the Ricci scalar $R$, $L_m$ is the matter Lagrangian and for our case $8\pi G = 1$. Variation of the action (1) with respect to metric tensor $g_{ik}$ yields following field equations

$$F'(R)R_{ik} - \frac{1}{2}g_{ik}F(R) - \nabla^i\nabla_k F'(R) + g_{ik}\Box F'(R) = kT_{ik} \tag{2}$$

where the prime a symbol means differentiation with respect to $R$ and $R_{ik}$ is a Riemann curvature tensor and $k$ is a coupling constant in gravitational units. Also, here $\Box = \nabla^i\nabla_k$ with $\nabla_k$ is a covariant derivative. Here $T_{\mu\nu}$ is the energy-momentum tensor and write this as

$$T_{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\delta\left(\sqrt{-g}L_m\right)}{\delta g^{\mu\nu}} = g_{\mu\nu}L_m - 2\frac{\partial L_m}{\partial g^{\mu\nu}}. \tag{3}$$

## 3. $F(R)$ gravity with $f$-essence

Action for model with a generalized fermionic field that is non-minimally coupled to gravity in the framework of $F(R)$ gravity written as

$$S = \int d^4x\sqrt{-g}\,\{h(u)F(R) + 2K(Y,u)\}\,, \tag{4}$$

where $F$ is some function of the scalar Ricci $R$, $K$ is the Lagrangian density of the fermionic field, $u = \bar{\psi}\psi$ where $\psi$ and $\bar{\psi} = \psi^\dagger\gamma^0$ denote the fermion field and its adjoint, respectively, the dagger represents complex conjugation, $h(u)$ is generic function, representing the coupling with gravity and fermionic field.

The canonical kinetic term has the form

$$Y = \frac{1}{2}i\left[\bar{\psi}\Gamma^\mu D_\mu\psi - (D_\mu\bar{\psi})\Gamma^\mu\psi\right], \tag{5}$$

where $\Gamma^\mu = e^\mu_a\gamma^a$ are the generalized Dirac-Pauli matrices satisfying the Clifford algebra $\{\gamma^\mu,\gamma^\nu\} = 2g^{\mu\nu}$, where the braces denote the anti-commutation relation, the covariant derivatives $e^a_\mu$ are given by

$$D_\mu\psi = \partial_\mu\psi - \Omega_\mu\psi,\ D_\mu\bar{\psi} = \partial_\mu\bar{\psi} + \bar{\psi}\Omega_\mu.$$

Above, the fermionic connection $\Omega_\mu$ is defined by

$$\Omega_\mu = -\frac{1}{4}g_{\rho\sigma}\left[\Gamma^\rho_{\mu\delta} - e^\rho_b\partial_\mu e^b_\delta\right]\Gamma^\sigma\Gamma^\delta,$$

with $\Gamma^\rho_{\mu\delta}$ denoting the Christoffel symbols.

We will consider the flat, homogeneous and isotropic Fridmann-Robertson-Walker (FRW) metric in the folowing form:

$$ds^2 = -dt^2 + a^2(t)\left(dx^2 + dy^2 + dz^2\right), \tag{6}$$

where $a(t)$ is the scale factor of the Universe. Then for this metric we can define the following expressions

$$\sqrt{-g} = a^3,\ R = 6\left(\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2}\right),\ Y = 0.5i\left(\bar{\psi}\gamma^0\dot{\psi} - \dot{\bar{\psi}}\gamma^0\psi\right).$$

where the dot represents differentiation with respect to time $t$. For the FRW metric (6) the point-like Lagrangian we can write the following form

$$L = a^3hF - a^3hRF_R - 6a\dot{a}^2hF_R - 6a^2\dot{a}F_Rh^{'}\dot{u} - 6a^2\dot{a}\dot{R}hF_{RR} + 2a^3K. \tag{7}$$

here the spinor field depends only on time and the prime denotes the derivative with respect to the bilinear function $u$. Then for the action (4) and of the metric (6) the equations of motion are defined as

$$3\frac{\dot{a}}{a}\dot{R}F_{RR} + \left(3\frac{\dot{a}^2}{a^2} + 3\frac{\dot{a}}{a}\frac{\dot{h}}{h} - \frac{1}{2}R\right)F_R + \frac{1}{2}F = \frac{1}{h}\rho_f, \tag{8}$$

$$F_{RRR}\dot{R}^2 + \left[\ddot{R} + 2\left(\frac{\dot{a}}{a} + \frac{\dot{h}}{h}\right)\dot{R}\right]F_{RR} + \left(2\frac{\ddot{a}}{a} + \frac{\dot{a}^2}{a^2} + \frac{\ddot{h}}{h} + 2\frac{\dot{a}}{a}\frac{\dot{h}}{h} - \frac{1}{2}R\right)F_R + \frac{1}{2}F = -\frac{1}{h}p_f, \tag{9}$$

$$K_Y\dot{\psi} + \frac{1}{2}\left(3\frac{\dot{a}}{a}K_Y + \dot{K_Y}\right)\psi - iK_u\psi\gamma^0 + \\ + \frac{i}{2}\left[\left(R - 6\frac{\ddot{a}}{a} - 6\frac{\dot{a}^2}{a^2}\right)h^{'}\psi\gamma^0 - 6\frac{\dot{a}}{a}\left(h^{'}\right)_t\psi\gamma^0 + 6\frac{\dot{a}}{a}\left(h^{'}\right)_{\bar{\psi}}\dot{u}\gamma^0\right]F_R - \frac{i}{2}Fh^{'}\psi\gamma^0 = 0, \tag{10}$$

$$K_Y\dot{\bar{\psi}} + \frac{1}{2}\left(3\frac{\dot{a}}{a}K_Y + \dot{K_Y}\right)\bar{\psi} + iK_u\bar{\psi}\gamma^0 - \\ - \frac{i}{2}\left[\left(R - 6\frac{\ddot{a}}{a} - \frac{\dot{a}^2}{a^2}\right)h^{'}\bar{\psi}\gamma^0 - 6\frac{\dot{a}}{a}\left(h^{'}\right)_t\bar{\psi}\gamma^0 + 6\frac{\dot{a}}{a}\left(h^{'}\right)_{\psi}\dot{u}\gamma^0\right]F_R + \frac{i}{2}Fh^{'}\bar{\psi}\gamma^0 = 0, \tag{11}$$

where $\rho_f = V$ is the energy density and $p_f = YK_Y - K$ is the pressure of the fermion field. In the following section we will use the Noether symmetry approach for find form function $F(R)$, the coupling function $h(u)$ and function $K(Y, u)$.

## 4. The Noether symmetries approach

One can express the Lagrangian for metric (6) in terms of the components of the spinor field $\psi = (\psi_1, \psi_2, \psi_3, \psi_4)^T$ and its adjoint $\bar{\psi} = ({\psi_1}^\dagger, {\psi_2}^\dagger, -{\psi_3}^\dagger, -{\psi_4}^\dagger)$, the point-like Lagrangian (7), we can rewritten as follows

$$L = a^3 hF - a^3 hRF_R - 6a\dot{a}^2 hF_R - 6a^2 \dot{a}F_R h^{'} \dot{\psi}_i^\dagger \psi_i - 6a^2 \dot{a}F_R h^{'} \psi_i^\dagger \dot{\psi}_i - 6a^2 h\dot{a}\dot{R}F_{RR} + 2a^3 K. \tag{12}$$

The symmetry an important role in physics because it is directly associated with the consevation laws of a dynamical systen. First used the Noether symmetry approach in cosmology models and gravitational theories in the works[13,14]. This approach tells us that Lie derivative of the Lagrangian function $L$ with respect to a given vector field $\mathbf{X}$ vanishes, i.e.

$$\mathbf{X}L = 0. \tag{13}$$

A vector fied $\mathbf{X}$ for the Lagrangian (12) is given by

$$\mathbf{X} = \alpha \frac{\partial}{\partial a} + \beta \frac{\partial}{\partial R} + \dot{\alpha} \frac{\partial}{\partial \dot{a}} + \dot{\beta} \frac{\partial}{\partial \dot{R}} + \sum_{j=0}^{3} \left( \eta_j \frac{\partial}{\partial \psi_j} + \dot{\eta}_j \frac{\partial}{\partial \dot{\psi}_j} + \chi_j \frac{\partial}{\partial \psi_j^\dagger} + \dot{\chi}_j \frac{\partial}{\partial \dot{\psi}_j^\dagger} \right), \tag{14}$$

Here

$$\dot{\alpha} = \frac{\partial \alpha}{\partial a}\dot{a} + \frac{\partial \alpha}{\partial R}\dot{R} + \sum_{j=0}^{3} \left( \frac{\partial \alpha}{\partial \psi_j}\dot{\psi}_j + \frac{\partial \alpha}{\partial \psi_j^\dagger}\dot{\psi}_j^\dagger \right), \tag{15}$$

$$\dot{\beta} = \frac{\partial \beta}{\partial a}\dot{a} + \frac{\partial \beta}{\partial R}\dot{R} + \sum_{j=0}^{3} \left( \frac{\partial \beta}{\partial \psi_j}\dot{\psi}_j + \frac{\partial \beta}{\partial \psi_j^\dagger}\dot{\psi}_j^\dagger \right), \tag{16}$$

$$\dot{\eta}_j = \frac{\partial \eta_j}{\partial a}\dot{a} + \frac{\partial \eta_j}{\partial R}\dot{R} + \sum_{j=0}^{3} \left( \frac{\partial \eta_j}{\partial \psi_j}\dot{\psi}_j + \frac{\partial \eta_j}{\partial \psi_j^\dagger}\dot{\psi}_j^\dagger \right), \tag{17}$$

$$\dot{\chi}_j = \frac{\partial \chi_j}{\partial a}\dot{a} + \frac{\partial \chi_j}{\partial R}\dot{R} + \sum_{j=0}^{3} \left( \frac{\partial \chi_j}{\partial \psi_j}\dot{\psi}_j + \frac{\partial \chi_j}{\partial \psi_j^\dagger}\dot{\psi}_j^\dagger \right), \tag{18}$$

where $\alpha, \beta, \eta_j$ and $\chi_j$ are unknown functions of the variables $a, R, \psi_j$ and $\psi_j^\dagger$. Then we can written at the following system of differential equations as

$$\alpha F_R + \beta a F_{RR} + 2aF_R \frac{\partial \alpha}{\partial a} + a^2 F_{RR} \frac{\partial \beta}{\partial a} + + aF_R \frac{h_u}{h} \sum_{i=0}^{3} \left( \epsilon_i \eta_j \psi_i^\dagger + \epsilon_i \chi_j \psi_i \right) + a^2 F_R \frac{h_u}{h} \sum_{i=0}^{3} \left( \frac{\partial \eta_j}{\partial a}\psi_i^\dagger + \frac{\partial \chi_j}{\partial a}\psi_i \right) = 0, \tag{19}$$

$$-6a^2 hF_{RR}\frac{\partial \alpha}{\partial R} = 0, \ -6a^2 F_R h_u \psi_i^\dagger \frac{\partial \alpha}{\partial \psi_j} = 0, \ -6a^2 F_R h_u \psi_i \frac{\partial \alpha}{\partial \psi_j^\dagger} = 0, \tag{20}$$

$$2\alpha F_{RR}+\beta aF_{RRR}+aF_{RR}\frac{\partial\alpha}{\partial a}+2F_R\frac{\partial\alpha}{\partial R}+aF_{RR}\frac{\partial\beta}{\partial R}+aF_{RR}\frac{h_u}{h}\sum_{i=0}^{3}\Big(\epsilon_i\eta_i\psi_i^\dagger+\epsilon_i\chi_i\psi_i\Big)+$$
$$+aF_R\frac{h_u}{h}\sum_{i=0}^{3}\left(\frac{\partial\eta_j}{\partial R}\psi_i^\dagger+\frac{\partial\chi_j}{\partial R}\psi_i\right)=0, \quad (21)$$

$$\left(2\alpha F_R+\beta aF_{RR}+aF_R\frac{\partial\alpha}{\partial a}\right)h_u\psi_i^\dagger+aF_R\sum_{i=0}^{3}\left(\frac{\partial h_u}{\partial\psi_i}\eta_i+\frac{\partial h_u}{\partial\psi_i^\dagger}\chi_i\right)\psi_i^\dagger+aF_R\chi_ih_u+$$
$$+2hF_R\frac{\partial\alpha}{\partial\psi_j}+ahF_{RR}\frac{\partial\beta}{\partial\psi_j}+aF_Rh_u\sum_{i=0}^{3}\left(\frac{\partial\eta_j}{\partial\psi_j}\psi_i^\dagger+\frac{\partial\chi_j}{\partial\psi_j}\psi_i\right)=0, \quad (22)$$

$$\left(2\alpha F_R+\beta aF_{RR}+aF_R\frac{\partial\alpha}{\partial a}\right)h_u\psi_i+aF_R\sum_{i=0}^{3}\left(\eta_i\frac{\partial h_u}{\partial\psi_i}+\chi_i\frac{\partial h_u}{\partial\psi_i^\dagger}\right)\psi_i+aF_R\eta_ih_u+$$
$$+2hF_R\frac{\partial\alpha}{\partial\psi_i^\dagger}+ahF_{RR}\frac{\partial\beta}{\partial\psi_i^\dagger}+aF_Rh_u\sum_{i=0}^{3}\left(\frac{\partial\eta_j}{\partial\psi_j^\dagger}\psi_i^\dagger+\frac{\partial\chi_j}{\partial\psi_j^\dagger}\psi_i\right)=0, \quad (23)$$

$$\sum_{i=0}^{3}\left(F_Rh_u\psi_i^\dagger\frac{\partial\alpha}{\partial R}+hF_{RR}\frac{\partial\alpha}{\partial\psi_i}\right)=0,\ \sum_{i=0}^{3}\left(F_Rh_u\psi_i\frac{\partial\alpha}{\partial R}+hF_{RR}\frac{\partial\alpha}{\partial\psi_i^\dagger}\right)=0, \quad (24)$$

$$\sum_{i=0}^{3}\left(\frac{\partial\alpha}{\partial\psi_j}\psi_i+\frac{\partial\alpha}{\partial\psi_j^\dagger}\psi_i^\dagger\right)=0,\ \sum_{i=0}^{3}\left(\frac{\partial\eta_j}{\partial a}\psi_i^\dagger-\frac{\partial\chi_j}{\partial a}\psi_i\right)=0,\ \sum_{i=0}^{3}\left(\frac{\partial\eta_j}{\partial R}\psi_i^\dagger-\frac{\partial\chi_j}{\partial R}\psi_i\right)=0, \quad (25)$$

$$3\alpha\psi_j^\dagger+a\chi_j+a\sum_{i=0}^{3}\left(\frac{\partial\eta_i}{\partial\psi_j}\psi_i^\dagger-\frac{\partial\chi_i}{\partial\psi_j}\psi_i\right)=0, \quad (26)$$

$$3\alpha\psi_j+a\eta_j-a\sum_{i=0}^{3}\left(\frac{\partial\eta_i}{\partial\psi_j^\dagger}\psi_i^\dagger-\frac{\partial\chi_i}{\partial\psi_j^\dagger}\psi_i\right)=0, \quad (27)$$

$$3\alpha\left(F-RF_R\right)-\beta aRF_{RR}+a\frac{h_u}{h}\left(F-RF_R\right)\sum_{i=0}^{3}\Big(\epsilon_i\eta_i\psi_i^\dagger+\epsilon_i\chi_i\psi_i\Big)=0, \quad (28)$$

$$3\alpha\left(K-YK_Y\right)+aK_u\sum_{i=0}^{3}\Big(\epsilon_i\eta_i\psi_i^\dagger+\epsilon_i\chi_i\psi_i\Big)=0. \quad (29)$$

After some mathematical calculations, we find the following particular solutions for the generators as

$$\alpha=\alpha_0a^{\frac{1}{3}}, \quad (30)$$

$$\beta = 2\alpha_0 a^{-\frac{2}{3}} R, \tag{31}$$

$$\eta_j = -\left(\frac{3}{2}\alpha_0 a^{-\frac{2}{3}} + \epsilon_j \eta_0\right)\psi_j, \tag{32}$$

$$\chi_j = -\left(\frac{3}{2}\alpha_0 a^{-\frac{2}{3}} - \epsilon_j \eta_0\right)\psi_j^{\dagger}, \tag{33}$$

where $\alpha_0$ and $\eta_0$ are some constant of integration. And find the functions $h$, $K$ and $F$ the following form

$$h = h_0 u^{\frac{5}{3}} \tag{34}$$

$$K = K_0 (Y - \nu u) \tag{35}$$

$$F = C_1 R, \tag{36}$$

where $h_0$, $K_0$, $(\nu)$ and $C_1$ are a integrable constant.

## 5. Cosmological solutions

In previous section we reconstructed the forms of $h$, $K$ and $F$ by using Noether symmetry. Now we're ready to solve equations of motion and find exact cosmological solutions. As a first step, we need to substitute the solutions (34), (35) and (36) in the field equations (10), (11). Then, we have

$$\dot{u} + 3\frac{\dot{a}}{a}u = 0, \tag{37}$$

so that

$$u = \frac{u_0}{a^3} \tag{38}$$

where $u_0$ is an integration constant.

If we put the equations (34)-(36) in equation (8), we find

$$\dot{a} = a_0 a. \tag{39}$$

Solution of differential equation

$$a(t) = C_2 e^{a_0 t}, \tag{40}$$

where $C_2$ is a constant of integration and $a_0$ is

$$a_0 = \frac{\nu}{2h_0 u^{\frac{2}{3}_0} C_1}. \tag{41}$$

The Hubble parameter is

$$H = \frac{\dot{a}}{a} = a_0 C_2, \tag{42}$$

Also, we find the energy density and pressure in these form

$$\rho = 3H^2 = 3(a_0 C_2)^2, \tag{43}$$

$$p = -3H^2 - 2\dot{H} = -3(a_0 C_2)^2. \tag{44}$$

For our model the equation of state parameter can be define as

$$\omega = \frac{p}{\rho} = -1. \tag{45}$$

We conclude that the fermionic field behaves as dark energy.

## 6. Conclusions

In this paper we investigated $F(R)$ gravity with $f$ -essence for Friedman-Robertson-Walker space-time metric. For this model, we have derived the point-like Lagrangian and the corresponding field equations. By using Noether symmetry approach we obtained solutions for $K$, $F$ and $h$ functions. By substitude these expressions we have some cosmological solutions. It is shown that this solutions describe the late time accelerated expansion of the Universe.

## Acknowledgments

The authors would like to thank the MG15 Meeting organisers for the kind invitation to present this talk. This work was supported in part by the Ministry of Edication and Science of Kazakhstan under grant 0118RK00935 as well as by grant 0118RK00693.

In this paper, we explore $f(T)$ gravity which non-minimally coupled to fermionic fields in (2+1) spatially flat Friedmann-Robertson-Walker (FRW) dimensions. Friedmann equations, equations for fermionic fields are derived. Forms of gravitational coupling, self-interaction potential and $f(T)$ gravity are reconstructed by Noether symmetry approach for the point-like Lagrangian. Cosmological solution of model which corresponding to the late-time accelerating expansion are obtained.

*Keywords*: $f(T)$ gravity; fermion fields; Friedman-Robertson-Walker metric; Noether symmetry.

## 1. Introduction

Cosmological observations indicate that our Universe has two acceleration phases: early-time inflation and late-time cosmic acceleration so called dark energy.[1,2] To describe these phenomena has been proposed several alternative models of gravity as $f(R)$ gravity, $f(T)$ gravity, Gauss-Bonnet gravity, massive gravity, scalar-tensor gravity and so on. All these theories assume as theoretical candidates to explain all evolutons of Universe.

To modify usual curvature formulation of general relativity (GR), one starts by the replaces the Ricci scalar $R$ in the Einstein Hilbert action by arbitrary functions of it. However, alternatively one can use torsional general relativity, namely the so called teleparallel equivalent of general relativity (TEGR). In teleparallel gravity the gravitational field is described not by the curvature tensor but by the torsion, namely the torsion scalar $T$. Hence, similarly to the $f(R)$ extension of GR, one can construct the $f(T)$ extension of TEGR.[3,4]

In cosmological framework *symmetry* technique like Noether symmetry,[5] Lie symmetry,[6] Hojman symmetry[7] has revealed a useful tool in order to examine exact solutions. Also exact cosmological solutions of the Dirac (fermion) equation in curved space-time are useful tools in examine the physical behavior of particles in the particular space-time. These solutions have considerable importance in cosmology. In the 3D theory the exact solutions of the Dirac equations have been recently found for various potentials in the flat and curved space-time.

One of the first works on gravity in (2+1) dimensions appeared in the literature.[8] Recently, the three dimensional gravity have also gained considerable importance. The (2+1) dimensional gravity has similar properties as the (3+1) dimensional theories of gravity. In 3D gravity Riemann tensor is reduced to the Ricci tensor in the (2+1) dimensions. It is more simple case than the (3+1) dimensional gravity.

Therefore, the (2+1) dimensional gravity is assume as toy model for a regular Einstein theory in (3+1) dimensions. Additionally, the (2+1) Dirac equations is less complicated than the (3+1) Dirac equation. The (3+1) Dirac equation includes the Dirac matrices and the Dirac spinors with the four components. However, in (2+1) dimensions, the Dirac matrices are reduced to Pauli matrices.[9] In[10,11] has been studied Dirac equations in framework of (2+1) dimensional Einstein-Hilbert and teleparallel gravity by Noether gauge symmetry approach, respectively. The aim of this study is to find exact solutions of the Dirac equation in a (2+1) dimensional $f(T)$ contracting and expanding curved space-time via Noether symmetry.

The structure of this paper organizing as following. In Sect. 2 we find field equations for $f(T)$ gravity which non-minimally coupled to fermionic fields in (2+1) dimensions. In Sect. 3 we apply Noether symmetry approach to find the form of $f(T)$ gravity, coupling function and the self-interaction potential. The cosmological solution is considered in Sect. 4.

The signature of metric used is $(+,-,-)$ and units have been chosen so that $8\pi G = c = \hbar = k = 1$.

## 2. Action and field equations

We start by writing the action in the framework of the (2+1) dimensional $f(T)$ gravity non-minimally coupled with Dirac field,

$$\mathcal{S} = \int d^3x|e|\Bigg\{h(u)f(T) + \frac{\imath}{2}\Big[\bar{\psi}\sigma^{\mu}(x)(D_{\mu}\psi) - (D_{\mu}\bar{\psi})\sigma^{\mu}(x)\psi\Big] - V(u)\Bigg\}, \quad (1)$$

where the $h(u)$ and $V(u)$ are the coupling functions and the self-interaction potential, respectively. These scalar functions depend on only function of a bilinear Dirac field $u = \bar{\psi}\psi$. Bilinear field $u$ is a quantity, where $\bar{\psi}$ is the adjoint of the Dirac field $\psi$, which $\bar{\psi}{=}\psi^{\dagger}\sigma^3$.

The (2+1) dimensional FRW spacetime background that is spatially flat, homogeneous and isotropic universe,

$$ds^2 = dt^2 - a^2(t)[dx^2 + dy^2], \quad (2)$$

where $a(t)$ is the scale factor of the universe. Using the metric (2), the torsion scalar becomes

$$T = -2\frac{\dot{a}^2}{a^2}. \quad (3)$$

Based on metric (2) we rewrite action (1) as

$$S = \int d^3xe\Big[h(u)f(T) - \frac{\imath a^2}{2}\left(\bar{\psi}\sigma^3\dot{\psi} - \dot{\bar{\psi}}\sigma^3\psi\right) - V(u)\Big]. \quad (4)$$

By using Lagrange multiplier

$$S = \int d^3xe\Big[h(u)f(T) + \lambda\left(T + 2(\frac{\dot{a}^2}{a^2})\right) - \frac{\imath a^2}{2}\left(\bar{\psi}\sigma^3\dot{\psi} - \dot{\bar{\psi}}\sigma^3\psi\right) - V(u)\Big]. \quad (5)$$

The variation of this action with respect to $T$ gives us

$$\lambda = hf_T. \tag{6}$$

By substitute (6) to above action we have

$$S = \int d^3xe\Big[h(u)f(T) + hf_T\left(T + 2(\frac{\dot{a}^2}{a^2})\right) - \frac{\imath a^2}{2}\left(\bar{\psi}\sigma^3\dot{\psi} - \dot{\bar{\psi}}\sigma^3\psi\right) - V(u)\Big]. \tag{7}$$

Considering the background (2), it is possible to obtain the point-like Lagrangian

$$L = a^2hf_TT - a^2hf + 2\dot{a}^2hf_T - \frac{\imath a^2}{2}\left(\bar{\psi}\sigma^3\dot{\psi} - \dot{\bar{\psi}}\sigma^3\psi\right) + a^2V. \tag{8}$$

Equation of motion for fermion fields and its adjoint $\psi$ and $\bar{\psi}$, respectively as

$$\dot{\psi} + H\psi + \imath V'\sigma^3\psi + 2\imath H^2f_Th'\sigma^3\psi + \imath f_TTh'\sigma^3\psi - \imath fh'\sigma^3\psi = 0 \tag{9}$$

$$\dot{\bar{\psi}} + H\bar{\psi} - \imath V'\sigma^3\bar{\psi} - 2\imath H^2f_Th'\sigma^3\bar{\psi} - \imath f_TTh'\sigma^3\bar{\psi} + \imath fh'\sigma^3\bar{\psi} = 0. \tag{10}$$

On the other hand, from the point-like Lagrangian (8) and by considering the Dirac's equations, we find the acceleration equation for $a$ from the Euler-Lagrange equation as

$$\frac{\ddot{a}}{a} = -\frac{p_{_f}}{2hf_T} \tag{11}$$

and Hamiltonian constraint (energy condition) corresponding to Lagrangian $\mathcal{L}$ defined by

$$E_L = \frac{\partial L}{\partial\dot{a}}\dot{a} + \frac{\partial L}{\partial\dot{T}}\dot{T} + \frac{\partial L}{\partial\dot{\psi}}\dot{\psi} + \dot{\bar{\psi}}\frac{\partial L}{\partial\dot{\bar{\psi}}} - L. \tag{12}$$

By substituting (8) into (12) with the energy condition, we obtain

$$H^2 = \frac{\rho_{_f}}{2hf_T}. \tag{13}$$

In the acceleration and Friedmann equations, $\rho_{_f}$ and $p_{_f}$ are the effective energy density and pressure of the fermion (spinor) field, respectively, so that they have the following forms

$$\rho_{_f} = hf_TT - hf + V, \tag{14}$$

$$p_{_f} = 2h'\ddot{u}Hf_T - 8hf_{TT}H^2\dot{H} - (fh' - f_TTh' + 2f_Th'H^2 - V')u + hf - hf_TT - V. \tag{15}$$

In order to solve the field equations we have to determine a form for the coupling function and the potential density of the theory. To do this, in the following section we will use the Noether symmetry approach.

## 3. Noether symmetry

The existence of Noether symmetries lead to a specific form of coupling function and the self-interaction potential, which they are important for obtaining the exact solutions of the fields equations. Noether symmetry approach tells us that Lie derivative of the Lagrangian with respect to a given vector field $\mathbf{X}$ vanishes, i.e.

$$\pounds_{\mathbf{X}} L = 0. \tag{16}$$

Letting the spinor field $\psi = (\psi_1, \psi_2)^T$ and its adjoint, $\bar{\psi} = \psi^\dagger \sigma^3$, the point-like Lagrangian (14) is reduced to the following

$$L = a^2 h f_T T - a^2 h f + 2\dot{a}^2 h f_T - \frac{\imath a^2}{2}\left[\sum_{i=1}^{2}(\psi_i^\dagger \dot{\psi}_i - \dot{\psi}_i^\dagger \psi_i)\right] + a^2 V. \tag{17}$$

Hence the Noether condition (16) and requiring the coefficients of $\dot{a}^2, \dot{a}\dot{T}, \dot{a}\dot{\psi}_j, \dot{a}\dot{\psi}_j^\dagger, \dot{a}, \dot{T}, \dot{\psi}_j$ and $\dot{\psi}_j^\dagger$ to be zero, leads to the system of equations. Further, by solve this system of equations analytically, we can get solution for $\alpha$ as

$$\alpha(a) = \alpha_0 a^k \tag{18}$$

and solution for $f(T)$ as

$$f(T) = f_0 T^{\frac{3s-2}{2k+2}}. \tag{19}$$

Generators $\nu$ and $\delta$ defined as

$$\nu_j = -(\alpha_0 a^{k-1} + \epsilon_j \nu_0)\psi_j, \tag{20}$$

$$\delta_j = -(\alpha_0 a^{k-1} - \epsilon_j \nu_0)\psi_j^\dagger. \tag{21}$$

Coupling function and potential written as

$$h = h_0 u^s, \tag{22}$$

$$V = V_0 u, \tag{23}$$

where $h_0$ and $V_0$ are an integration constants.

For Noether symmetry the first integral or conserved quantity (Noether charge) defined as

$$Q = \xi^j \frac{\partial \mathcal{L}}{\partial \dot{q}^j} = 4\alpha h f_T \dot{a} = const. \tag{24}$$

Here $\xi^j$ is some symmetry generators, $q^j$ is variables.

In the next section we will search cosmological solutions of the field equations using the obtained coupling functions $h(u)$ and potential $V(u)$.

## 4. Cosmological solutions

To find the time evolution of the scale factor, $a(t)$, firstly, we need to know the form of bilinear function, $u$. Thus, we insert the coupling function $h$ given by (22) in the fermionic equations (9) and in its adjoint (10) we can get

$$\dot{u} + 2\frac{\dot{a}}{a}u = 0. \tag{25}$$

Then, the form of the bilinear function is calculated as

$$u = \frac{u_0}{a^2}, \tag{26}$$

where $u_0$ is a constant of integration.

From the above solution, the acceleration and Friedmann equations become only a function of the cosmic scale factor. Using the potential (23) in the Friedmann equation together with the equation (14), the time evolution of the scale factor can be easily calculated as

$$\dot{a} = a_0 a^{\frac{2sk-s-2k}{3s-2}}, \quad \text{where} \quad a_0 = \frac{v^{\frac{k+1}{3s-2}} u_0^{\frac{(1-s)(k+1)}{3s-2}}}{\sqrt{2}}, \quad v = \frac{V_0}{h_0 F_0}\left(\frac{k+1}{3s-k-3}\right) \tag{27}$$

The general solution of the equation is

$$a(t) = (tv - ntv + c_1)^{-\frac{1}{n-1}}, \quad \text{where} \quad n = \frac{2sk-s-2k}{3s-2} \tag{28}$$

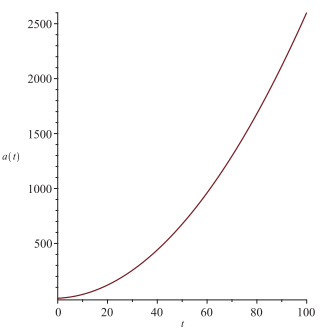

Fig. 1. Scale factor $a$ depends on cosmic time $t$ at $v = 1$, $c_1 = 1$, $n = \frac{1}{2}$.

In Fig. 1. shows the dependence of scale factor $a$ on cosmic time $t$. For our model in order to describe the accelerated expansion of the Universe, it is necessary that $0 < n < 1$.

## 5. Conclusion

In this paper, we have investigated a model with a fermionic field that is non-minimally coupled to gravity in the framework of $f(T)$ gravity in (2+1) dimensions. By using the Noether symmetry approach we determined form of the potential and coupled function as function of bilinear $u$. We also find scale factor for our model. Our result shown that fermion field may considered as source of dark energy in framework $f(T)$ gravity.

# Forecasting interacting dark energy models with future experiments

L. Santos[1,2] and W. Zhao

[1] *Center for Gravitation and Cosmology, College of Physical Science and Technology, Yangzhou University, Yangzhou 225009, China.* [2] *CAS Key Laboratory for Researches in Galaxies and Cosmology/School of Astronomy and Space Science, Department of Astronomy, University of Science and Technology of China, Chinese Academy of Sciences, Hefei, Anhui 230026, China*

[*] *E-mail: larissa@ustc.edu.cn*

We perform a forecast analysis on the ability of future baryonic acoustic oscillation (BAO) and cosmic microwave background (CMB) experiments in constraining 3 specific interacting dark energy models using the well known Fisher-matrix formalism. In addition to a future ground-based CMB experiment, we consider a Euclid-like experiment, which is supposed to put tight constraints on the dark sector parameters. In the interacting dark energy scenario, a coupling between dark matter and dark energy modifies the conservation equations such that the fluid equations for both constituents are conserved as the total energy density of the dark sector. In this context, we consider three phenomenological models which have been deeply investigated in literature in the past years. We find that the combination of both CMB and BAO can break degeneracies among the parameters for every studied model. We found powerful constraints on, for example, the coupling constant when comparing it with present limits for two of the models, and their future statistical 3-$\sigma$ bounds could potentially exclude the null interaction for the combination of probes that is considered.

*Keywords*: Dark energy, dark matter, BAO, CMB.

## 1. Introduction

Considering the standard cosmological model, the dark energy assumes its simplest form as the cosmological constant $\Lambda$, leading to the so-called $\Lambda$CDM model. Despite of successfully explaining the observations [1], the the standard model faces some difficulties, especially in the dark sector. The dark matter particles are far from detection, and its physics is still unknown. The cosmological constant theoretical predictions estimate the value of a vacuum energy density orders of magnitude larger than its actual observed value. In addition, the present values of the dark matter and dark energy densities are at the same other of magnitude even though they do not share the same cosmological evolutionary behavior, problem known as cosmic coincidence [2]. To overcome some of these problems, models where dark matter and dark energy interact started to be considered, becoming very useful to alleviate this coincidence problem. An interacting dark matter and dark energy scenario would affect the overall evolution of the universe and its expansion history, thus observationally distinguishable from the $\Lambda$CDM model. The interaction can then be constrained by the data, becoming a testable theory for the universe.The present observations, however, are not able to confidently distinguish between these alternative interacting dark energy models and the $\Lambda$CDM. Our goal is to test the ability of future experiments to constraint the interacting dark energy models described in the next section.

## 2. The interacting dark energy models

In the standard cosmological model the energy density of radiation, baryons, cold dark matter and dark energy is conserved separately, for each component. Conversely, in an interacting dark energy model, the fluid equations for the dark energy and dark matter are not conserved individually, but together as the total energy density of the dark sector such that $\dot{\rho}_{DM} + 3H\rho_{DM} = +Q$ and $\dot{\rho}_{DE} + 3H(1 + \omega_{DE})\rho_{DE} = -Q$, where $H$ is the Hubble parameter, $\rho_{DM}$ and $\rho_{DE}$ are the energy densities for dark matter and dark energy, respectively, and $\omega_{DE} = P_{DE}/\rho_{DE}$ is the dark energy EoS. $Q$ represents the interaction kernel that can be written phenomenologically as $Q = 3H(\xi_1\rho_{DM} + \xi_2\rho_{DE})$, being the coupling coefficients ($\xi_1$ and $\xi_2$) constants to be determined by observations [4, 5]. The energy flow from dark energy to dark matter is defined by $Q > 0$, and the opposite for $Q < 0$. Considering the stability of the model (see, for instance, [6]), two choices are made: The first, $\xi_1 = 0$ and $\xi_2 \neq 0$, satisfying a constant dark energy EoS within the range $-1 < \omega_{DE} < 1$ (described as model 1), or $\omega_{DE} < -1$ (model 2). The second, $\xi_2 = 0$ and $\xi_1 \neq 0$ for $\omega_{DE} < -1$ (model 3). For all three models, the other components follow the standard conservation equations. For a review on the topic refer to [7].

## 3. The fisher formalism

The BAO is an important observable currently used to constrain the cosmological parameters, more efficiently in combination with other probes, such as the CMB. The information stored in the BAO can precisely determine the Hubble parameter $H(z)$ and the angular diameter distance $Da(z)$ as a function of the redshift, which subsequently enables the calculation of the dark energy parameters constraints (for details on this methodology see [8]). The energy densities for dark matter and dark energy for the models considered here can be found in [9]. For the matter power spectrum obtained from galaxy surveys the Fisher matrix is given by [11][a]

$$F_{ij} = \int_{-1}^{1}\int_{k_{\min}}^{k_{\max}} \frac{\partial \ln P(k,\mu)}{\partial p_i}\frac{\partial \ln P(k,\mu)}{\partial p_j} V_{\text{eff}}(k,\mu)\frac{2\pi k^2 dk d\mu}{2(2\pi)^3}, \tag{1}$$

being $V_{\text{eff}}$ the effective volume of the survey. We present the expected cosmological implications of the BAO measurements for an Euclid-like survey (for specifications on Euclid, see, for example, [12]).

Furthermore, we use the CMB information as a second probe to forecast the parameters of the interacting dark energy models described here. We do not consider

[a]The matter power spectrum was generated using a modified version of CAMB software package [10].

the primordial $B-$mode contribution. We then construct the Fisher matrix for the CMB temperature anisotropy and polarization [13].

$$F_{ij} = \sum_l \sum_{XY} \frac{\partial C_l^X}{\partial p_i} (Cov_l^{-1})_{XY} \frac{\partial C_l^Y}{\partial p_j}, \tag{2}$$

being $C_l^X$ the power in the $l$-th multipole, $X$ stands for $TT$ (temperature), $EE$ (E-mode polarization), $TE$ (temperature and E-mode polarization cross-correlation) and $(Cov_l^{-1})_{XY}$ the covariance matrix. For the definition and the elements of the covariance matrix refer to [13]. We consider the Advanced Atacama Cosmology telescope (ACTadv) instrumental setup as described in [14]. The ACTadv is supposed to obtain precise measurements of the CMB small-scale polarization, which can lead on probing alternative cosmological models.

## 4. Results and conclusions

We combine the Fisher matrices for the BAO and CMB future measurements from Euclid and ACTadv surveys, respectively. The marginalized error for the dark energy EoS in model 1 improves drastically for the combined analysis, being $\sigma(\omega) = 0.026$ for Euclid, $\sigma(\omega) = 0.028$ for the ACTadv and $\sigma(\omega) = 0.0044$ for their combination: an improvement by a factor of $\sim 6$ when compared with each individual probe. The constraint on the dark matter density improves by a factor of $\sim 3$ for the combined analysis ($\sigma(h^2\Omega_c) = 0.00053$), compared with Euclid alone ($\sigma(h^2\Omega_c) = 0.0017$). A similar improvement occurs for the coupling constant, where we find $\sigma(\xi_2) = 0.0037$ for Euclid alone and $\sigma(\xi_2) = 0.0019$ for ACTadv + Euclid. Such stringent constraint would exclude the null interaction correspondent to the $\Lambda$CDM model with high confidence. Present constraints on $h^2\Omega_c$, $\omega$ and $\xi_2$ for a combination of probes (Planck+BAO+SNIa+H0) show $h^2\Omega_c = 0.0792^{+0.0348}_{-0.0166}$, $\omega = -0.9191^{+0.0222}_{-0.0839}$ and $\xi_2 = -0.1107^{+0.085}_{-0.0506}$ [3]. The constraints on model 1 from the present datasets are affected by the degeneracies among the parameters, more evident between $h^2\Omega_c$ and $\xi_2$. It is clear by our analysis that Euclid information can help break the degeneracies between these parameters, therefore providing tight constraints on $h^2\Omega_c$, $\omega$ and $\xi_2$. As an example, we show the Fisher contours on the dark sector parameters for model 1 in Figure 1.

The same occurs for model 2. The combined result leads to stringent constraints on $\sigma(h^2\Omega_c)$, $\sigma(\omega)$ and $\sigma(\xi_2)$, the latter being $\xi_2 = 0.03798 \pm 0.00310$ at $1\sigma$. A zero positive interaction is excluded by [3] with $\xi_2 = 0.02047^{+0.00565}_{-0.00667}$ at $1\sigma$. The future combination of ACTadv and Euclide-like surveys would be able to improve this constraint by a factor of $\sim 2$.

As for model 3, degeneracies between the dark sector parameters do not play such an important role compared with models 1 and 2. However, the significance on the $\xi_1$ constraint is low at the current observational stage, being $\xi_1 = 0.0007127^{+0.000256}_{-0.000633}$ at $1\sigma$, considering a combination of probes: Planck, SNIa, BAO, $H_0$ [3]. We found $\xi_2 = 0.0007273 \pm 0.00034$ (ACTadv + Euclid), which does not improve the actual

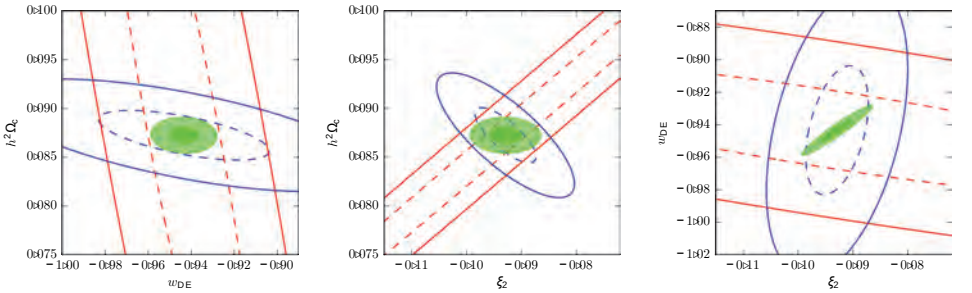

Fig. 1. Fisher forecast contours for model 1 with CMB and BAO information using AdvACT (red curves) and Euclid (blue curves) experimental setups, respectively. The dashed curves represent 68% C. L. and the solid curves represent 99.9% C. L. The combined contours are shown by the green filled ellipses. Similarly, the darker ellipses represent 68% C. L. and the fainter ones represent 99.9% C. L.

best constraint. For this model, a combination of other probes is still needed in order to tighten the present limits.

It is well known the advantages of combining different observational probes in constraining cosmological parameters, and its implication to interacting dark energy models has been widely addressed. In our context, for models 1 and 2, stringent constraints were found in the dark sector parameters for the combined probes, especially for the coupling constant, being the $1-\sigma$ bound of $\xi_2 = -0.0929 \pm 0.0019$ and $\xi_2 = 0.03798 \pm 0.00310$, respectively. Future CMB and BAO experiments combined, such as presented here, would be able to exclude the null interaction with more than $3\sigma$ C.L. (for the full reference on these results refer to [16]).The present dataset and the future CMB information alone are affected by degeneracies that can be broken by the addition of Euclid BAO measurements, thus tighten the constraints on the dark sector cosmological parameters, and enabling a deeper discussion on these interacting dark energy scenarios. Conversely, the constraint on the coupling constant for model 3 is not improved by the combination of future CMB and BAO information compared with its constraint derived by present dataset. Extra information is still necessary for probing this model.

# Cosmographic analysis as framework to evaluate cosmological models

Hugo Solís-Sánchez*[12], Manuel Ortega-Rodríguez[1], Luis A. Álvarez[1], Esteban Dodero[1], E. Gabriela Barrantes[2], and José M. Gamboa[1]

[1] *Escuela de Física and* [2] *Centro de Investigaciones en Tecnologías de la Información y Comunicación, Universidad de Costa Rica, San José, 11501-2060, Costa Rica*

* *E-mail: hugo.solis@ucr.ac.cr*

*www.ucr.ac.cr*

By using a cosmographic analysis of the redshift data of type Ia supernovae, we are able to get the expansion of the scale factor, obtaining the current values of the Hubble, deceleration, jerk and snap parameters. Our data is then used to compare the fitness of various proposed alternative cosmological models. Since our method assumes only the validity of general relativity at the cosmic scale, along with the isotropy and homogeneity of the universe, they are very useful for comparison between different cosmological models, including the fitness of ΛCDM model. Our method is based on the order expansion of the scale factor present in the FRW metric and using a Monte Carlo integration to find the best fit order parameters of the scale factor to reproduce the observed data, we make use of parallel paradigm to improve the computational time behind the model. We find the known result of an accelerated expansion of the universe. With access to better measurements of type Ia supernovae redshifts and more data, the cosmographic results will be significantly improved.

*Keywords*: Cosmography; Type Ia Supernovae; ΛCDM; deceleration parameter; Monte Carlo Integration.

## 1. Introduction

Although there is almost complete agreement on the accelerated expansion of the universe[1], ΛCDM being the most favored cosmological model by the current data, there is no consensus to the current specific value of this decelerated expansion and to whether or not this model is still prevalent in the future[2]. The decelerated expansion $q_0$ is the parameter indicating the current rate of acceleration of the expansion of the universe. Therefore, it is the first indicator of the fitness of any cosmological model, so a precise determination of its value is necessary for the diagnostic of any cosmological model. There recently have been plenty of research but there is no consensus for its current value[3].

We obtain the expansion terms of the scale factor in the FRW line element to test different cosmological models. We compare the expected value of the apparent magnitude in terms of the measured redshift to each supernova with the measured value of its apparent magnitude. This comparison is made by means of a likelihood ratio test to find the current values of the coefficients in the expansion of the factor scale that best fit the measured data.

Our interest is in comparing the results from our analysis with proposed cosmological models (as in ref. 4 and ref. 5). Even though cosmographic analysis has been previously studied (as in ref. 6 and ref. 7), we are performing the analysis using parallel computing what permits to make the expansion to higher orders than the

usuals. We found that some results have significant changes when calculations are improved and how the cosmography works as a framework to assess cosmological models.

## 2. Friedmann-Robertson-Walker and cosmography

### 2.1. *Friedmann-Robertson-Walker*

The line element for all the homogeneous and isotropic models of the universe is the Friedmann-Robertson-Walker metric, shown in 1. Where $a(t)$ is the expansion factor of the universe, which gives us the rate at which the universe is expanding. This value depends on the content and matter-energy densities for the universe and it is theoretically found using the Friedmann equation, which is obtained from Einstein's field equations. The constant $k$ is only determined by its sign, if $k < 0$ the universe is said to be open and the spatial hypersurfaces have negative constant curvature, if $k > 0$ the universe is said to be closed and spatial hypersurfaces have positive constant curvature, for $k = 0$ the universe is said to be flat with the spatial hypersurfaces being Euclidean with curved spacetimes.

$$ds^2 = c^2dt^2 - a(t)^2\left[\frac{dr^2}{(1-kr^2)} + r^2(d\theta^2 + \sin^2\theta d\phi^2)\right] \tag{1}$$

### 2.2. *Cosmographic analysis*

We proceed by using a cosmographic approach to determine the value of cosmological parameters. We seek to make a comparison of the measured values of the apparent magnitude ($m$) of the supernovae with the expected values given its measured redshift ($z$). The apparent magnitude is given by (2) in terms of the luminosity distance ($d_L$) and the absolute magnitude ($M$) which is known for supernovae to constant. Since the luminosity distance (3) is given in terms of the physical distance ($r_0$) between the source signal and the observer and the measured $z$ we need to express $r_0$ in terms of the measured redshift. We do this by using the null geodesic in FRW and the cosmographic redshift. By the null geodesic we have:

$$m = 5\log\frac{d_L}{10} + M \tag{2}$$

$$d_L = (1+z)r_0a_0 \tag{3}$$

$$-c\int_{t_*}^{t_0}\frac{dt}{R(t)} = f(r_0) = \int_{r_0}^{0}\frac{dr}{\sqrt{(1-kr^2)}} \tag{4}$$

$$\text{Where: } f(r_0) = \begin{cases} -\sin^{-1}(r_0) & (k=+1) \\ -r_0 & (k=0) \\ -\sinh^{-1}(r_0) & (k=-1) \end{cases}$$

We expand the scale factor in FRW:

$$R(t) = R(t_0)\left[1 + H_0(t-t_0) - \frac{1}{2!}q_0 H_0^2 (t-t_0)^2 + \frac{1}{3!}j_0 H_0^3 (t-t_0)^3 + \frac{1}{4!}s_0 H_0^4 (t-t_0)^4 + \cdots\right]$$

and using the cosmological redshift relation with the scale factor expansion[8], we obtain the flight time from the source to us ($T \equiv t_0 - t_*$ where $t_*$ is the time at which the signal was emitted) as a function of the measured redshift.

$$z + 1 = \frac{R(t_0)}{R(t_*)}$$

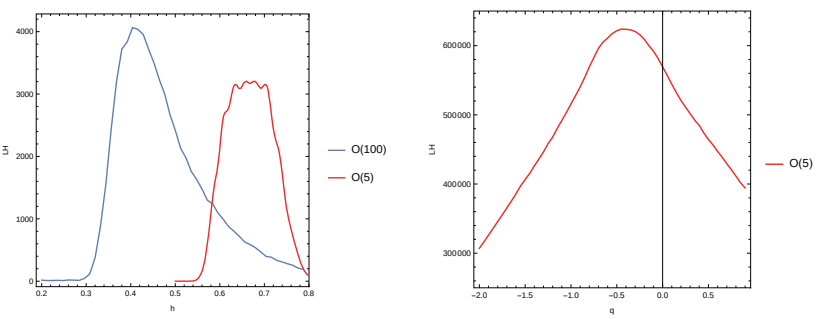
$$\frac{R(t_0)}{R(t_*)} = 1 + H_0 T + \frac{2+q_0}{2} H_0^2 T^2 + \frac{6(1+q_0)+j_0}{6} H_0^3 T^3 + \frac{24 - s_0 + 8j_0 + 36q_0 + 6q_0^2}{24} H_0^4 T^4 + \cdots$$

Numerically inverting:

$$T\left(\frac{z}{H_0}\right)^{-1} = 1 - \left[1 + \frac{q_0}{2}\right] z + \left[1 + q_0 + \frac{q_0^2}{2} - \frac{j_0}{6}\right] z^2$$

$$- \left[1 + \frac{3}{2}q_0(1+q_0) + \frac{5}{8}q_0^3 - \frac{1}{2}j_0 - \frac{5}{12}q_0 j_0 - \frac{s_0}{24}\right] z^3 + \ldots$$

We solve the left side integral in eq. 4 with the expansion of the scale factor and substitute $T$ in terms of $z$ as found above. Therefore we are able to use the luminosity distance in terms of the redshift, to which we then employ a marginal likelihood ratio analysis in order to find the best fit values for the cosmological parameters. We are then able to use this data (from ref. 6) to compare with any cosmological model.



(a) (b)

Fig. 1. Here are the results of our cosmographic analysis. (a) The Hubble parameter (b) The deceleration parameter.

In figure 1 (a), we are showing the results for the Hubble parameter for two orders of expansion. It is visible how when the order is higher the average is lower than the usual value, for 5 order we found $\langle H\rangle = 100\,\langle h_0\rangle = 67$ and for 100 order is $\langle H\rangle = 47$. The figure 1 (b) shows the deceleration parameter which in agreement with recent results is negative[3] $\langle q_0\rangle = -0.48$.

## 3. Comparison of different models

We compare our obtained factor scale with two different theoretically proposed cosmological models. The first one[4] proposes the gravitational constant ($G$) and the cosmological constant ($\Lambda$) are not constants but instead functions of time. With the standard Friedmann equations derivation and proposing they relate to each other by $G\rho = \frac{\eta\Lambda}{8\pi}$ with $\rho$ the density of the perfect fluid and $\eta$ a constant, there are two possible scale factors and deceleration parameters:

- Case A: $n \neq 0$

$$a(t) = (nlt + C_1)^{\frac{1}{n}} \tag{5}$$

$$q = n - 1 \tag{6}$$

- Case B: $n = 0$

$$a(t) = C_2 e^{lt} \tag{7}$$

$$q = -1 \tag{8}$$

The second one[5] proposes measuring the average expansion rate in a universe in which a set of spherically symmetric sub-regions expand in an accelerated way, *Average Expansion Rate Approximation (AvERA)*. It has the appeal that it conclusively resolves the tension between the measured values of the *Hubble constant* but the great drawback is that it is difficult to match with the homogeneity observed in the CMB.

We plot them in figure 2 with our obtained results to see how they compare to each other. We see that although one has several parameters to adjust to get greater similarity with our results can be more closely approximated by Case A of the given model, Case B is an exponential, so it starts at the value one and never approximates the rest of the curves.

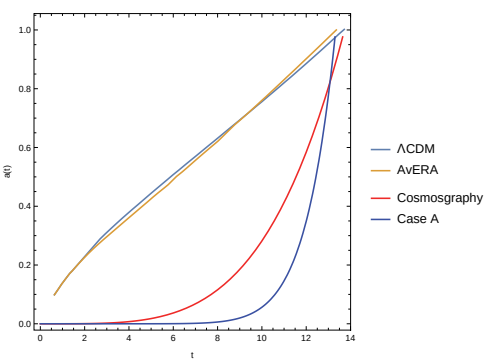


Fig. 2. Comparison of different models with the cosmographic result.

Scalar fields which are favorite among the possible candidates for the dark energy usually have degenerate minima at $\pm\phi_{min}$. In the presented work, we discuss a two Higgs doublet model with the non-degenerate vacuum named inert uplifted double well type two-Higgs doublet model (UDW-2HDM) for the dark energy. It is shown that when the both Higgs doublets lie in their respective true minima then one Higgs doublet can cause the current accelerated expansion of the Universe.

*Keywords*: Dark energy; Uplifted double well two Higgs doublet model.

## 1. Introduction

Modeling the accelerated expansion of the Universe which is also in agreement with at least the standard model of the Particle Physics is a very hot question. We in this context earlier showed that the Higgs field(s) of the inert doublet model (IDM) and the general two Higgs doublet model (2HDM) can provide the current accelerated expansion of the Universe. In this short work we show that a new kind of two Higgs doublet model where both the Higgs vacuums are non-degenerate can also be used for dark energy modeling. We call this model to be uplifted double well two Higgs doublet model (UDW-2HDM). We in this short review give the very brief review and the results with necessary model information. The complete full length paper will be submitted to an ISI indexed journal later.

## 2. Uplifted double well two-Higgs double model

The Lagrangian which describes any model in Particle Physics is

$$\mathcal{L} = \mathcal{L}_{gf}^{SM} + \mathcal{L}_Y + T_H - V_H \ , \tag{1}$$

where $\mathcal{L}_{gf}^{SM}$ is the $SU_C(3)\otimes SU_L(2)\otimes U_Y(1)$ SM interaction of the fermions and gauge bosons (force carriers), $\mathcal{L}_Y$ is the Yukawa interaction of fermions with the Higgs field(s), $T_H$ is the kinetic term of the Higgs field and $V_H$ is the potential of the Higgs field. The last two terms form the Higgs Lagrangian $\mathcal{L}_{Higgs}$. In UDW-2HDM

$$\begin{aligned} T_H = (D_{1\mu}\phi_1)^\dagger (D_1{}^\mu \phi_1) + (D_{2\mu}\phi_2)^\dagger (D_2{}^\mu \phi_2) \\ + \left[\chi (D_{1\mu}\phi_1)^\dagger (D_2{}^\mu \phi_2) + \chi^* (D_{2\mu}\phi_2)^\dagger (D_1{}^\mu \phi_1)\right] , \end{aligned} \tag{2}$$

and

$$
\begin{aligned}
V_H = {} & \rho_1 \exp(\Lambda_1 m_{11}^2 (\phi_1 - \phi_{1_0})^\dagger (\phi_1 - \phi_{1_0})) \\
& + \rho_3 \exp\left(\frac{1}{2}\Lambda_3 \lambda_1 ((\phi_1 - \phi_{1_0})^\dagger (\phi_1 - \phi_{1_0}))^2\right) \\
& + \rho_2 \exp(\Lambda_2 m_{22}^2 (\phi_2 - \phi_{2_0})^\dagger (\phi_2 - \phi_{2_0})) \\
& + \rho_4 \exp\left(\frac{1}{2}\Lambda_4 \lambda_2 ((\phi_2 - \phi_{2_0})^\dagger (\phi_2 - \phi_{2_0}))^2\right) \\
& + \lambda_3 (\phi_1^\dagger \phi_1)(\phi_2^\dagger \phi_2) + \lambda_4 (\phi_1^\dagger \phi_2)(\phi_2^\dagger \phi_1) + \left[m_{12}^2 (\phi_1^\dagger \phi_2) + \frac{\lambda_5}{2}(\phi_1^\dagger \phi_2)^2\right. \\
& \left. + \lambda_6 (\phi_1^\dagger \phi_1)(\phi_1^\dagger \phi_2) + \lambda_7 (\phi_2^\dagger \phi_2)(\phi_1^\dagger \phi_2) + \text{h.c.}\right], \qquad (3)
\end{aligned}
$$

where

$$
D_{p_\mu} = \partial_\mu + i\frac{g_p}{2}\sigma_i W^i{}_\mu + i\frac{g_p'}{2} B_\mu, \qquad p = 1 \text{ or } 2 \,,
$$

$$
\phi_i = \begin{bmatrix} \phi_i^+ \\ \eta_i + i\chi_i + \nu_i \end{bmatrix} \,, \qquad \phi_{i_0} = \begin{bmatrix} 0 \\ \tau_i \end{bmatrix} \qquad \text{and} \qquad \phi_i^\dagger = \begin{bmatrix} \phi_i^- & \eta_i - i\chi_i + \nu_i \end{bmatrix} .
$$

The Higgs fields $\phi_i^+$, $\phi_i^-$, $\eta_i$ and $\chi_i$ are hermitian ($\phi_i^\pm$ are charged whereas the others are neutral), $\nu_i$ is the VeV of the doublet $\phi_i$, $\phi_{i_0}$ in the potential is the true minimum of the field $\phi_i$. The shape of the UDW-2HDM Higgs potential is shown in fig. 1.

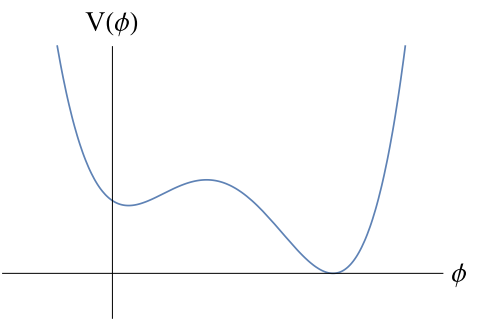

Fig. 1. The uplifted double well potential

The $Z_2$ symmetry ($\phi \to -\phi$) is very important in determining the stability of the Higgs fields. There are two types of $Z_2$ symmetry breaking: 1) soft; and 2) hard. The term containing $m_{12}^2$ describes the soft $Z_2$ symmetry breaking, whereas the terms containing $\lambda_6$ and $\lambda_7$ describe the hard $Z_2$ symmetry breaking. In the absence of these terms along with no cross kinetic term i.e. $\chi = 0$, the UDW-2HDM's Higgs Lagrangian has a perfect $Z_2$ symmetry.

The extrema of the potential are found by taking

$$\frac{\partial V_H}{\partial \phi_1}\Big|_{\phi_1=\langle\phi_1\rangle} = \frac{\partial V_H}{\partial \phi_1^\dagger}\Big|_{\phi_1^\dagger=\langle\phi_1^\dagger\rangle} = 0 \quad \text{and} \quad \frac{\partial V_H}{\partial \phi_2}\Big|_{\phi_2=\langle\phi_2\rangle} = \frac{\partial V_H}{\partial \phi_2^\dagger}\Big|_{\phi_2^\dagger=\langle\phi_2^\dagger\rangle} = 0. \quad (4)$$

The most general solution of the conditions (4) is

$$\langle\phi_1\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}0\\ \nu_1\end{pmatrix} \qquad \text{and} \qquad \langle\phi_2\rangle = \frac{1}{\sqrt{2}}\begin{pmatrix}u\\ \nu_2\end{pmatrix}.$$

We must remember that now $\nu^2 = \nu_1^2 + \left|\nu_2^2\right| + u^2$, where $\nu = 1/\sqrt[4]{2{G_F}^2} \approx 246$ GeV is the VeV of the Higgs field in the SM. For a nonzero $u$, the "charged" type dark energy is obtained, which obviously is not the case. For this reason, choose $u = 0$. Solving eq. (4) for the potential truncated to the forth power of field gives

$$\begin{aligned}&\rho_1\Lambda_1 m_{11}^2(\nu_1-\tau_1) + \rho_1\Lambda_1^2 m_{11}^4(\nu_1-\tau_1)^3 + \rho_3\Lambda_3\lambda_1\nu_1(\nu_1^2-\tau_1^2) + {m_{12}^2}^*\nu_2\\ &+(\lambda_3+\lambda_4+\lambda_5^*)\nu_1\nu_2^2 + (\lambda_6+2\lambda_6^*)\nu_1^2\nu_2 + \lambda_7^*\nu_2^3 = 0,\end{aligned} \quad (5)$$

$$\begin{aligned}&\rho_2\Lambda_2 m_{22}^2(\nu_2-\tau_2) + \rho_2\Lambda_2^2 m_{22}^4(\nu_2-\tau_2)^3 + \rho_4\Lambda_4\lambda_2\nu_2(\nu_2^2-\tau_2^2) + m_{12}^2\nu_1\\ &+(\lambda_3+\lambda_4+\lambda_5)\nu_1^2\nu_2 + \lambda_6\nu_1^3 + (2\lambda_7+\lambda_7^*)\nu_1\nu_2^2 = 0.\end{aligned} \quad (6)$$

Imposing the $Z_2$ symmetry ($\chi = 0, \quad m_{12}^2 = 0, \quad \lambda_6 = 0, \quad \lambda_7 = 0$), which makes the lightest Higgs field is stable, on eqs. (5, 6) with $\lambda_3+\lambda_4+\lambda_5 = 0$ [1a] we get four solutions for $\nu_1$ and $\nu_2$, which are

$$\nu_1 = \tau_1\ , \qquad \nu_2 = \tau_2\ ; \quad (7)$$

$$\nu_1 = \tau_1\ , \qquad \nu_2 = \frac{2m_{22}^4\Lambda_2^2\rho_2\tau_2 - \lambda_2\Lambda_4\rho_4\tau_2 - \sqrt{\Xi_2}}{2\left(m_{22}^4\Lambda_2^2\rho_2 + \lambda_2\Lambda_4\rho_4\right)}\ ; \quad (8)$$

$$\nu_1 = \frac{2m_{11}^4\Lambda_1^2\rho_1\tau_1 - \lambda_1\Lambda_3\rho_3\tau_1 - \sqrt{\Xi_1}}{2\left(m_{11}^4\Lambda_1^2\rho_1 + \lambda_1\Lambda_3\rho_3\right)}\ , \qquad \nu_2 = \tau_2\ ; \quad (9)$$

$$\nu_1 = \frac{2m_{11}^4\Lambda_1^2\rho_1\tau_1 - \lambda_1\Lambda_3\rho_3\tau_1 - \sqrt{\Xi_1}}{2\left(m_{11}^4\Lambda_1^2\rho_1 + \lambda_1\Lambda_3\rho_3\right)}\ , \qquad \nu_2 = \frac{2m_{22}^4\Lambda_2^2\rho_2\tau_2 - \lambda_2\Lambda_4\rho_4\tau_2 - \sqrt{\Xi_2}}{2\left(m_{22}^4\Lambda_2^2\rho_2 + \lambda_2\Lambda_4\rho_4\right)}\ ; \quad (10)$$

where

$$\Xi_1 = -4m_{11}^6\Lambda_1^3\rho_1^2 - 4m_{11}^2\lambda_1\Lambda_1\Lambda_3\rho_1\rho_3 - 8m_{11}^4\lambda_1\Lambda_1^2\Lambda_3\rho_1\rho_3\tau_1^2 + \lambda_1^2\Lambda_3^2\rho_3^2\tau_1^2,$$

$$\Xi_2 = -4m_{22}^6\Lambda_2^3\rho_2^2 - 4m_{22}^2\lambda_2\Lambda_2\Lambda_4\rho_2\rho_4 - 8m_{22}^4\lambda_2\Lambda_2^2\Lambda_4\rho_2\rho_4\tau_2^2 + \lambda_2^2\Lambda_4^2\rho_4^2\tau_2^2.$$

If we choose $\tau_2 = 0$ then the fields $\phi_1^\pm$ and $\chi_1$ become Goldstone bosons and the other fields become physical. With $\tau_2 = 0$, the Yukawa interactions are described by the interaction of $\phi_1$ with fermions (as $\phi_2$ does not couple to fermions but appears in loops). This scenario makes the lightest field of $\phi_2$ stable.

[a] With $\lambda_3+\lambda_4+\lambda_5 \neq 0$ the solution to the VeV contain complex part.

## 3. Higgs fields as dark energy

For the field $\phi_2$ to be the dark energy field, we need to solve the Euler-Lagrange equations in FRW flat, ($\kappa$), Universe, ($\sqrt{-g} = a(t)^3$), which for the fields $\phi_2^{\pm}$, $\eta_2$ and $\chi_2$ are

$$\ddot{\eta}_2 + 3\frac{\dot{a}}{a}\dot{\eta}_2 + \frac{1}{2}\eta_2\left(\nu^2\left(\lambda_3+\lambda_4+\lambda_5\right) + 2m_{22}^2\Lambda_2\rho_2 e^{m_{22}^2\Lambda_2\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)/2}\right.$$
$$\left. + \lambda_2\Lambda_4\rho_4 e^{\lambda_2\Lambda_4\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)^2/8}\left({\chi_2}^2+2{\phi_2^c}^2\right)\right)$$
$$+ \frac{1}{2}\lambda_2\Lambda_4\rho_4 e^{\lambda_2\Lambda_4\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)^2/8}{\eta_2}^3 = 0, \tag{11}$$

$$\ddot{\chi}_2 + 3\frac{\dot{a}}{a}\dot{\chi}_2 + \frac{1}{2}\chi_2\left(\nu^2\left(\lambda_3+\lambda_4-\lambda_5\right) + 2m_{22}^2\Lambda_2\rho_2 e^{m_{22}^2\Lambda_2\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)/2}\right.$$
$$\left. + \lambda_2\Lambda_4\rho_4 e^{\lambda_2\Lambda_4\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)^2/8}\left({\eta_2}^2+2{\phi_2^c}^2\right)\right)$$
$$+ \frac{1}{2}\lambda_2\Lambda_4\rho_4 e^{\lambda_2\Lambda_4\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)^2/8}{\chi_2}^3 = 0, \tag{12}$$

$$\ddot{\phi}_2^c + 3\frac{\dot{a}}{a}\dot{\phi}_2^c + \phi_2^c\left(\nu^2\lambda_3 + 2m_{22}^2\Lambda_2\rho_2 e^{m_{22}^2\Lambda_2\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)/2}\right.$$
$$\left. + \lambda_2\Lambda_4\rho_4 e^{\lambda_2\Lambda_4\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)^2/8}\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)\right) = 0, \tag{13}$$

where $c$ is $+$ or $-$. The energy density and pressure after expansion of UDW-2HDM Higgs Lagrangian for physical fields become

$$\rho_{\rm DE}/{\rm P}_{\rm DE} = \frac{1}{2}{\dot{\chi}_2}^2 + \frac{1}{2}{\dot{\eta}_2}^2 + \frac{1}{2}\dot{\phi}_2^{c2} \pm \left(\rho_1+\rho_3 + \frac{1}{2}\nu^2\lambda_3\phi_2^{c2} + \frac{1}{4}\nu^2\left(\lambda_3+\lambda_4+\lambda_5\right){\eta_2}^2\right.$$
$$+ \frac{1}{4}\nu^2\left(\lambda_3+\lambda_4-\lambda_5\right){\chi_2}^2 + \rho_2 e^{m_{22}^2\Lambda_2\left({\chi_2}^2+{\eta_2}^2+2{\phi_2^c}^2\right)/2}$$
$$\left. + \rho_4 e^{\lambda_2\Lambda_4\left({\chi_2}^4+2{\chi_2}^2{\eta_2}^2+{\eta_2}^4+4{\chi_2}^2\phi_2^{c2}+4{\eta_2}^2\phi_2^{c2}+4\phi_2^{c4}\right)/8}\right). \tag{14}$$

The initial conditions used are $\eta_{2ini} = M_P$, $\chi_{2ini} = M_P$, $\phi_{2ini}^c = 0$, $\dot{\chi}_{2ini} = 0$, $\dot{\chi}_{2ini} = 0$, $\dot{\phi}_{2ini}^c = 0$. The masses of the Higgs bosons in the analysis are taken to be $m_{\eta_2} = m_{\chi_2} = 1.0247 \times 10^{-59}$ GeV, the charged Higgs mass is arbitrary. The solution of the eqs. (11, 12, 13) along with Friedmann equations is shown below in the graphs.

During the initial stages $Z \gg 1$, the evolution of the Higgs fields, $\eta_2$, $\chi_2$ and $\phi_2^{\pm}$, is frozen, and acts as a negligibly small vacuum energy component with $\omega = -1$. As time proceeds the Higgs fields begin to evolve towards the minimum of the potential, the energy density in the Higgs fields starts to dominate cosmologically. During the evolution, $\omega_{Higgs}$ starts to increase and becomes $> -1$ as shown in fig. 2. In the very late (future) Universe ($Z \ll 0$), the fields come to rest at the minimum of the potential and a period with $\omega = -1$ is re-achieved to give an accelerating Universe similar to a pure cosmological constant.

As discussed before, the Higgs field stability is provided by imposing $Z_2$ symmetry. The lightest Higgs fields, $\eta_2$ and $\chi_2$, do not decay into any other Higgs field

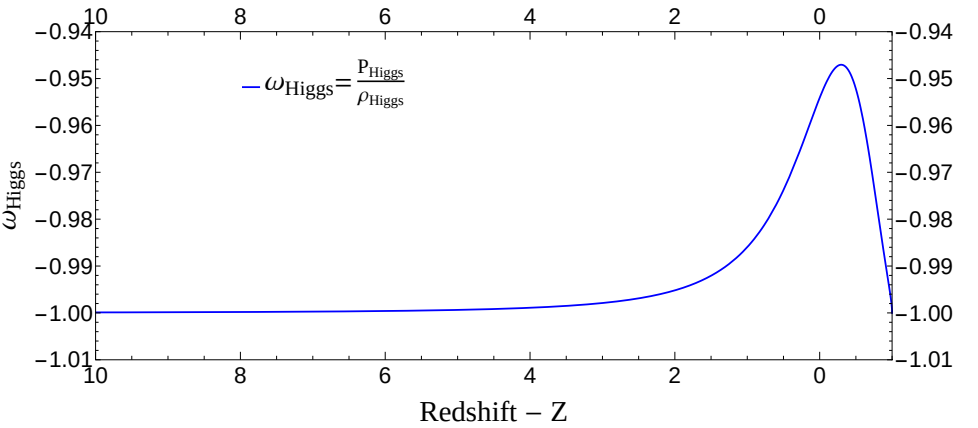

Fig. 2. Effective equation of state parameter for Higgs fields $\omega_{Higgs}$, as seen it starts with $-1$ then evolves towards quintessence regime after large enough time it comes back at $-1$.

(since these fields are lighter than the SM-like and charged Higgs) or into fermions (since they do not couple to them at tree level).

Note that the initial conditions for the charged field took the dark energy (vacuum) not to be charged. Since it does not contribute to relic density, this does not mean that it can not exist, it can appear in the loop process.

## 4. Conclusion

In the work presented, we assumed that dark energy is actually some scalar field which is present as the Higgs in a model where the potential has the non-degenerate vacua, we called this model uplifted double well two-Higgs doublet model (UDW-2HDM).

We found that if the present Universe is described by the true vacua of UDW-2HDM then the component fields of the second doublet $\phi_2$ (which acts as the inert doublet) can be one possible candidate for the dark energy. As the present contribution of the dark energy to the critical energy density is about 0.7, this value is obtained by taking the mass of the CP-even field's mass small ($O(10^{-59})$GeV). The most important thing is that with the initial conditions set, the mass of the charged ($\phi_2^{\pm}$) field becomes arbitrary. Hence this model will fit for any value of mass of $\phi_2^{\pm}$. One also needs to keep in mind that the values of masses were chosen arbitrarily so as to get dark energy relic density $\approx 0.7$. Changing the values of the masses, the relic density does not change much.

It should also be mentioned that if we remove the $Z_2$ symmetry, the second Higgs doublet does not remain inert. Thus in the case of $Z_2$ violation (soft or hard), the CP-even Higgs fields will mix by an angle $\beta$. In that case a new parameter ($\beta$) will arise in the theory. Obtaining a dark energy candidate in that model will require fine tuning in the Yukawa interactions in such a way that either the dark energy field does not couple or couple very weakly with the fermions.

# Structure formation in the early universe, the three-body problem, and gravity modification w.r.t. possible replacement of DE

Andrew Walcott Beckwith

*Physics Department, Chongqing University, Chongqing 401331, People's Republic of China*
*E-mail: Rwill9955b@gmail.com; abeckwith@uh.edu*
*english.cqu.edu.cn*

We find that having the scale factor close to zero due to a given magnetic field value in an early-universe magnetic field affects how we would interpret Mukhanov's chapter on self-reproduction of the universe. A stronger early-universe magnetic field suggests a greater likelihood of production of about 20 new domains of size $\frac{1}{H}$, with $H$ the early-universe Hubble constant per Planck time interval in evolution. Fluctuations in the Hubble expansion parameter, $H$, may affect structure. Finally, $\alpha$ in a gravitational potential is proportional to $r^{-\alpha}$. This adjustment affects the three-body problem.

## 1. Introduction

Part 1: We examine how a scale factor is affected by the NLED paradigm, also linked to *self-reproduction,*[1] another way to outline how this affects the evolution of density in the early universe. Next, after having done this, we give a description of an equation for setting the value of $\alpha$ in a gravitational potential proportional to $r^{-\alpha}$. This $\alpha$ has real and complex values, unlike the Newtonian real value.

Part 2: We summarize what this has to do with possible revisions of the three-body problem[2] with a particular mention as to how this affects astrophysics.[2] (p. 141)

## 2. How a Scale Factor Is Affected by the NLED Paradigm

First we look at structure formation, mainly self-reproduction of inhomogeneity in terms of early-universe conditions.[1] In this, the starting point is the meme of chaotic inflation. That is, inflation generated by a potential:[1,3]

$$V_{\text{potential}} \sim \phi^2. \tag{1}$$

In this, one can look at a scalar field at the end of (chaotic) inflation,[1] with an amplitude given by $\phi_i$ for the initial value of the inflaton such that

$$\delta_{\phi_{\text{Max}}} \sim m \cdot \phi_i^2, \tag{2}$$

where $m$ will be determined by NLED inputs to be brought up later. In terms of the initial inflaton, inhomogeneities do not form if the initial inflaton is bounded:[1]

$$m^{-1} > \phi_i > m^{-\frac{1}{2}}. \tag{3}$$

This leads to (low?) inflation-generated inhomogeneity in space–time. Inflation is eternal[1,3] if there is only the inequality

$$\phi_i > m^{-\frac{1}{2}}. \tag{4}$$

### 2.1. *NLED Applied to Eq. (4) Plus Details of Structure Formation*

We examine the following treatment of mass with this as our starting point. If $l_{\text{Planck}}$ is the Planck length and $\alpha > 0$, then

$$m \sim 10^{\alpha} \cdot l_{\text{Planck}}^{3} \cdot \rho_{\text{density}}. \tag{5}$$

Then we can consider the following formulation of density. If we do not wish to consider a rotating universe, then Camara et al.[4] has an expression as to density, with a $B$-field contribution to density, and we also can used the Weinberg result[5] of scaling density with one over the fourth power of a scale factor, which we will remark upon in the general section, as well as the Corda and Mosquera Cuesta result[6] for density is for a star, whereas the Camarade et al. result[4] is for a universe). In addition, Corda and Mosquera Cuesta[6] use quintessential density to falsify the null energy condition of a Penrose theorem.[7] With further details of what Penrose was trying to do as to this issue of GR,[8] and to answer how to violate the null-energy condition, one should go to[6] for quintessential density defined, with the constant in Eq. (4) greater than zero. Then in both the massive star and the early universe, this density result is applicable.

$$\rho_{\gamma} = \frac{16}{3} \cdot c_1 \cdot B^4. \tag{6}$$

Keeping in mind what was said as to choices of what to do about density, and its relationship to Eq. (5), we then can reference structure formation as follows.[1] Look at how a Hubble parameter changes with respect to cosmic evolution. It changes with respect to $H_{\text{today}}$ being the Hubble parameter in the recent era, and the scale factor $\alpha$, with this scale factor being directly responsive to changes in density.[5] That is, $\rho \sim a^{-4}$. In the next section, we examine how to vary the scale factor cited in Eq. (7).[4] In this section, we note of what the scale factor does[4] to the Hubble parameter given in Eq. (7), and then in the section afterwards review a possible reconciliation of how Eq. (6) and Eq. (7) define early-universe parameters. To understand, we consider what happens to the Hubble parameter:

$$H \sim \frac{H_{\text{today}}}{a^{\frac{3}{2}}}. \tag{7}$$

If Eq. (4) holds,[1] then inhomogeneous patches of space–time appear in a causal region of space–time for which

$$\textit{Causal–domain} \sim H^{-1} \sim \frac{a^{\frac{3}{2}}}{H_{\text{today}}}. \tag{8}$$

Furthermore, about 20 such domains are created in a Hubble time interval $\Delta t_H \propto H^{-1}$.[1] As a function of say $10^{\alpha}$ times Planck time, for a domain size given by Eq. (8) and this requires then a clear statement as to how the scale factor changes[4] and reconciling the density expressions given in Eq. (6) and Eq. (7).

### 2.2. *Nonzero Initial Universe Radius from Nonlinear Space–Time*

We assert a scaled parameter $\lambda$,[1] and $a_0$, paired with $\alpha_0$. For the sake of argument, we will set $a_0 \propto \sqrt{t_{\text{Planck}}}$, with $t_{\text{Planck}} \sim 10^{-44}$ s. Also, $\lambda$ is a cosmological "constant" parameter described later as quintessence:[4,9]

$$\alpha_0 = \sqrt{\frac{4\pi G}{3\mu_0 c}} B_0, \text{ and } \lambda = \frac{\Lambda c^2}{3}. \tag{9}$$

Then if, initially, Eq. (9) is large, due to a very large $\Lambda$ the time[4] (Eq. 53) is such that, even though there is an expanding and contracting universe, the key time parameter may be set to $t_{\min} \approx t_0 \equiv t_{\text{Planck}} \sim 10^{-44}$ s. Whenever one sees the coefficient like the magnetic field, with the small 0 subscript, for large values of $\Lambda$, this should be the initial coefficient at the beginning of space–time which helps us make sense of the nonzero but tiny minimum scale factor.[1]

$$a_{\min} = a_0 \cdot \left[ \frac{\alpha_0}{2\lambda} \left( \sqrt{a_0^2 + 32\lambda\mu_0\omega B_0^2} - \alpha_0 \right) \right]^{\frac{1}{4}}. \tag{10}$$

The minimum time most likely means, due to large $\Lambda$ that Eq. (10) is of the order of about $10^{-55}$, 33 orders of magnitude smaller than the square root of Planck time. We next will be justifying the relative size of the $\Lambda$.

### 2.3. *An NLED Large, Varying $\Lambda$ and Early-Universe Scale Factor*

Dispite the temperature variation[9] for the cosmological Hubble parameter, we can set $\Lambda(t) \sim H^2_{\text{inflation}}$.[4] In short, we obtain its equivalence with $\Lambda_{\text{Max}} \sim c_2 T \widetilde{\beta}$.[9] Then, comparing Eq. (6) and Eq. (7) leads to the following constraints.

$$(\rho \sim a^{-4})^{-1} \sim a^4 \sim \frac{16}{3} \cdot c_1 \cdot B^4 \sim \frac{a_0^{-4}}{\frac{\alpha_0}{2\lambda}\left( \sqrt{a_0^2 + 32\lambda\mu_0\omega B_0^2} - \alpha_0 \right)}. \tag{11}$$

Equation (11) suggests a large $B$ field in Eq. (11). Note that[10]

$$\frac{\Delta H}{H} \sim \Omega_m^2 h^2 \Delta_{\Re} \sim 10^{-5}. \tag{12}$$

Here, if there is a flat universe[11] and taking $H^2 = \frac{8\pi}{3} \cdot \rho$ and using the magnetic field's relation to density,[12,6] then the number of operations, $n$,

$$n \sim \rho_{\text{crit}} \times t^4 \sim \left( \frac{t}{t_p} \right)^2 \Leftrightarrow \rho_{\text{crit}} \sim \frac{1}{t^2} \propto \rho_\gamma = \frac{16}{3} \cdot c_1 \cdot B^4$$
$$\Leftrightarrow n \sim \left( \frac{t}{t_p} \right)^2 \cdot \frac{1}{B^8} \sim \frac{1}{t_p B^4} \sim \frac{1}{B^4}. \tag{13}$$

Adding Lloyd's treatment of information,[12] we estimate an early-universe fluctuation at, if we have a baseline number for initial (expansion) value of the Hubble

parameter, $H_{\text{baseline}}$. This is a starting point for an expanding universe with $n$[12] as an initial function of entropy. So then, we may see in the CMBR

$$\Delta H_{\text{thermal}} \sim h_{\text{baseline}} \cdot n^{\frac{1}{4}} \cdot 10^{-5} \cdot \sqrt{\frac{t}{t_{\text{Planck}}}}. \tag{14}$$

In Eq. (15)–(16), with $H$ given by Eq. (16) and, as in Adamek et al.,[10] (Fig. 2) we have, perhaps, the beginning of how NLED may impact fluctuations in $H$. That, in turn, may lead to the issue that opened our discussion. Equation (14) may give some insight as to the fluctuations in Adamek et al.[10] (Fig. 2)

## 3. The Problem of $\alpha \propto r^{-\alpha}$ in a Gravitational Potential

To review this, we use the following treatment of the Klein–Gordon equation:[13]

$$\ddot{\varphi}_k + 3H\dot{\varphi}_k + \tfrac{k^2}{a^2}\varphi_k = 0, \quad \varphi_k \approx \tfrac{H\tau}{\sqrt{2k}}\left(1 + \tfrac{1}{ik\tau}\right)\mathrm{e}^{-ik\tau}, \quad \text{and } \tau = -\tfrac{\mathrm{e}^{-Ht}}{H}. \tag{15}$$

Here, $k$ is the wave number and $H$ is constant in the early universe. Thus $k = \frac{2\pi}{\lambda}$, with $\lambda$ proportional to the "width" of a would-be preuniverse "bubble"[14] in place of a singularity. Also, one would have for a constant $H$, during this time,[15]

$$H = \sqrt{\frac{8\pi G}{3} \cdot \rho - \frac{\kappa}{a^2}} = \sqrt{\frac{8\pi G}{3}} \cdot \sqrt{\rho - \frac{3}{8\pi G} \cdot \frac{\kappa}{a^2}} \approx \sqrt{\frac{8\pi G}{3}} \cdot \sqrt{V(\varphi) - \frac{\dot{\varphi}^2}{2}}$$
$$\Leftrightarrow \frac{\dot{\varphi}^2}{2} = \left(\frac{3}{8\pi G} \cdot \frac{\kappa}{a^2} + V(\varphi)\right) - \rho, \tag{16}$$

where $\rho$ is energy density and $\kappa$ is curvature. Chaotic inflation uses $V(\varphi) \approx \frac{k^2}{a^2} \cdot \varphi^2$, the time derivative is $\frac{\mathrm{d}}{\mathrm{d}\tau}$, and $\varphi = \varphi_k$:

$$\frac{\dot{\varphi}^2}{2} = \frac{3}{8\pi G} \cdot \frac{\kappa}{a^2} + \frac{k^2}{a^2} \cdot \varphi_k^2 - \rho = \frac{3}{8\pi G} \cdot \frac{\kappa}{a^2} + \frac{k^2}{a^2} \cdot \varphi_k^2 - \frac{16}{3} \cdot c_1 \cdot B^4 \approx \Delta E. \tag{17}$$

The last term of Eq. (17) states that, if we apply it to the Pre-Planckian-to-Planckian regime, there will be a change in the energy, We call this shift in energy equivalent to a change in *kinetic* energy, and then reference the Virial theorem:[16]

$$\left\langle \psi \middle| \Delta E \approx \frac{3}{8\pi G}\frac{\kappa}{a^2} + \frac{k^2}{a^2}\varphi_k^2 - \frac{16}{3}c_1 B^4 \middle| \psi \right\rangle \approx \left\langle \psi \middle| r \cdot \Delta\left(V_{\text{PE}} \approx \frac{c_2}{r^\alpha}\right) \middle| \psi \right\rangle, \tag{18}$$

where $V_{\text{PE}}$ is potential energy. In Pre-Planckian–Planckian space–time, we approximate, in the instant before time is initialized, the mean-value theorem for the computed values of both Eq. (17) and (18) with our results:

$$\frac{3}{8\pi G}\frac{\kappa}{a^2} + \frac{k^2}{a^2}\varphi_k^2 - \frac{16}{3}c_1 B^4 \approx -\frac{\alpha}{r^\alpha} \equiv -\frac{\alpha}{l^\alpha} \Leftrightarrow \frac{\alpha}{l^\alpha} \approx \frac{16}{3}c_1 B^4 - \frac{3}{8\pi G}\frac{\kappa}{a^2} - \frac{k^2}{a^2}\varphi_k^2. \tag{19}$$

Here, the magnetic field is determined by $B$, the scale factor $a$ (Eq. (12)), and $\varphi_k$ (Eq. (19)). $\alpha$ is no longer strictly real and is influenced by the complex $\varphi_k$. We next conclude with how the three-body problem, and in fact other experimental science could be impacted by Eq. (19). This merits scrutiny of the Lagrangian equilateral

triangle[2] (p. 134) and possible orbits from the three-body problem.[17] (p. 15) Here, we consider both in terms of KAM theory,[2,15] a highly restricted set of equations:

> When the system is slightly perturbed most of the invariant tori are not destroyed but only slightly shifted in the phase space. This has important implications on stability of orbits in the general and restricted three body problem. The proof of the KAM theorem by Moser [1962] and Arnold [1963] also demonstrated that convergent power series solutions exist for the three-body (as well as for the $n$-body) problem. The KAM theorem seems to be very useful for studying the global stability in the three-body problem [Robutel, 1993a, Montgomery, 2001, Simó, 2002]; however, some of its applications are limited only to small masses of the third body.[17] (p. 15)

The limitation of KAM theory is that, most of the time, we have that the KAM results require a third body to be low mass, a classic dynamic-system result.

## 4. Conclusion

Via careful use of Eq. (19), we must remove dependence upon third-mass size, and examine if this can still recover much of the stability analysis. Later, this question in terms of a serious application of the value of Eq. (19) will be pursued, Second, orbital changes in encounters with planets is a restricted three-body problem,[2] (p. 154) frequently used as to the interaction of say comets (comparatively small mass) with planets circulating the Sun, where we have two "massive" masses, and the third body. This could be used to show how the hyperbolic trajectory of a minor mass object (comet) is impacted in a simple solar-system model. We hope that, by judicious investigation of the arguments given for Eq. (19), the restrictions as to the smallness of the third mass may be partly ameliorated. If this is done, and it will require through investigations, then a template as to how to reliably simulate $N$ bodies interacting may be a doable problem. To do this, one must investigate if the classical KAM problem may be generalized beyond its present restrictions.

# Constraining time-dependent dark energy with the flux power spectrum of the Lyman $\alpha$ forest

Calculations of the flux power spectrum of the Lyman $\alpha$ forest are performed as a means to quantify the possible effects of time-dependent dark energy. We use a parameterized version of the time-dependent dark energy equation of state consistent with the *Planck* analysis. We have run high-resolution, large-scale cosmological simulation with a modified version of the publicly available SPH code `GADGET-2`. These simulations were used to extract synthetic Lyman $\alpha$ forest spectra. These were then used to simulate the flux power spectrum at various observed quasar redshifts. We conclude that the effect of time-dependent dark energy on the flux power spectrum is of marginal statistical significance compared to the intrinsic cosmic variance.

*Keywords*: Cosmology: dark energy — cosmology: theory — methods: numerical.

## 1. Introduction

The origin of the present cosmic acceleration remains a mystery. Within the dark energy paradigm several time-dependent models have been proposed as the physical mechanism for cosmic acceleration.[1]. The simplest model is that of a cosmological constant. Another possibility, however, is a self-coupled, slowly evolving scalar field that manifests as either a cosmic quintessence[2] or k-essence[3]. The empirical difference between the cosmological constant and all other dark energy models is that the energy density of the later can vary in time. Hence, discriminating between various dark energy models can be made by observing how the dark energy changes in time.

Current observational constraints on time-dependent dark energy, however, are quite weak[4]. In the work described here[5] we consider using the Lyman-$\alpha$ forest as a means to constrain the time evolution of dark energy. The motivation for using the Lyman-$\alpha$ forest is that the effects of dark energy, should be most apparent on the morphology of voids in the cosmic web.[6–12] The absorbers responsible for the Lyman-$\alpha$ forest should reside primarily in the clusters and filaments.[13,14] Along the line of sight to distant quasars these absorbers will be separated by the voids. As such, the separation of these absorbers in redshift space should act as a tracer of the evolution of the voids.[15] Hence, the flux power spectrum acts as a proxy for the matter power spectrum and should contain complementary information about how each dark energy model affects the expansion of the universe. Thus, studying the Lyman-$\alpha$ forest could be an independent approach to searches based on the SNIa redshift-distance relation, the CMB, BAO, ISW, and gravitational lensing, and one that has received comparatively little attention in the literature.

## 2. Simulations

Previously Ref. [15] considered the effects on the Lyman-$\alpha$ forest from various values of cosmological constant in the context of a semi-analytic treatment of the Lyman-$\alpha$ forest. In Ref. [5] we expanded upon that work by making use of high-resolution N-body simulations, from which we extracted synthetic Lyman-$\alpha$ spectra. Moreover, we have explored dynamical models of dark energy.

Our simulations were run with the publicly available smoothed-particle-hydrodynamics (SPH) code GADGET-2[16], modified[5] to work with dynamical dark energy.[17] Simulating the Lyman-$\alpha$ forest requires a very high resolution. It has been suggested[18] that a resolution of $\approx 40\ h^{-1}$ kpc in a box of size $L \approx 40\ h^{-1}$ Mpc is needed to adequately resolve the structure of the Lyman-$\alpha$ forest and achieve convergence in the power spectrum. With these requirements in mind, we simulated $1024^3$ dark matter particles in a box of length $40\ h^{-1}$ comoving Mpc.

Due to the high resolution requirements of our simulations, we evolve a distribution of only dark matter particles out of consideration for the total run-time. This is justified because in the low-density, mildly non-linear environments typically responsible for the Lyman-$\alpha$ forest, the baryon distribution largely follows that of the dark matter on large scales.[19] Additionally, the effects of non-linear baryonic physics, such as galactic winds, have been shown[20] to be small at large scales where the effects of dark energy should be most prominent.

Our cosmological parameters are those given in Ref. [21]. Other simulation parameters are given in Ref. [5]. We ran five simulations both with a cosmological constant and with various dynamical dark energy where $w(a)$ is the linear slope of the dark energy equation of state with redshift. The dynamical models were chosen such that their parameters were as close to the edges of the allowed 95% confidence range for the $(w_0, w_a)$ parameter space given in the *Planck* analysis.[4] We chose points at the fringes of the allowed parameter space since these models should produce flux power spectra with the largest differences between them. The only exception to this is model DE2-40-1024, $(w_0, w_a) = (-1.1, 1.3)$ which was deliberately chosen from the region of the $(w_0, w_a)$ parameter space that is outside the bounds permitted by *Planck*'s marginalized posteriors. This was done for two reasons: first, we wanted to determine if very extreme values the dark energy parameters were capable of producing a distinct signature in the flux power spectrum of the Lyman-$\alpha$ forest, and second, we were interested in whether or not the flux power spectrum provided constraints on the dark energy parameter space that were in accord with the results determined from other observational probes. The values of $w_0$ and $w_a$ that we used are $(w_0, w_a) = (-1.0, 0.0), (0.0, -3.0), (-1.1, 1.3), (-2.0, 0.0), (-2.0, 2.0)$.

Each of our simulations was started from the same initial conditions and evolved from $z = 49$ to $z = 2.2$. Our initial conditions were generated using the publicly available second-order Lagrangian perturbation theory code `2LPTIC`[22]. We generated snapshots of each simulation for quasars located at observed redshifts of $z = 4.2, 3.8, 3.0, 2.7$, and $z = 2.2$ as described in Ref. [5]. Our simulations

required on the order of $\approx 10$ days on 72 processors to run. Following this, the post-processing took on the order of one week per snapshot, with the majority of the time (about four or five days) being devoted to halo-finding.

## 3. Implementation of Dynamical Dark Energy

The publicly available version of GADGET-2 assumes that dark energy arises from the cosmological constant. However, we make use of the parameterization given in 5. Nevertheless, modifying GADGET-2 to include the effects of dynamical dark energy was relatively straight forward. Calculating a synthetic spectrum requires knowledge of the densities, temperatures, and H*I* neutral fractions for each of the simulation particles. Since these are not properties of dark matter particles in GADGET-2, and we ran dark matter only simulations, we calculated these quantities in post-processing. Details of the GADGET calculations and the extraction of the Lyman-$\alpha$ spectra are given in Ref. [5].

The absorption in the Lyman-$\alpha$ forest serves as a way of mapping out the large-scale structure between the observer and the distance source quasar. Thus, the flux power spectrum serves as a proxy for the power spectrum of the underlying matter field that gives rise to the absorption in the Lyman-$\alpha$ forest. Since the matter power spectrum is a measure of the density amplitudes as a function of scale, and these amplitudes depend upon the expansion history of the universe, we can, in principle, use the flux power spectrum to discriminate between dark energy models.

Following Ref. [23], we do not analyze the flux directly but instead consider the quantity:

$$F_p = \frac{e^{-\tau}}{\langle e^{-\tau} \rangle} - 1. \tag{1}$$

$F_p$ is used in place of $F$ because $F$ is sensitive[23] to changes in the mean flux $\langle e^{-\tau} \rangle$. We then take the Fourier transform of $F_p$ using the publicly available package `FFTW3`[a] to calculate the power spectrum. That is, the power spectrum is constructed from the Fourier transform of $F_p$, which we denote $F_{p,k}$,

$$P_{F_p}(k) = |F_{p,k}|^2. \tag{2}$$

We normalize the spectrum by dividing out the total counts within each bin of frequency $k$. The frequencies are found via:

$$k_i = \frac{2\pi i}{T}, \tag{3}$$

where $i$ indicates the bin index and $T$ is the period. For discrete Fourier Transforms (DFTs), the signal is assumed to be periodic over the range in which there is data, so the period is simply the length of the spectrum in velocity space.

## 4. Results

Using the procedure described in Ref. [5], we extract one-thousand synthetic spectra for each model at each redshift. This pool of spectra was then used to calculate an average power spectrum for each dark energy model at each redshift, along with errors. Figure 1 shows the spectrum through the center of the simulation volume for each of our dark energy models. These are offset from one another for visual clarity. All of the spectra, save for the DE2-40-1024 model, are nearly identical to one another.

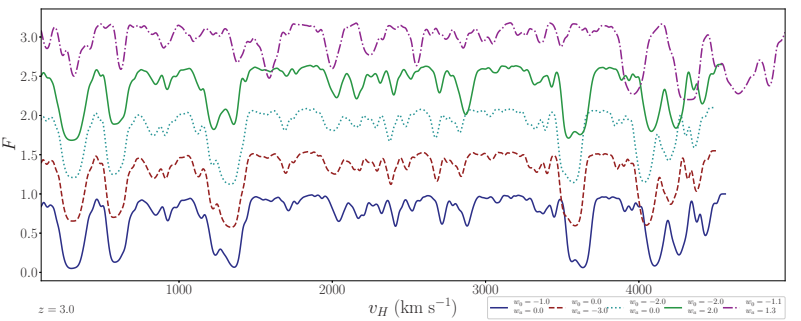

Fig. 1. The synthetic spectrum through the center of the simulation volume for each of our dark energy models at $z = 3.00$. This figure highlights the fact that the spectrum for each of our dark energy models, save for DE2-40-1024 (magenta), are all nearly identical to one another. Each spectrum is offset from the others for reasons of visual clarity.

In order to calculate an average power spectrum at each redshift, we bootstrap a sample of eight-hundred synthetic Lyman-$\alpha$ forest spectra from our pool of one-thousand. The process described in Ref. [5] is then applied to this bootstrapped sample in order to calculate one instance of the power spectrum. This process is then repeated one thousand times to generate one thousand instances of the power spectrum. These instances are then averaged on a $k$-by-$k$ basis in order to obtain a mean value of $P$ for each $k$ along with a standard deviation, which we take to be the errors on our simulated power spectra.

We applied[5] a k-sample Anderson-Darling (AD) test[24] to analyze the statistical significance of the differences among power spectra. This test places more emphasis on the tails of the distribution. Since dark energy is a large-scale phenomenon, we expect the differences between power spectra to be greatest on the largest scales (smallest $k$). The key feature of the AD test is the fact that it is distribution-free. This is because the underlying distribution function giving rise to the power spectrum is unknown. With no *a priori* reason to prefer one distribution function over any other, a reasonable place to start is to assume a Gaussian distribution, though we would not necessarily expect this to be the case given that cosmic structure is not normally distributed.

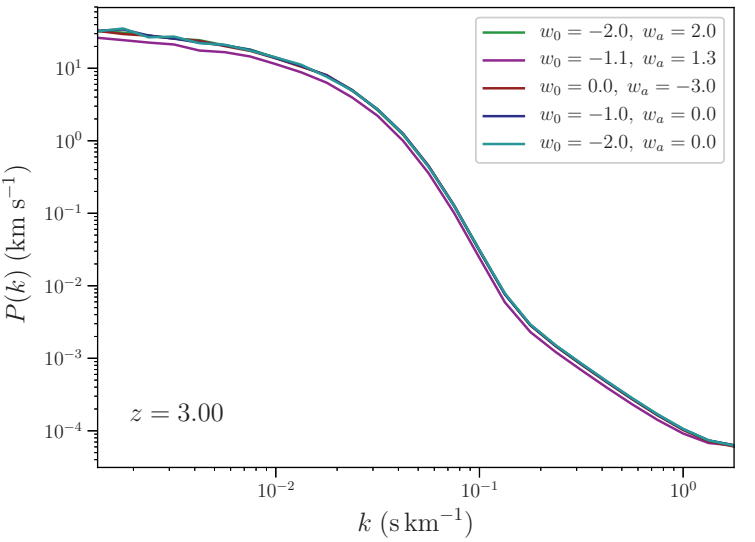

Fig. 2. Power spectrum from each of our dark energy models at $z = 3$. This figure shows that effect of various time-dependent dark energy models on the flux power spectrum of the Lyman-$\alpha$ forest is small.

In summary, his work has explored whether the flux power spectrum of the Lyman-$\alpha$ forest can be used as a probe of time-dependent dark energy. We extracted synthetic Lyman-$\alpha$ forest spectra from high-resolution N-body simulations and used these to calculate the flux power spectrum. We used five different dark energy models, including the cosmological constant and four dynamical, parameterized dark energy models. These models were chosen from the $(w_0, w_a)$ posterior distributions as determined by *Planck*. In particular, of the four dynamical dark energy models we employed, three of them were chosen to lie at the fringes of this posterior, while the fourth was deliberately chosen to lie outside of the 95% C.L. bounds determined by *Planck* to serve as an extreme example from which we might discern an effect on the power spectrum.

Based our pool of synthetic Lyman-$\alpha$ forest spectra, we calculated an average power spectrum for each dark energy model at each redshift. We used k-sample Anderson-Darling test, which shows that there are only marginal differences between the power spectra. Thus, the effects of dark energy on the Lyman-$\alpha$ forest are less significant than the probes based upon the baryonic physics in the IGM. This implies that it is challenging to discriminate among dark-energy models based upon the power spectrum of the Lyman-$\alpha$ forest.

The recent analysis of low-redshift supernovae (SN) has increased the apparent tension between the value of $H_0$ estimated from low and high redshift observations such as the cosmic microwave background (CMB) radiation. At the same time other observations have provided evidence of the existence of local radial inhomogeneities extending in different directions up to a redshift of about 0.07. About 40% of the Cepheids used for SN calibration are directly affected because are located along the directions of these inhomogeneities. We compute with different methods the effects of these inhomogeneities on the low-redshift luminosity and angular diameter distance using an exact solution of the Einstein's equations, linear perturbation theory and a low-redshift expansion. We confirm that at low redshift the dominant effect is the non relativist Doppler redshift correction, which is proportional to the volume averaged density contrast and to the comoving distance from the center. We derive a new simple formula relating directly the luminosity distance to the monopole of the density contrast, which does not involve any metric perturbation. We then use it to develop a new inversion method to reconstruct the monopole of the density field from the deviations of the redshift uncorrected observed luminosity distance respect to the $\Lambda CDM$ prediction based on cosmological parameters obtained from large scale observations.

The inversion method confirms the existence of inhomogeneities whose effects were not previously taken into account because the $2M++$ [1] density field maps used to obtain the peculiar velocity [2] for redshift correction were for $z \leq 0.06$, which is not a sufficiently large scale to detect the presence of inhomogeneities extending up to $z = 0.07$. The inhomogeneity does not affect the high redshift luminosity distance because the volume averaged density contrast tends to zero asymptotically, making the value of $H_0^{CMB}$ obtained from CMB observations insensitive to any local structure. The inversion method can provide a unique tool to reconstruct the density field at high redshift where only SN data is available, and in particular to normalize correctly the density field respect to the average large scale density of the Universe.

*Keywords*: Luminosity distance; inversion method; Hubble parameter.

## 1. Introduction

The recent analysis of low-redshift supernovae (SN) luminosity distance measurements [3] have given an estimate of the the Hubble parameter $73.24 \pm 1.74$ km s$^{-1}$ Mpc$^{-1}$ which is more than 9% larger than the one obtained from CMB data [4], $66.93 \pm 0.62$ km s$^{-1}$ Mpc$^{-1}$. The difference is significant at about $3.4\sigma$ confidence level, making it a discrepancy which is definitely worth investigating and cannot be easily attributed to a statistical fluke. On the other hand there is evidence [5] from luminosity density observations that the radial density profile is not homogeneous in certain directions. In one direction, corresponding to subregion 3 in [5], the radial profile is underdense up to about 300 Mpc/h.

In order to check the effects of local inhomogeneities on the luminosity distance and that redshift correction is sufficiently accurate we compute the full relativistic effects on the luminosity distance using an exact solution of the Einstein's equations and compare to results obtained using linear perturbations theory and a low-redshift

expansion. In the perturbative limit we obtain a formula relating directly the density field to the luminosity distance, showing that the effects are proportional to the volume average of the density field, not to the local value of the density contrast. This explains naturally why large scale observations are not affected by low redshift inhomogeneities, since their volume average is negligible on large scales.

We use this formula to derive a new inversion method to obtain the density contrast from redshift uncorrected observed luminosity distance observation.The method gives a value of the density contrast in subregion 3 in agreement with[5] observations.Note that no assumption about a large void extending in all directions is made, and only the radial inhomogeneity in subregion 3 is considered, but since about 40% of the Cepheids are affected by this inhomogeneity, the entire analysis can be affected even if the local Universe is homogeneous in other directions.

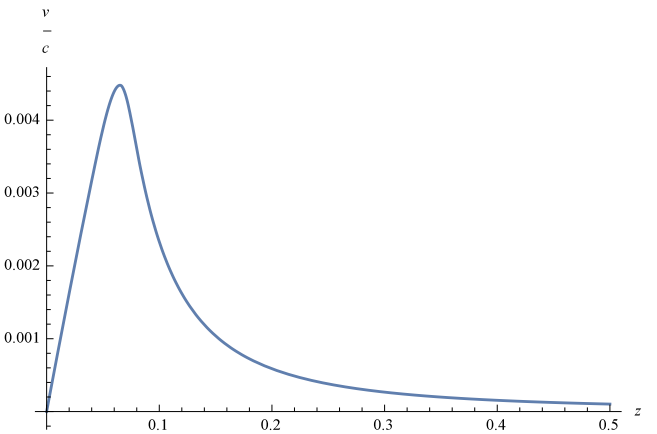

Fig. 1. The peculiar velocity associated to an inhomogeneity profile as the one shown in the upper panel of fig. 2 is plotted in units of the speed of light $c$ as a function of redshift. As can be seen the effect reaches its peak around the hedge of the inhomogeneity and is then asymptotically suppressed due to volume averaging.

Due to the insensitivity of high redshift luminosity distance to local structure, we argue that any local deviation from the theoretical prediction of a FRW model based on cosmological parameters estimated using large scale observations such as the CMB radiation, should be considered an evidence of local structures with a size larger than the depth of the density maps used to apply redshift correction to observational data.

The inversion method we developed could be hence particularly useful to reconstruct the density field from SN luminosity distance observations on scales where galaxy surveys data is not available, not just to resolve the $H_0$ tension.

## 2. Effects of inhomogeneities on the luminosity distance

Unless differently specified, we use a system of units in which $8\pi G = c = 1$. The effects of inhomogeneities on the angular diameter distance were calculated to first

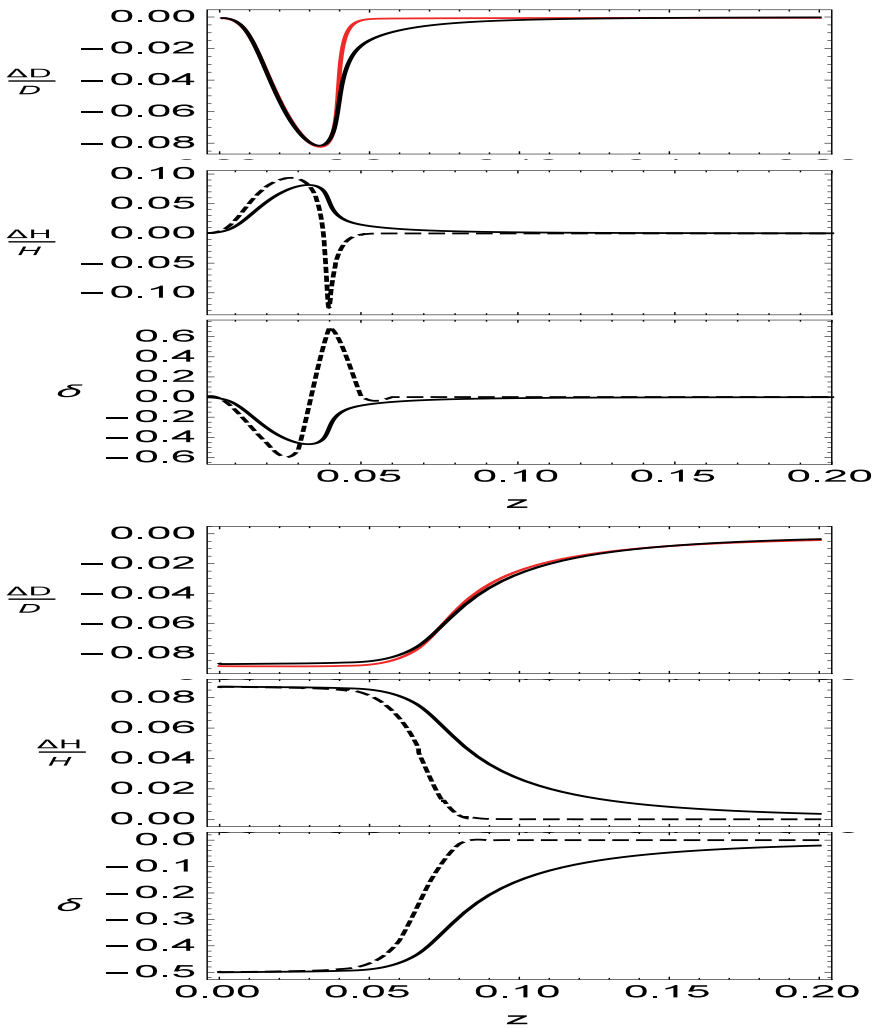

Fig. 2. The fractional difference of the luminosity distance $\Delta D_L/\overline{D_L}$ and the local Hubble parameter $\Delta H/\overline{H_0}$ are plotted as a function of the redshift for a compensated (top) inhomogeneity such as the one studied in[6] and an uncompensated (bottom) void. For $\Delta D/D$ the effects of the inhomogeneity are computed with a non pertubative approach using a LTB metric (red line) and are in good agreement with the approximation (black line) given in eq. (11), confirming that $k_v$ in eq. (9) produces the dominant effect at low redshift. The relative fractional difference $\Delta H/H$ is computed with eq. (14) (black line) and with eq. (12) (dashed line). For the compensated case the difference is particularly important since eq. (12) would predict a negative variation, while eq. (14) gives the correct sign, in agreement with the results of a local fitting procedure.The volume averaged fractional density contrast $\overline{\delta}$ defined in eq. (7) is plotted with a black line and the local density contrast $\delta$ with a dashed line.

order in perturbation theory in[7] and to second order in[8]. The results in the Newton gauge can be written in this form[9,10]

$$D_A(z) = \overline{D}_A(z)\,[1 - k(z)]\ , \tag{1}$$

where $\overline{D}_A(z)$ is the diameter distance for a homogeneous Universe. The convergence $k(z) = \sum_i k_i(z)$ is the sum of different terms among which the most important ones are

$$k(z) \approx k_\delta(z) + k_v(z)\,, \tag{2}$$

$$k_v = \left[1 - \frac{1}{a_e \chi_e H_e}\right] v_e \cdot n + \frac{1}{a_e \chi_e H_e} v_o \cdot n\,, \tag{3}$$

$$k_\delta = \frac{3}{2} H_0^2 \Omega_m \int_0^{\chi_e} \mathrm{d}\chi \frac{(\chi_e - \chi)}{a_e \chi_e} \chi \delta(\chi)\,, \tag{4}$$

where $\chi$ is the comoving distance, we are denoting respectively with a lower-script $e$ or $o$ any quantity evaluated at the point of emission of the photons or at the observer, and the unit vector $n$ is in the direction of propagation from the emitter to the observer. The term $k_\delta$ is known as the gravitational lensing magnification [11] while $k_v$ is due to the peculiar velocities. The other $k_i$ terms are related to the line of sight integral of the gravitational potential and its time derivatives, such as the integrated Sachs-Wolf effect for example, and are sub-dominant at low-redshift [9]. We will show later using both an exact solution of the Einstein's equations and a low-redshift Taylor expansion that the most important term is $k_v$.

## 3. Peculiar velocity and density maps

In the Newtonian limit the peculiar velocity field can be related to the density field by integrating the Euler's equation [12]

$$v(\chi) = \frac{afH}{4\pi} \int^{R_{Max}} \delta(\chi') \frac{\chi' - \chi}{|\chi' - \chi|^3} d^3\chi'\,. \tag{5}$$

In [3,13,14] $R_{Max}$ corresponds to $z < 0.06$, which is less than the size of the local inhomogeneity, $z \approx 0.07$. While the redshift correction method is quite precise at low redshift as we will show later, the velocity field they obtain is missing the peculiar velocity component due to the local void which can be obtained only by integrating eq. (5) over scales larger than the size of the void. The correct background density value $\overline{\rho}$ entering the definition of the fractional density contrast $\delta = \delta\rho/\overline{\rho}$ should be the volume average of the density $\rho$ on a scale larger than the void size, otherwise the underdensity of the void respect to the rest of the Universe will not be taken into account.

Density maps for $z < 0.06$ cover regions inside the void and cannot be used to find the relative density difference respect to the outside region, located at $z > 0.07$. In other words if we only consider density maps for $z < 0.06$ we cannot detect the presence of the local void, while extending the analysis to a higher redshift range [5] gives $\delta \approx -0.5$ inside the void. It turns out that the component of the peculiar velocity due to the void is crucial to explain the apparent tension in the $H_0$ estimation.

## 4. Perturbative monopole correction

The peculiar velocity associated to a spherically symmetric inhomogeneity can be obtained in the Newtonian limit as[12]

$$v(\chi) = -\frac{1}{3} a f H \overline{\delta}(\chi) \chi \,, \tag{6}$$

$$\overline{\delta}(\chi) = \frac{3}{4\pi\chi^3} \int^{\chi} 4\pi \chi'^2 \delta(\chi')\, d\chi' \tag{7}$$

where $\overline{\delta}$ is the density contrast averaged over the sphere of comoving radius $\chi$, it has been assumed that the density contrast can be factorized as the product of a space and a time dependent function as $\delta = A(x)D(t)$, and $f = \frac{1}{H}\frac{\dot{D}}{D}$ is the growth factor. The negative sign in front of eq. (6) implies that for an underdensity the velocity is directed outward from the center, which is what we intuitively would expect since the region outside the void is denser. From the above equation we can see that the monopole component of the peculiar velocity is zero for a central observer, implying that the observer velocity is not affected by the monopole component of the local structure. Since the effects of the inhomogeneity depends on $\overline{\delta}(z)$, they extend slightly beyond the edge of the void, because the volume averaged density contrast does not go to zero immediately after it.

Eq. (6) is used to plot in fig. 1 the peculiar velocity as function of the red-shift inside an inhomogeneity with a density profile given in fig. 2. As expected the velocity is zero at the center, reaches its pick at the edge of the inhomogeneity and tends asymptotically to zero due to the volume average.

Using eq. (6), and only considering the effects due to the emitter velocity $v_e$, since, as shown in eq. (6), a spherical symmetric inhomogeneity does not affect the observer velocity, we can re-write $k_v$ in terms of the averaged density density and get

$$k_v = \frac{1}{3} f \overline{\delta}\, (aH\chi - 1) \,. \tag{8}$$

Note that we have used that $v_e \cdot n = \frac{1}{3} f \overline{\delta} a H \chi$ because $n$ is directed from the emitter to the observer, while in eq. (6) the unit vector is in the opposite direction, i.e the positive radial direction, since we are assuming a coordinate system centered at the observer.

## 5. Low redshift effects of a local inhomogeneity

At low redshift we have $aH\chi \approx z$ and consequently only the second term in eq. (8) is important at leading order in $z$, giving

$$k_v(z) = -\frac{1}{3} f \overline{\delta}(z) \,. \tag{9}$$

In the case of $k_\delta$ we can also perform a low-redshift expansion and assuming $\overline{\delta} = \delta_c + \delta_1 z + ..$, the leading order term is

$$k_\delta = \frac{3}{4} \Omega_m \delta_c z^2 \,, \tag{10}$$

which is a second order term which can be safely neglected at low redshift.

Now that we know that the dominant contribution at low redshift is $k_v$, we can compute the leading order correction to the angular diameter distance

$$D_A(z) = D_L(z) = \overline{D_L}(z)\left[1 + \frac{1}{3}f\overline{\delta}(z)\right] . \tag{11}$$

In the above equation we have used that at leading order in redshift the reciprocity relation $D_L(z) = (1+z)^2 D_A(z)$ implies that $D_L(z) = D_A(z)$.

As shown in fig. 2 eq. (11) is in very good agreement with the results obtained from the calculation of the full relativistic effects of the inhomogeneity using the LTB solution, confirming that the approximations used to derive eq. (11) are well justified.

$$\frac{\Delta H}{\overline{H}} = -\frac{1}{3}f\delta\,. \tag{12}$$

$$H_0^{loc} = \overline{H_0} + \Delta H(z)\,, \quad \overline{H_0} = \lim_{z\to 0}\frac{z}{\overline{D}_L(z)} \tag{13}$$

$$\frac{\Delta H(z)}{\overline{H_0}} = -\frac{\Delta D_L(z)}{\overline{D}_L(z)} = -\frac{1}{3}f\overline{\delta}(z) \tag{14}$$

# Relativistic corrections to large scale structures

Lina Castiblanco, Radouane Gannouji, Jorge Noreña and Clément Stahl

*Instituto de Física, Pontificia Universidad Católica de Valparaíso, Casilla 4950, Valparaíso, Chile*
*clement.stahl@pucv.cl*

We investigate the relativistic corrections to the standard model of formation of large scale structures. In matter domination and in the Poisson gauge, we use the weak-field approximation which allows to keep compact expressions even for the one-loop bispectrum. Whereas in the Newtonian limit, the choice of gauge is marginally important as all gauge coincides, when relativistic corrections are taken into account, it matters as a change of gauge may induce a change of gravitational potential and introduce fictitious modes in the finial result for the power spectrum. It is precisely what happens in the example presented in this talk as the equivalence principle is not fulfilled in the Poisson gauge and the cancellation of the IR divergence at one-loop does not occur. We will discuss how other choices of gauge may solve this issue.

*Keywords*: Cosmology, Large Scale Structures, Relativistic corrections, Bispectrum, Non-gaussianities.

## 1. Introduction

Most of the large scale structures observables can be computed within a Newtonian approximation (see Ref. 1 for a review). On the large scales, at early enough time, the universe is in the linear regime and all gauges coincide with the Newtonian one. On the small scales, local processes for the formation of structures happen and gravity is well described by Newton's theory. However, reporting on Ref. 2, we argue that a proper calculation of the one-loop bispectrum requires to take into account relativistic corrections. Unlike the power spectrum which depends only on one Fourier mode by translation and rotation invariances, the bispectrum couples the scales[a] and therefore could get non-linear relativistic corrections that requires to go beyond the Newtonian gauge. We will present some steps toward calculating the one-loop bispectrum. In section 2, we present a weak field scheme which allows to keep the leading relevant relativistic corrections for cosmological spacetimes. In section 3, we describe the equations of motions for the dark matter perturbations and we solve them using perturbation theory. We present our results for the bispectrum in section 4 and finally present some further subtleties of this calculation and conclude in section 5.

## 2. Weak field approximation

The task of computing relativistic corrections in full GR is quite challenging even at second order, see *eg.* Refs. 3–5. However, on cosmological scales, gravity is

[a]It is possible to consider triangle configurations that have one large scale and two small scales: the so-called squeezed limit.

weak and to obtain reliable results, one does not need to consider the full GR. Mathematically, the weak field approximation[6–8] relies on the fact that the root mean square of the velocity of dark matter perturbations is small: $v \sim 10^{-3}$ and furthermore the gravitational potential is also small $\phi \sim 10^{-5}$. This allows to tread those two quantities perturbatively in the equation of motion. We note however that to derive the equations of motion of section 3, nothing is assumed regarding the density contrast of the dark matter field: $\delta \sim 1$ can happen in the small scales, at shell-crossing. A more systematic description of the weak field approximation can be found in table 1 of Ref. 2 and in the text around it.

## 3. Equations of motion

The metric we consider reads:

$$ds^2 = -(1+2\phi)dt^2 + 2\omega_i dx^i dt + a(t)^2\left[(1-2\psi)\delta_{ij} + h_{ij}\right]dx^i dx^j\,, \tag{1}$$

where we considered two gravitational potentials $\phi$ and $\psi$, frame dragging effects $\omega_i$ and gravitational waves $h_{ij}$. Applying the weak field scheme of section 2 and calculating the first two moments of the Boltzmann equation, supplemented by the Einstein equations, one finds[2]:

$$\dot{\delta}_R + \theta_R = -\int_{\boldsymbol{k}_1,\boldsymbol{k}_2} \alpha(\boldsymbol{k}_1,\boldsymbol{k}_2)(\theta_R(\boldsymbol{k}_1)\delta_N(\boldsymbol{k}_2) + \theta_N(\boldsymbol{k}_1)\delta_R(\boldsymbol{k}_2)) + \mathcal{S}_\delta[\delta_N]\,, \tag{2}$$

$$\dot{\theta}_R + 2H\theta_R + \frac{3}{2}H^2\delta_R = -2\int_{\boldsymbol{k}_1,\boldsymbol{k}_2} \beta(\boldsymbol{k}_1,\boldsymbol{k}_2)\theta_N(\boldsymbol{k}_1)\theta_R(\boldsymbol{k}_2) + \mathcal{S}_\theta[\delta_N]\,. \tag{3}$$

We have split the dynamical quantities ($\delta$, $\theta \equiv \partial_i v^i$) between a Newtonian part and a relativistic part, denoted by superscripts $N$ and $R$. The left hand sides of these equations describe the linear terms, an expression for the relativistic sources is given in appendix C of Ref. 2. The standard kernels $\alpha$ and $\beta$ describes usual non-linearities terms.

To solve Eqs. (2)-(3), we perform perturbation theory in the usual sense (see *eg.* Ref. 9) and expand the dark matter fields in powers of the linear density contrast $\delta_l$. This allows to define Newtonian kernels $F_n$ together with their relativistic counterparts $F_n^R$:

$$\delta(\boldsymbol{k},t) = \sum_{n=1}^{\infty} a^n(t) \int_{\boldsymbol{k}_1\ldots\boldsymbol{k}_n} \Big[F_n(\boldsymbol{k}_1,\ldots,\boldsymbol{k}_n) + a^2(t)H^2(t)F_n^R(\boldsymbol{k}_1,\ldots,\boldsymbol{k}_n)\Big]\delta_l(\boldsymbol{k}_1)\ldots\delta_l(\boldsymbol{k}_n)\,. \tag{4}$$

In appendix D of Ref. 2, expressions for the kernel up to $n = 4$ are presented in two gauges of interest: Poisson and synchronous-comoving.

## 4. Results

After solving the equations of motion, we are in position to present our main results: a plot of the bispectrum defined as

$$\langle\delta(\boldsymbol{k}_1,t)\delta(\boldsymbol{k}_2,t)\delta(\boldsymbol{k}_3,t)\rangle = (2\pi)^3\delta_D(\boldsymbol{k}_1+\boldsymbol{k}_2+\boldsymbol{k}_3)B(k_1,k_2,k_3,t)\,. \tag{5}$$

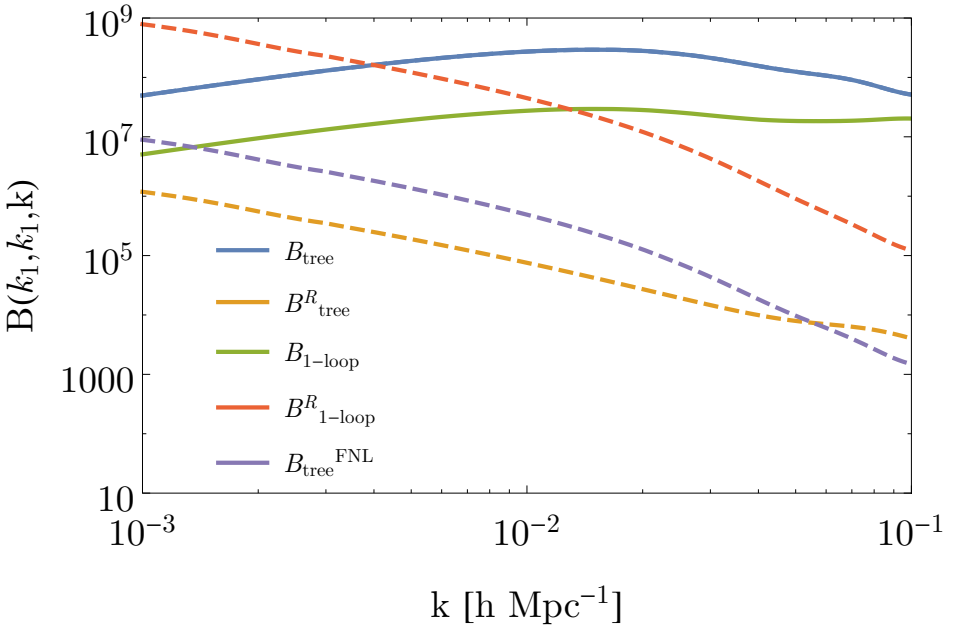

Fig. 1. In the squeezed configuration: $B(k_1, k_1, k)$, one-loop corrections to the linear bispectrum in Poisson gauge, with $k_1 = 0.1$ h Mpc$^{-1}$. Doted lines denotes a negative contribution. The qualitative reasoning discussed in the introduction holds and indeed relativistic corrections are important at large scales (small $k$) in squeezed configurations. Observe even that the relativistic one-loop results become larger than the tree-level Newtonian results and the perturbation theory breaks down in the IR. In purple, we ploted a signal that could come from primordial non-gaussianities with $f_{NL} = 1$.

Those results are contrasted with a synchronous gauge in Ref. 2.

## 5. Conclusions and perpectives

Due to lack of space, several issues were eluded in this proceeding, in particular, in section 5 of Ref. 2, some details are given about the renormalization of the background which is required in order to avoid infinities, the UV and IR behavior of the loop-integrals is also discussed there.

We have reported in this proceeding our new results on the one-loop bispectrum. We argued that taking into account GR is necessary as the bispectrum couples scales. We indeed found that the relativistic corrections becomes of the same order of magnitude than the Newtonian (linear) results.

These encouraging results invite to perform several steps in order to observe the bispectrum:

- Take into account, not only dark matter but galaxies which is done by introducing a set of bias parameters [10,11].

- Take into account the fact that what is observed in our telescopes is a redshift and a direction in the sky and not a position and a time. To do so, one goes to redshift space and takes into account the propagation of photons in our cuspy universe: those effects are sometimes dubbed *redshift space distortions* [12,13].

Other interesting roads includes to more precisely model th short scales, either with effective field theory [14], resummation [15] or renormalization group [16] techniques. The inclusion of a cosmological constant [17] $\Lambda$ is also in order opening also the door to further generalize to modified gravity scenario for cosmology.

## Acknowledgments

It is a pleasure to thank all the participants and speakers of this session for stimulating scientific discussions ans interaction during the meeting and during the nights. I am also very grateful to all the people who organized the Marcel Grossmann meeting: professors, staffs, secretaries, students....

# Self interacting dark matter and small scale structure

N. Q. Lan, G. J. Mathews, J. A. Coughlin and I.-S. Suh

*Center for Astrophysics, Department of Physics, University of Notre Dame*

*https://physics.nd.edu/people/faculty/grant-j-mathews*

The core-cusp problem remains as one of the unresolved challenges between observation and simulations in the standard ΛCDM model for the formation of galaxies. Basically, the problem is that ΛCDM simulations predict that the center of galactic dark matter halos contain a steep power-law mass density profile. However, observations of dwarf galaxies in the Local Group reveal a density profile consistent with a nearly flat distribution of dark matter near the center. A number of solutions to this dilemma have been proposed. We summarize investigations the possibility that the dark matter particles themselves self interact and scatter. The scattering of dark matter particles then can smooth out their profile in high-density regions. We also summarize theoretical theoretical models as to how self- interacting dark matter may arise. We summarize our own implementation this form in simulations of self-interacting dark matter in models for galaxy formation and evolution. Constraints on self-interacting dark matter are then summarized.

*Keywords*: Interacting Dark Matter; Dwarf Galaxies; Galactic Structure.

## 1. Introduction

The nature of most of the matter in the universe remains as one of the most challenging questions in modern physics.[1] Nevertheless, observational evidence from the Cosmic Microwave Background, galaxies cluster, weakly lensing, and the Lyman-$\alpha$ forest agree with the predictions of the ΛCDM model. Such models contain a mixture of roughly 25% collisionless cold dark matter such as WIMPs, axions, etc. interacting through the weak and gravitational forces only, and 70% vacuum energy or quintessence.[2,3] Only a fraction of the present total matter can be made of ordinary baryons has an unknown, nonbaryonic origin[4].

However, it is now appreciated (e.g. Ref. [5] and refs. therein) that conventional models of collisionless cold dark matter lead to problems with regard to galactic structure. They are only able to fit the observations on large scales ($\gg 1Mpc$). In particular, high-resolution $N$-body simulations in these models result in a central singularity of the galactic halos[6] and a large number of sub-halos[7] than observed. This is called the *Core-Cusp Problem*. A number of other inconsistencies are discussed in Refs. [5, 8, 9, 10]. In particular, the mass density profile for CDM halos increases toward the center, scaling approximately as $\rho_{\rm dm} \sim r^{-1}$. However, many observed rotation curves of disk and dwarf spheroidal galaxies prefer[11–13] a constant density profile $\rho_{\rm dm} \sim r^0$, as evidenced by a linearly rising circular velocity in the inner regions. This is most evident in dwarf and low surface brightness (LSB) galaxies since they are highly DM-dominated.

A possible way to avoid these problems is to hypothesize *self-interacting dark matter*[14] (SIDM). [Although self-interacting models lead to spherical halo centers in clusters. This is not in agreement with the inferred ellipsoidal centers indicated

by gravitational lensing[15] and by Chandra observations[16].]

Self-interacting dark matter models are well motivated as a model for particle dark matter. The key property of dark-matter particles is that they are non-relativistic and have have a weak scattering cross-section. The Spergel-Steinhard model[14] has motivated many follow-up studies[4,17,18] to identify a dark matter particle with self interactions. Here we constrain one particular model[19] with right-handed (RH) neutrinos for self-interacting dark matter based upon simulations of galactic structure. We deduce that the mass of the SIDM in this model in about an MeV. We compare numerical simulations to the observations.

The range of mass for SIDM is from ∼MeV with a mean free path and total cross section over mass from 0.1 cm$^2$ g$^-$1 to 100 cm$^2$ g$^{-1}$ can solve the core-cusp and the missing satellite problems of the ΛCDM model. In our model the cross section over mass $\sigma/m$ is in the range of 4 to 5 cm$^2$ g$^{-1}$. In large scale structure there is no difference between that of normal CDM and SIDM. However, on small scales galactic cores are consistent with all of the observational constraints. We analyze the small scale structure of the dark matter based upon the hydrodynamic simulations described in this work.

## 2. Model for self-interaction dark matter

The SM offers no options for dark matter. The first gauge model[20] for SIDM was found in the 3-3-1 model. To keep the Higgs sector with three triplets in that model the existence of *exotic leptons* was proposed. The 3-3-1 models were proposed with an independent motivation[21–23]. These models have the intriguing features that they are anomaly free only if the number of families $N$ is a multiple of three. If one adds the condition of QCD asymptotic freedom, which is valid only if the number of families of quarks is to be less than five, it follows that $N$ is equal to 3.

I this work we summarize the argument that the 3-3-1 model with right-handed (RH) neutrinos[24] contains such self-interacting dark matter.

The main properties that a good dark matter candidate must satisfy are stability and neutrality. Therefore, one should consider the scalar sector of the model, more specifically, the neutral scalars.[14]. In addition, such dark matter particles must not overpopulate the Universe. On the other hand, since our dark matter particle is not imposed arbitrarily to solve this specific problem, one must check that the necessary values of the parameters do not spoil the other bounds of the model.

Under the assumption of discrete symmetry $\chi \to -\chi$, the most general potential can then be written in the following form,[25]

$$\begin{aligned} V(\eta,\rho,\chi) = {} & \mu_1^2\eta^+\eta + \mu_2^2\rho^+\rho + \mu_3^2\chi^+\chi + \lambda_1(\eta^+\eta)^2 + \lambda_2(\rho^+\rho)^2 + \lambda_3(\chi^+\chi)^2 \\ & +(\eta^+\eta)[\lambda_4(\rho^+\rho) + \lambda_5(\chi^+\chi)] + \lambda_6(\rho^+\rho)(\chi^+\chi) + \lambda_7(\rho^+\eta)(\eta^+\rho) \\ & +\lambda_8(\chi^+\eta)(\eta^+\chi) + \lambda_9(\rho^+\chi)(\chi^+\rho) + \lambda_{10}(\chi^+\eta + \eta^+\chi)^2. \end{aligned} \quad (1)$$

Next one can write the expansion of the scalar fields which acquire a VEV:

$$\eta^o = \frac{1}{\sqrt{2}}\,(v + \xi_\eta + i\zeta_\eta)\,;\ \rho^o = \frac{1}{\sqrt{2}}\,(u + \xi_\rho + i\zeta_\rho)\,;\ \chi^o = \frac{1}{\sqrt{2}}\,(w + \xi_\chi + i\zeta_\chi)\,. \quad (2)$$

For the prime neutral fields which do not have a VEV, one finds analogously:

$$\eta'^{o} = \frac{1}{\sqrt{2}}\left(\xi'_{\eta} + i\zeta'_{\eta}\right);\ \chi'^{o} = \frac{1}{\sqrt{2}}\left(\xi'_{\chi} + i\zeta'_{\chi}\right). \tag{3}$$

To satisfy the requirements of stability and neutrality, one can go to the scalar sector of the model, more specifically to the neutral scalars. One must then whether any of them can be stable and are self-interacting. [14] In addition, such a dark matter particle must freeze out at the correct cosmic abundance. One can check through a direct calculation by employing the relevant Lagrangians that the Higgs scalar $h_0$ and $H_3^0$ can, satisfy these criteriona. Remarkably, they do not interact directly with any SM field except for the standard Higgs $H_1^0$. However, $h_0$ must be favored, since it is easier to obtain a large scattering cross section.

In contrast to the singlet models of Refs. 4, 18, 28, 29, 26, 27, where an extra symmetry must be imposed to account the stability of the dark matter, the decay of the $h_0$ scalar is automatically forbidden in all orders of perturbative expansion. This is because this scalar comes from the triplet $\chi$, that induces the spontaneous symmetry breaking of the 3-3-1 model to the standard model. Therefore, the SM fermions and the standard gauge bosons cannot couple with $h^0$. Also, the $h^0$ scalar comes from the imaginary part of the Higgs triplet $\chi$.The imaginary parts of $\eta$ and $\rho$ are pure massless Goldstone bosons. Thus, there are no physical scalar fields which can mix with $h^0$ and the only interactions of $h^0$ come from the scalar potential. They are $H_3^0 h^0 h^0$ and $H_1^0 h^0 h^0$. If $v \sim u \sim (100 \sim 200)$ GeV and $-1 \leqslant a_5 \sim a_6 \leqslant 1$, the $h^0$ can interact only weakly with ordinary matter through the Higgs boson of the standard model $H_1^0$. The relevant quartic interaction for scattering is thus $h^0 h^0 h^0 h^0$.

## 3. Structure formation in a SIDM Universe

In the work of Lan and Long, [19] it was deduced that the mass range for the dark matter is from 4.7MeV to 29 MeV. Our dark matter is non-relativistic with decoupling temperature $\sim$ 1eV. Dark matter does not interact with any particles in the standard model except Higgs Boson, so one need not deal with any collision terms. The self-interacting dark matter in the 3-3-1 model of Ref. [19] is non-relativistic driving the decoupling era with a decoupling temperature about 1eV. So we have $g_{\mu\nu}P^{\mu}P^{\nu} = m^2$, where m is the mass of the dark matter particles, $g_{\mu\nu}$ is the full metric tensor, and $P^0 = \sqrt{q^2 + m^2 a^2}(1 - \phi)$. We can define the energy $q = \sqrt{(p^2 + m^2)}$, where $p$ the is magnitude of momentum.

If one defines $\beta = n_h/T^3$ in the radiation dominated era one write the evolution Boltzmann Equation as

$$\frac{d\beta}{dT} = -\frac{\Gamma\beta}{KT^3} = -\frac{\alpha}{8\pi^3 K e^{m_1/T}}\left(\frac{\Theta}{T^2}\right)^2 \tag{4}$$

where $K^2 = 4\pi^3 g(T)/45m_{Pl}^2$ and $\beta = \frac{n_h}{T^3}$ are parameters of thermal equilibrium and $m_{PL}$ is the Planck mass. We take $T = m_1$ so that the cosmic density of the $h_0$

scalar is

$$\Omega_h = 2g(T_\Gamma)T_\gamma^3 \frac{m_h \beta}{\rho_c g(T)} \tag{5}$$

where $T_\gamma = 2.4 \times 10^{-4}$ eV is the present photon temperature, $g(T_\gamma) = 2$ is the photon degree of freedom and $\rho_c = 7.5 \times 10^{-47} h^2$, with h = 0.71, being the critical density of the Universe. Let us take $m_h = 7.75$ MeV, v = 174 GeV, $a_5 = 0.65$, $-a_6 = 0.38$ (actually in our calculations, we have used a better precision for $a_5$ and $a_6$) and $m_1 = 150$ GeV. Thus, from we obtain $\Omega_h = 0.3$. Therefore, without imposing any new fields or symmetries, the 3-3-1 model possesses a scalar field that can satisfy all the properties required for the self-interacting dark matter and does not overpopulate the Universe.

## 4. Constraint with CMB and galaxy simulation

We have simulated of the formation of a dwarf galaxy of $10^{10} M_\odot$ halos of self interacting dark matter (SIDM) with cross section over mass in the range $\sigma/m = 3.7$ to 5.2 cm$^2$ g$^{-1}$. We used a cosmological model with parameters $\Omega_\Lambda = 0.734$, $\Omega_m = 0.266, \Omega_b = 0.0449, n_s = 0.963, h = 0.71, \sigma_8 = 0.801$ (Komatsu et al. 2011). We start with isolated halo galaxies with a stellar mass of $M_{star} = 1.4 \times 10^{11} M_\odot$ and temperature $T = 10^4$K with in a box size of $50 Mpch^{-1}$.

Figure 1 shows an example of our inferred SIDM radial profile for a best fit of $\sigma/m = 4$ cm$^2$ g$^{-1}$. It shows a flattening toward the center as required by observation.

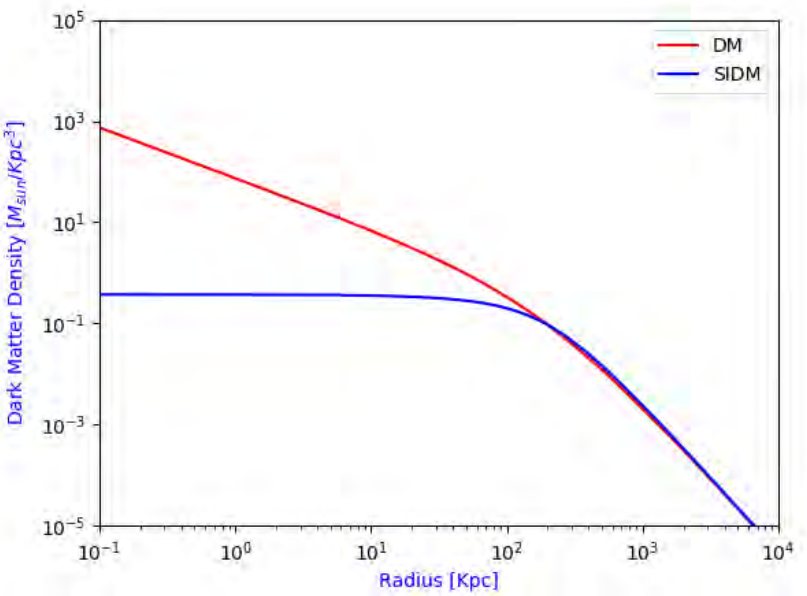

Fig. 1. Galaxy profile calculated with (blue line) and without (red line) SIDM from a fit to the numerical simulations.

This brief review covers recent results on searches for dark matter in collider experiments, as well as from direct and indirect detection observatories. It focuses on generic searches for dark matter signatures at the LHC, e.g. mono-$X$, dijets, etc. Recently observed astrophysical signals that may provide hints of dark matter are also discussed.

*Keywords*: Dark matter; Direct detection; Indirect detection; LHC.

## 1. Introduction

Dark matter (DM) still remains one of the most puzzling and fascinating mysteries in Fundamental Physics nowadays. The quest for unveiling its nature encompasses Cosmology, Astroparticle and Particle Physics. Observations over the past decades — obtained by combining a variety of astrophysical data, such as type-Ia supernovae, cosmic microwave background (CMB), baryon oscillations and weak lensing data — indicate that most of our Universe energy budget consists of unknown entities: $\sim 27\%$ is dark matter and $\sim 68\%$ is dark energy,[1] a form of ground-state energy.

## 2. DM Candidates

Weakly interacting massive particles (WIMPs) are the leading class of candidates for cold DM (CDM). They are thermal relics from Big Bang and the measured relic density implies that the DM annihilation cross section is of the same order as the one characterising the weak interaction scale, constituting the so-called "WIMP miracle". Specific theoretical models may provide naturally a DM particle, such as supersymmetry (SUSY), extra dimensions and little Higgs models.

Other non-WIMP possibilities to explain the DM observations are superWIMPs (gravitinos, axinos), axions, (sterile) neutrinos, fuzzy CDM, Q-balls, WIMPzillas and macroscopic objects, such as primordial black holes.[2] New paradigms are continuously being proposed, partly as a result of interplay with observations. For instance, self-interacting DM has been proposed to ameliorate observed tensions between $N$-body simulations of collisionless CDM and astrophysical observations on galactic scales: cusp-vs-core problem, too-big-to-fail problem, missing-satellite problem, diversity problem.[3–5]

## 3. Direct Detection

Direct detection (DD) of DM involves the observation of elastic scattering of WIMP off nuclei. It is sensitive to the WIMP mass $m_\chi$ and the cross section $\sigma_{\chi\text{–nucleon}}$.

A low-energy threshold in the WIMP-induced recoils is required for an efficient DD experiment, as well as reliable shielding of the detector from radioactive sources and cosmic backgrounds. The background suppression relies on the ability to distinguish nuclear recoils against other possible processes, such as electrons and $\alpha$-particles. Lastly, stable detector operation during annual and diurnal modulation is required.

The use of different targets safeguards against nuclei-related systematic uncertainties. Liquid noble gases, such as Xenon and Argon, offer sensitivity over the widest WIMP-mass range from 5 GeV to 1 TeV (Darkside, DARWIN, DEAP3600, LUX, LZ, Panda-X, XENON). The (oldest) technology of cryogenic crystals presents new innovations and covers $m_\chi \sim 1 - 10$ GeV (CRESST, EDELWEISS, SuperCDMS). Alternative targets with unique properties include NaI crystals and bubble chambers (ANAIS, COSINE, DAMA/LIBRA, SABRE, PICO). A recent review of DD concepts and status is given in Ref. 6.

No signal of dark matter in direct detection has been observed so far. The only persisting "anomaly" over several years is the annually modulating signal observed by DAMA/LIBRA, a massive array of low-background NaI(Tl) crystals installed in the Gran Sasso underground laboratory. This modulation has been seen in various phases of the detector and its period and phase are consistent with the expectation from the standard DM halo model.[7]

As the sensitivity in cross section lowers, it reaches the so-called "neutrino floor", i.e. where the (irreducible) neutrino-flux background becomes dominant. Some DM models, e.g. SUSY or Composite Higgs[8] models, are still viable in regions of the $\sigma_{\chi\text{–nucleon}}$-vs.-$m_\chi$ plane. Some caveats apply to the DD results. The astrophysical uncertainties on the local DM density and DM velocity distribution are typically large. On the particle physics side, the way DM interacts with the detector is only partially known, while other nuclear-physics uncertainties may be considerable.

## 4. Indirect Detection

In the indirect detection (ID) of DM, the focus is on the DM-particle decay or annihilation products in the galactic centre, dwarf galaxies, etc. Several probes are used as messengers, such as neutrinos, photons, antiprotons, and positrons. This class of observations may distinguish among different WIMP candidates: neutralinos, KK states, etc. Detection and analysis techniques used in ID and results are detailed in Ref. 9. Several hints of DM annihilation have been observed in data over the years frequently being attributed to astrophysical origin. Here, we outline two recent observations: excess of GeV gamma rays and the 21-cm signal line.

A spatially extended excess of $\sim 1 - 3$ GeV $\gamma$ rays from the region surrounding the Galactic Center has been identified, consistent with the emission expected from annihilating dark matter. High resolution $\gamma$-ray maps, such as the one shown in Fig. 1, render the excess robust and highly statistically significant, with a spectrum, angular distribution, and overall normalisation that is in good agreement with that predicted by simple annihilating $36 - 51$ GeV DM particle annihilating to $b\bar{b}$.[10]

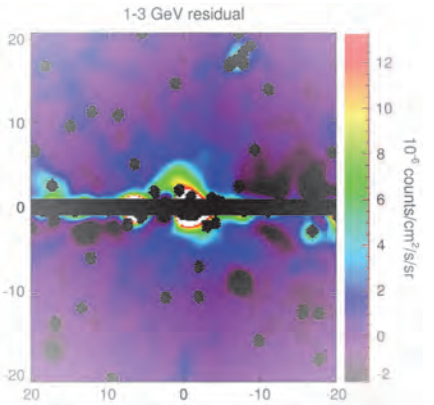

Fig. 1. Gamma-ray sky map after subtracting the point source model and the best-fit Galactic diffuse model, Fermi Bubbles, and isotropic templates. From Ref. 10.

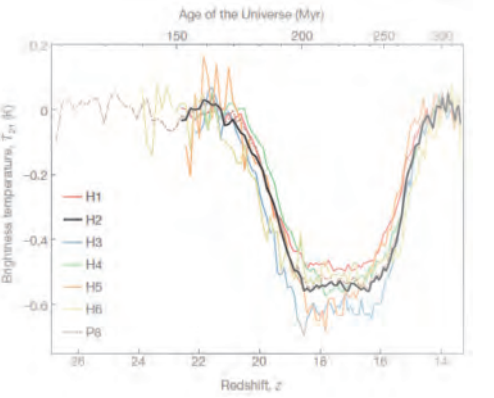

Fig. 2. Best-fitting 21-cm absorption profiles for different hardware cases of the EDGES experiment. The thick black line is the model fit with the highest signal-to-noise ratio. From Ref. 11.

The Experiment to Detect the Global EoR Signature (EDGES) is a radio-telescope for detection of hydrogen signatures from the Epoch of Reionisation (EoR), soon after the formation of the first stars and galaxies. The Collaboration reported the observation of an unexpectedly deep absorption in the radio background at 78 MHz, shown in Fig. 2, based on their low-band instruments and interpreted it as a redshifted 21-cm line.[11] It is unlikely that radiation from stars and stellar remnants to account for this discrepancy. Cooling of gas as a result of interactions between dark matter and baryons seems to explain the observed amplitude.

## 5. Searches at the LHC

The ATLAS and CMS experiments have embarked upon searches for signals of DM produced at the LHC early on during data taking.[12] Theoretical models, such as supersymmetry[13] or theories with extra-dimensions[14] provide a natural DM candidate, hence searches targeting these models implicitly cover dark matter, too. Since the candidate is only weakly interacting with matter, the common feature among these analyses is the requirement for large missing momentum $E_{\mathrm{T}}^{\mathrm{miss}}$. These models offer definite predictions, however they are characterised by a large number of parameters and this approach is profoundly model dependent.

The first generic approach towards DM searches involved the deployment of effective field theories (EFTs), extensively used in Run 1 (2010–2012). In this method, the interaction between DM and Standard Model (SM) particles is described by effective operators. It is clearly less model independent, yet it is only valid for low-momentum transfers $Q^2 \ll M_{\mathrm{med}}^2$, where $M_{\mathrm{med}}$ is the mediator mass.

A third approach extensively followed in Run 2 (2015–2018) assumes simplified topologies where the DM and SM particles interact via a mediator $(Z', H)$.[15] Its

advantage is that it covers features of a whole class of models and remains valid at high energies. In addition, it is described by a relatively small number of free parameters, namely the mediator and DM masses $M_{\text{med}}$ and $m_\chi$ and the mediator couplings to SM and DM particles $g_{\text{SM}}$ and $g_{\text{DM}}$, respectively.

Concerning the final states, DM cannot be directly observed at the LHC, however DM-pair production can be detected via the presence of an imbalance in measured transverse momenta of visible particles. The DM pair may only give rise to large $E_{\text{T}}^{\text{miss}}$, if it recoils to an energetic particle $X$, hence the so-called mono-$X$ searches, where $X$ is a jet,[16] a photon,[17] a top, a (hadronically[16] or leptonically[18] decaying) $W/Z$ boson. When $X = H(\to b\bar{b}, \gamma\gamma, \tau\tau)$ coupled to DM through a BSM effective vertex, it provides a direct probe of the DM–SM coupling. Additionally, the associated production of DM with $t\bar{t}$[19,20] and $b\bar{b}$[20] pairs is considered.

In addition to the dedicated analyses for DM, constraints can be extracted from recasting searches for heavy resonances. For an assumed $Z'$ mediator, the final states can be two quarks ("dijet"),[21,22] two Higgs bosons ($\to b\bar{b}, \tau\tau$), $H\gamma \to b\bar{b}\gamma$. Such searches are only sensitive to the mediator–SM particle coupling, e.g. the mediator–quark coupling in the case of dijet resonances. A wide range of mediator masses are covered with these analyses with/without jet/$\gamma/W$ initial state radiation.

The complementarity between the results from DM direct detection and related LHC searches is shown in Fig. 3. CMS limits do not include relic-density constraints and their relative importance strongly depend on the chosen coupling and model

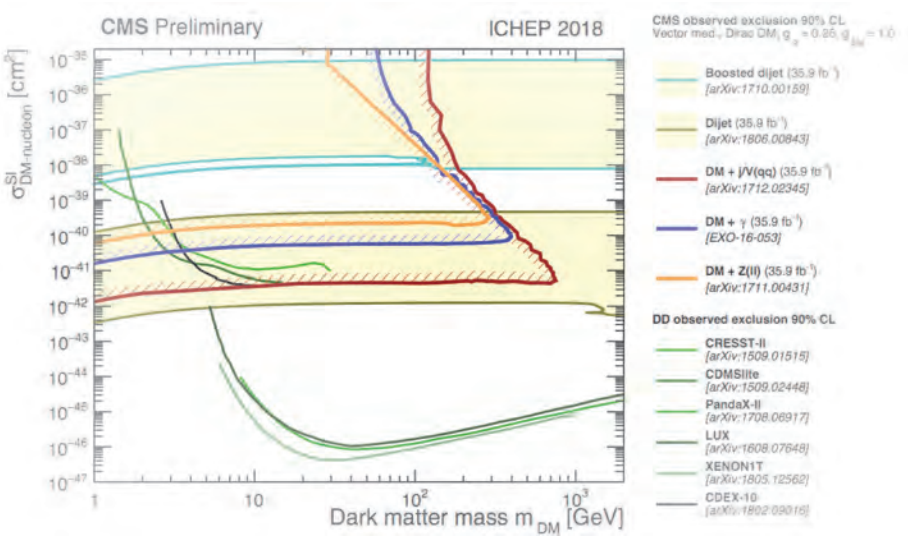

Fig. 3. CMS DM exclusion limits at 90% CL in the $m_{\text{DM}} - \sigma_{\text{SI}}$ plane for a vector mediator, Dirac DM and couplings $g_q = 0.25$ and $g_{\text{DM}} = 1.0$ compared with the XENON1T,[23] LUX,[24] PandaX-II,[25] CDMSLite[26], CDEX[27] and CRESST-II[28] limits, which constitute the strongest constraints in the shown mass range. From Ref. 29.

scenario. Therefore, the shown CMS exclusion regions in this plot are not applicable to other choices of coupling values or models.

## 6. Summary

Signals of dark matter are sought after in direct and indirect detection and in production in colliders. Additional constraints are obtained from cosmological observations on its nature (thermal/non-thermal, super/sub/relativistic, etc.) and on its relic density. Some still unexplained evidence in DD and ID are under investigation taking into account additional systematic uncertainties that matter–DM interactions may hinder and the strong dependence of the ID & DD results interpretation on astrophysical assumptions. In parallel, the LHC experiments search for DM in a variety of channels following different approaches and strategies characterised by high dependency on theoretical models and/or assumptions. Some approaches provide access to the mediator nature than to DM itself, rendering a possible signal difficult to be assigned to DM. The quest for dark matter continues in all fronts.

We consider the impact of dynamical dark energy (DDE) in the possible solution of the existing tensions in the ΛCDM. We test both interacting and non-interacting DE models with dark matter (DM). Among the former, the running vacuum model (RVM) interacting with DM appears as a favored option. The non-interacting scalar field model based on the potential $V \sim \phi^{-\alpha}$, and the generic XCDM parametrization, also provide consistent signs of DDE. The important novelty of our analysis with respect to the existing ones in the literature is that we use the matter bispectrum, together with the power spectrum. Using a complete and updated set of cosmological observations on SNIa+BAO+$H(z)$+LSS+CMB, we find that the crucial triad BAO+LSS+CMB (i.e. baryonic acoustic oscillations, large scale structure formation data and the cosmic microwave background) provide the bulk of the signal. The bispectrum data is instrumental to get hold of the DDE signal, as our analysis shows. If the bispectrum is not included, the DDE signal could not be currently perceived at a significant confidence level.

*Keywords*: Cosmological constant; dark energy theory; cosmological parameters; structure formation; cosmic microwave background.

## 1. Introduction

The cosmological constant problem in the context of quantum field theory (QFT) is well known. Already in the standard model of particle physics the value of the vacuum energy density $\rho_\Lambda$ is predicted to be some 55 orders of magnitude higher than the measured value, $\rho_\Lambda \sim 10^{-47}$ GeV$^4$ see Refs. 1–5. Rather than attempting to solve this problem here, we adopt a pragmatic point of view and consider the possibility to test whether the vacuum energy, and in general the dark energy (DE), is dynamical or not in the light of the current observations. This might help to shed some light not only on how to cure the CC-problem eventually, but also on how to solve some of the existing tensions between the ΛCDM model and observations, like the $H_0$-tension (the mismatch between the Planck measurements of $H_0$ and the local measurements based on the distance ladder approach)[6–8] and the $\sigma_8$-tension, which is described in terms of the combined observable $f(z)\sigma_8(z)$, where $f(z)$ is the linear growth rate and $\sigma_8(z)$ is the RMS matter fluctuation on scales of $R_8 = 8h^{-1}$ Mpc at redshift $z$. The corresponding prediction of the ΛCDM is known to be exceedingly large and hence the description of the LSS data is poorly accounted for by the concordance model.[9,10] In the following we briefly review how dynamical dark energy (DDE) can lend a helping hand on trying to solve some of these problems, although the evidence of DDE (or lack of it) varies significantly if taking different

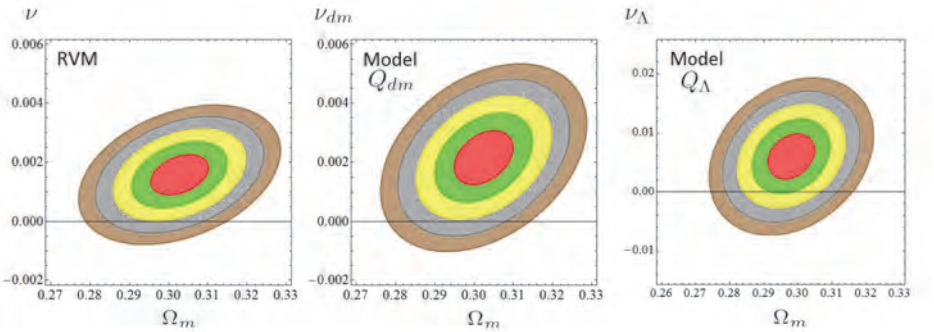

Fig. 1. Likelihood contours for the three DVMs (3)-(5) in the $(\Omega_m, \nu_i)$ plane up to $5\sigma$ c.l. after marginalizing over the rest of the fitting parameters. Use is made of SNIa+BAO+$H(z)$+LSS data and compressed CMB Planck 2015 data. The $\Lambda$CDM ($\nu_i = 0$) appears disfavored in front of the DVMs. In particular, the RVM and the $Q_{dm}$ are favored at $\sim 3\sigma$ c.l. See Ref. 14 for details on the SNIa+BAO+$H(z)$+LSS+CMB data used in our fit. We note, in particular, that bispectrum data is also included.[20]

studies in the literature, see Refs. 11–17 and the more recent analyses 18, 19 and references therein.

## 2. Cosmology beyond $\Lambda$ = const.

The Friedmann and acceleration equations when the vacuum evolves with the cosmic expansion, $\rho_\Lambda = \rho_\Lambda(t)$ can be written formally similar to the standard case when $\rho_\Lambda$ =const. If we focus on flat FLRW metric, the field equations that incorporate vacuum dynamics read

$$3H^2 = 8\pi G(\rho_m + \rho_\Lambda(t))\,, \qquad 2\dot{H} + 3H^2 = -8\pi G(w_m\rho_m + w_\Lambda\rho_\Lambda(t))\,, \tag{1}$$

where $w_m = 1/3, 0$ for relativistic and nonrelativistic matter, and $w_\Lambda = -1$ for the vacuum (irrespective of its time evolution). Hereafter we assume $w_\Lambda = -1$ – see 12 for the analysis of the general case with $w_\Lambda = -1+\epsilon$ ($|\epsilon| \ll 1$), i.e. for quasivacuum models. The total matter density $\rho_m$ involves the contributions from baryons and cold dark matter (DM): $\rho_m = \rho_b + \rho_{dm}$. We assume that the DM component is the only one that interacts with vacuum, whilst radiation and baryons are taken to be self-conserved, hence $\rho_r(a) = \rho_r^0\, a^{-4}$ and $\rho_b(a) = \rho_b^0\, a^{-3}$, where the superscript zero denotes the current values. The DM component, instead, exchanges energy with the vacuum, and the local conservation law reads

$$\dot{\rho}_{dm} + 3H\rho_{dm} = Q\,, \qquad \dot{\rho}_\Lambda = -Q\,. \tag{2}$$

The form of the source function $Q$ depends on the assumptions made on the dynamical vacuum model (DVM). Let us consider three model possibilities, one is the "running vacuum model" (RVM) — see Refs. 3–5. and references therein — and the other two are called the $Q_{dm}$ and $Q_\Lambda$ models, whose names bear relation to the

structure of the interaction source. For convenience they can also be labeled I, II and III:

$$\text{Model I (RVM)}: \; Q = \nu\, H(3\rho_m + 4\rho_r) \tag{3}$$

$$\text{Model II } (Q_{dm}): \; Q_{dm} = 3\nu_{dm} H \rho_{dm} \tag{4}$$

$$\text{Model III } (Q_\Lambda): \; Q_\Lambda = 3\nu_\Lambda H \rho_\Lambda\,. \tag{5}$$

Each model is characterized by a (dimensionless) coupling parameter $\nu_i = \nu, \nu_{dm}, \nu_\Lambda$ in the interaction source, to be fitted to the observational data. In the RVM case, the source function $Q$ in (3) can be derived from the following vacuum energy density:

$$\rho_\Lambda(H) = \frac{3}{8\pi G}\left(c_0 + \nu H^2\right)\,, \tag{6}$$

which can be motivated in QFT, see Ref. 3.[a] The other two models do not possess an analogous property and therefore are more *ad hoc*. The additive constant $c_0$ in (6) is fixed by the boundary condition $\rho_\Lambda(H = H_0) = \rho_\Lambda^0$, where $H_0$ is the current Hubble rate and $\rho_\Lambda^0$ is the present measured value for $\rho_\Lambda$. The dimensionless parameter $\nu$ encodes the dynamics of the vacuum and can be related with the $\beta$-function of the $\rho_\Lambda$-running.[3] Therefore we naturally expect $|\nu| << 1$ in QFT. Here we will treat $\nu$ as a free parameter of the RVM and, as indicated, it will be fitted to the data.

In Fig. 1 we display the fitting results on the $(\Omega_m, \nu_i)$-planes for the three models I, II and III (corresponding to $\nu_i = \nu, \nu_{dm}, \nu_\Lambda$), where $\Omega_m$ is the usual matter parameter at present. In Fig. 2 we can better appraise the impact of the various data sources on these contour plots in the specific case of the RVM, see Ref. 14 for details. The DDE option ($\nu \neq 0$, actually $\nu > 0$) is clearly favored in the last plot when we combine the crucial triad of BAO+LSS+CMB data.

## 3. Analytical solution of the dynamical vacuum models

One can solve Models I, II and III analytically in terms of the scale factor.[14] The DM density in the case of the RVM (Model I) as a function of the scale factor is

$$\rho_{dm}^{(I)} = \rho_{dm}^0\, a^{-3(1-\nu)} + \rho_b^0\left(a^{-3(1-\nu)} - a^{-3}\right) - \frac{4\nu\rho_r^0}{1+3\nu}\left(a^{-4} - a^{-3(1-\nu)}\right) \tag{7}$$

and that of the vacuum energy density reads

$$\rho_\Lambda^{(I)} = \rho_\Lambda^0 + \frac{\nu}{1-\nu}\left[\rho_m^0\left(a^{-3(1-\nu)} - 1\right) + \rho_r^0\left(\frac{(1-\nu)\,a^{-4} + 4\nu a^{-3(1-\nu)}}{1+3\nu} - 1\right)\right]. \tag{8}$$

The total matter density is just the sum of the conserved baryonic and radiation densities and the above DM density. As can be easily checked, for $\nu \to 0$ we recover the corresponding results for the ΛCDM, as it should.

[a] The structure of the vacuum energy density in the running vacuum model can also be motivated from the effective behavior of the power-law solutions of Brans-Dicke gravity, see Ref. 21.

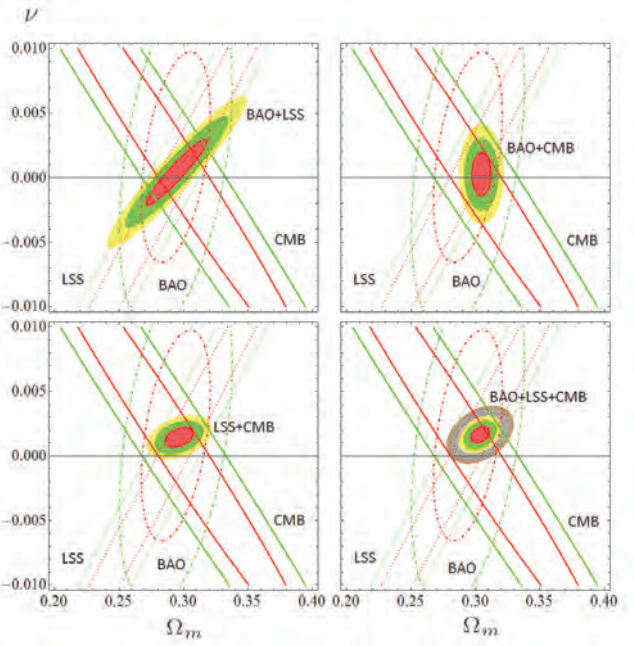

Fig. 2. Contour lines for the RVM by considering the effect of only BAO, LSS and CMB in all the possible pairings. Same data as in Fig. 1. Remarkably the simultaneous combination of these three observables is able to capture signs of running vacuum at a confidence level of $\gtrsim 3\sigma$ .

For Model II:

$$\rho_{dm}^{(II)}(a) = \rho_{dm}^{0}\, a^{-3(1-\nu_{dm})} \tag{9}$$

and

$$\rho_{\Lambda}^{(II)}(a) = \rho_{\Lambda}^{0} + \frac{\nu_{dm}\,\rho_{dm}^{0}}{1-\nu_{dm}}\left(a^{-3(1-\nu_{dm})} - 1\right). \tag{10}$$

And for Model III:

$$\rho_{dm}^{(III)}(a) = \rho_{dm}^{0}\, a^{-3} + \frac{\nu_{\Lambda}}{1-\nu_{\Lambda}}\rho_{\Lambda}^{0}\left(a^{-3\nu_{\Lambda}} - a^{-3}\right) \tag{11}$$

and

$$\rho_{\Lambda}^{(III)}(a) = \rho_{\Lambda}^{0}\, a^{-3\nu_{\Lambda}}\,. \tag{12}$$

Let us also briefly consider the simplest parametrization for DDE, namely the XCDM,[22] in which the DE density as a function of the scale factor is simply given by $\rho_X(a) = \rho_{X0}\, a^{-3(1+w_0)}$, with $\rho_{X0} = \rho_{\Lambda 0}$. Here $w_0$ is the (constant) EoS parameter. Last, but not least, we also study a scalar field model, denoted as $\phi$CDM. In this type of models the DE has a well-defined local Lagrangian description in terms

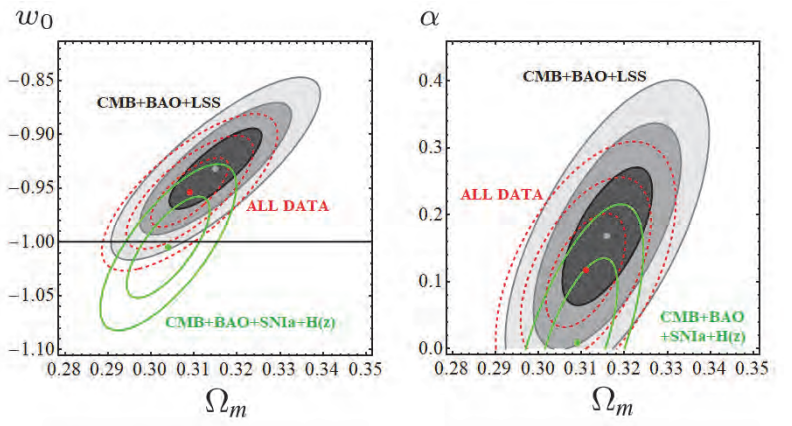

Fig. 3. Contour plots for the XCDM parametrization (left) and $\phi$CDM (right), using all sources of data (including LSS with bispectrum) as compared to using all data except LSS. Here we use Planck 2018 data with compressed CMB likelihood. When LSS (with bispectrum) is included, DDE appears once more favored at $\sim 3\sigma$ c.l. See Ref. 18 for details.

of a scalar field. Taking $\phi$ dimensionless the energy density and pressure read

$$\rho_\phi = \frac{M_P^2}{16\pi}\left(\frac{\dot\phi^2}{2} + V(\phi)\right) \qquad p_\phi = \frac{M_P^2}{16\pi}\left(\frac{\dot\phi^2}{2} - V(\phi)\right), \tag{13}$$

where $M_P$ is the Planck mass, which in natural units takes the value $M_P = 1/\sqrt{G}$ $= 1.2211\times10^{19}$ GeV. Note that in our conventions $V(\phi)$ has dimension 2 in natural units. The scalar field satisfies the Klein-Gordon equation in the context of the FLRW metric $\ddot\phi + 3H\dot\phi + \partial V(\phi)/\partial\phi = 0$. Here, as a particular case, we consider the original quintessence potential by Peebles and Ratra:[23]

$$V(\phi) = \frac{1}{2}\kappa M_P^2 \phi^{-\alpha}, \tag{14}$$

where $\kappa$ and $\alpha$ are dimensionless. The parameter $\alpha$ should be positive and sufficiently small so that $V(\phi)$ can mimic approximately a CC slowly decreasing with time, such that it can eventually surface (near our time) over the rapidly decaying matter density. In Fig. 3 we can see the corresponding contour lines for both the XCDM and $\phi$CDM, using SNIa+BAO+$H(z)$+LSS data (including the bispectrum component for the LSS+BAO data from Ref. 20) and compressed CMB Planck 2018 likelihood. The DDE option is consistently favored in both cases since $w_0 > -1$ (for the XCDM) and $\alpha > 0$ (for the $\phi$CDM) at $\lesssim 3\sigma$ c.l. after marginalizing over $\Omega_m$ [b]. Failure of including the bispectrum component (which seems to be particularly sensitive to the dynamics of the DE) may explain why other recent analyses on interacting vacuum and $\phi$CDM could not trace signs of DDE, see e.g., Refs. 16, 17.

[b]We should point out that a similar level of evidence is obtained using Planck 2015 data with full (i.e. non-compressed) CMB likelihood, see Ref. 18 for details.

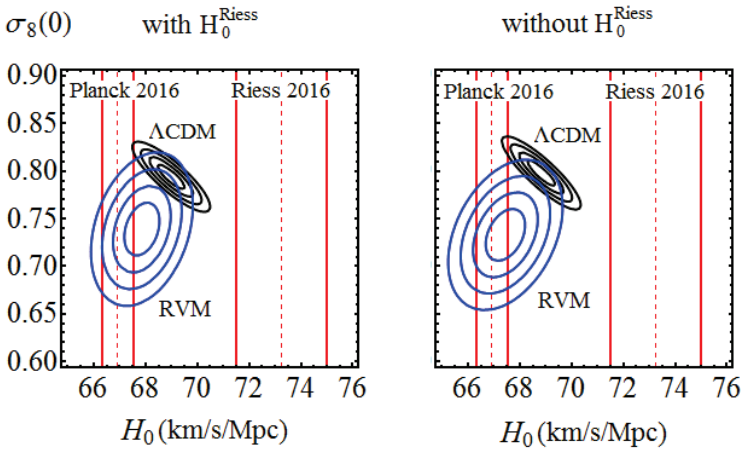

Fig. 4. Contour lines for the ΛCDM (black) and RVM (blue) up to $4\sigma$ in the $(H_0, \sigma_8(0))$-plane[12]. On the left plot we have included the R16 point[8] on $H_0$ in our fit, whereas on the right plot it was not included. In both cases the favored range for $H_0$ is the Planck range. At the same time the optimal (lower) $\sigma_8(0)$ values are attained by the RVM, see Eq. (3), whereas the ΛCDM yields too large values.

## 4. Dealing with the tensions through vacuum dynamics

As indicated in the introduction, one of the persisting tensions with the ΛCDM is the discrepancy between the Planck value of the Hubble parameter $H_0$ obtained from the CMB anisotropies, and the local HST measurement (based on distance ladder estimates from Cepheids). The latter reads $H_0 = 73.24 \pm 1.74$ km/s/Mpc (referred to as R16) and $H_0 = 73.48 \pm 1.66$ km/s/Mpc (R18).[8] In contrast, the CMB value is $H_0 = 67.51 \pm 0.64$ km/s/Mpc, as extracted from Planck 2015 TT,TE,EE+lowP+lensing data, or $H_0 = 66.93 \pm 0.62$ km/s/Mpc, based on Planck 2015 TT,TE,EE+SIMlow data.[6] In both cases there is a tension above $3\sigma$ c.l. with respect to the local measurement. This controversial situation has stimulated a lot of discussion in the literature. For instance, in Ref. 24 the phantom DE option is exploited as a means to solve the tension. In contrast, in Ref. 12 it is proposed that vacuum and quasivacuum dynamics support the Planck measurement of $H_0$ against the local measurement with no need of phantom behavior. A similar conclusion is reached with the XCDM and $\phi$CDM models studied here.[18] In addition, a variety of model-independent approaches such as the Inverse Distance Ladder method or the Multi-Task Gaussian Process[25] as well as other techniques (e.g., the Weighted Polynomial Regression[26]) do also support a lower value of $H_0$ in the ballpark of Planck CMB measurements and hence in full consistency with DDE.

The $H_0$-tension is closely connected with another type of problem, which is the role played by the LSS data, namely the data on $f(z)\sigma_8(z)$. There seems to be no way at present to correctly account for both the CMB and the LSS data within

the ΛCDM. This new pitfall is at the root of the so-called $\sigma_8$-tension, one of the most intriguing phenomenological problems of the ΛCDM.[9,10] The problem has been dealt with in the literature from a variety of points of view, see e.g., Refs. 27, 28. Here we will focus once more on the possibility of DDE.[12–14,18]

In the presence of interacting vacuum the perturbations equations of the ΛCDM must be modified appropriately.[13,14] The detailed analysis of these matters performed in the mentioned references provides the basis for a possible solution to the $\sigma_8$-tension within the RVM. In Fig. 4, we present the likelihood contours in the $(H_0, \sigma_8(0))$-plane. In the left plot we show the situation when the local $H_0$ value R16 is included in the fit, whereas in the right plot we show the case when that local value is *not* included. The plots for the more updated R18 value would be almost indistinguishable from the R16 ones. From Fig. 4 we can see that in order to reach the R16 neighborhood the contours should be extended beyond the $5\sigma$ c.l., which would lead to a too large value of $\sigma_8(0)$ for the RVM. One can also show that it would lead to a too low value of $\Omega_m$.[12]

Notice that $H_0$ and $\sigma_8(0)$ are positively correlated in the RVM (i.e. $H_0$ increases/decreases when $\sigma_8(0)$ increases/decreases, respectively), whilst they are anticorrelated in the ΛCDM ($H_0$ increases when $\sigma_8(0)$ decreases, and vice versa). The simultaneous $H_0$ and $\sigma_8(0)$ tensions could only be resolved simultaneously if the contours are extended well beyond $5\sigma$ at the expense of values of $\Omega_m$ below 0.27. However, this does not seem to be the most likely solution. Vacuum dynamics offers a better scenario. The opposite correlation feature with respect to the ΛCDM allows e.g., the RVM to improve the LSS fit in the region where both $H_0$ and $\sigma_8(0)$ are smaller than the respective ΛCDM values (cf. Fig. 4). This explains why the Planck range for $H_0$ is clearly preferred by the RVM, as it allows a much better description of the LSS data. One can also derive similar conclusions using the XCDM and $\phi$CDM, see Ref. 18, where again a positive correlation between $H_0$ and $\sigma_8(0)$ is found and the LSS tension can then be relaxed in the range of Planck values of $H_0$.

## 5. Conclusions

We have analyzed the ability of dynamical dark energy (DDE) models to fit the overall cosmological observations as compared to the ΛCDM. We find that there is non-negligible evidence that these models are more favored. Furthermore, DDE is capable of smoothing out the LSS tensions of the concordance model with the data, and they favor the (lower) Planck value of $H_0$ over the local one.

# Tests of Pauli Exclusion Principle as a new frontier of quantum gravity phenomenology

Andrea Addazi*

*Department of Physics & Center for Field Theory and Particle Physics, Fudan University, 200433 Shanghai, China*
** E-mail: andrea.addazi@lngs.infn.it*

Pauli Exclusion Principle violating transitions in atoms and nuclei are predicted from many models of non-commutative space-time, such as $\theta$-Poincaré theory. Exclusion sensitivity curves from DAMA/LIBRA and BOREXINO are so powerful to exclude many non-commutative space-time models until the Planck energy scale. A new frontier of quantum gravity phenomenology is opened, inspiring future underground projects with a higher sensitivity then current experiments.

*Keywords*: Pauli Exclusion Principle violations, quantum gravity, underground experiments.

The Pauli Exclusion Principle (PEP) states that no any electrons, or other identical fermions, can be in the same quantum mechanical state [1]. On the basis of it, electrons organize themself in the well known tower of atomic levels, as similarly nucleons in nuclei. A state with two electrons with the same aligned spins on the same orbital level is prohibited. Therefore, PEP is directly connected to the same anthropic existence since related to atomic and nuclei matter stability. However, the anthropic argument is not the only reason of PEP in Nature: such a principle emerges out from the Spin Statistic Theorem (SST) of relativistic quantum field theory – defining the quantum statistical properties of bosons (integer spins) and fermions (1/2 spin).

Many examples, in which the SST is effectively violated, can be found in many exotic new condensed matter materials, where, of course, pseudo-particle fields propagate in a non-Lorentz invariant background. Typical pseudo-particle excitations found in superconductors, dubbed anyons, have a mix fermionic/bosonic statistics not described by standard Bose-Einstein and Fermi-Dirac distributions. Inspired by such a rich phenomenology in materials, it is highly not obvious that electron creation/annihilation operators would obey to the same quantum mechanical anti-commutation rules at energies close to the Planck quantum gravity scale. Such an issue may be intimately connected with the Nature of Space and Time as well as Quantum Gravity UV completion. Indeed, the SST is formulated on the basis of Lorentz invariance, locality and microcausality. If one of these principles is violated or deformed, any particle fields may exhibit energy dependent anyonic statistics. Possible effects of high energy Lorentz symmetry deformations, such as in many cases the PEPV, can be probed with high accuracy, competitive with panckian

suppressions! Non-commutative space-time models, such as $\theta$-Poincaré, provide examples of theories which substitute or deform the Lorentz invariance. Quantum field theories can be reformulated in many non-commutative frameworks through the redefinition of product rules such as the Moyal plane model for $\theta$-Poincaré [2, 3, 4]. Non-commutative space-time theories like $\theta$-Poincaré typically predict a energy scale dependent deformation of the co-algebra which percolates on a deformation of commutator and anticommutator relations for fields creation/annihilation operators. The energy scales entering in quantum gravity corrections are depending from the specific models and they can be related to the particle masses, kinetic energy of PEP violating energy transitions of the specific process considered. The predicted energy dependence can be parametrized as $(\bar{E}/\Lambda)^k$, where $\bar{E}$ is typically $<< \Lambda$ in every realistic non-commutative quantum gravity models and in every processes in underground experiments. Such a factor corrects the creation/annihilation commutators as (for boson) $[a_i, a_j^\dagger]_{\bar{E},\Lambda,k} = a_i a_j^\dagger - [1+\eta(\bar{E}/\Lambda)^k/2+O(\bar{E}/\Lambda)^{k+1})]a_j^\dagger a_i = \delta_{ij}$, where $\eta = \pm 1$ just determines the sign of the quantum gravity correction. It is worth to note that for $\Lambda \to \infty$, the (anti)commutator just reduces to the standard model one. In non-commutative space-time models, the scale $\Lambda$ is related to the non-commutative critical energy scale. Around (lenght) $\simeq \Lambda^{-1}$, space-time coordinates start to fully exhibit a non-commutative nature as $[x_\mu, x_\nu] = i\Lambda^{-2}\theta_{\mu\nu}$, where $\theta_{\mu\nu}$ is a fully antisymmetric tensor. Once again, one can check that for $\Lambda \to \infty$, standard commutative space-time coordinates are re-obtained. The deformation of the spin statistics can be directly related to transition rate processes. Indeed the decay width of a single nucleon transition to an ith already filled state, $\Gamma_i$, can be expressed as $\Gamma_i = (\bar{E}/\Lambda)^k \Gamma_i^{(0)}$ where $\Gamma_i^{(0)}$ is the width of the corresponding PEP preserving transition in all possible final states. More generically, there can also be an angular dependence of the processes that here we ignore but are fully considered in Refs. [3, 4].

Considering the comparison between the best constrains from DAMA/LIBRA and BOREXINO, we infer very strong bounds on the $(k, \Lambda)$ parameter space (see Fig. 1 and Ref. [2]). As we can see from Fig.1, both DAMA/LIBRA [8] and BOREXINO [9] are able to exclude corrections up to the order $(\bar{E}/\Lambda)^2$ until the Planck energy scale, i.e. the case of $\Lambda \simeq M_{Pl}$ and $k = 2$ is excluded. Such high precision measures can be achieved by virtue of an extremely low backgrounds in the 10 MeV-range, of both the experiments, as well as a large statistical sample for increasing the limits on PEPV transition time scale. It is also worth to note that exotic scenarios where $\Lambda \simeq 10 \div 100\,\mathrm{TeV}$ are ruled out at practically every order of k-power series. From the theoretical side, non-commutative space-time models are highly motivated in both string theory and loop quantum gravity frameworks and this may be not a coincidence but a matter of a hidden duality between the two theories [5, 6, 7]. On the other hand, alternatives for quantum gravity phenomenology from gravitational waves seem to be much less realistic, as discussed in Ref. [10]. In a certain class of models, the non-commutativity of space-time may also be related

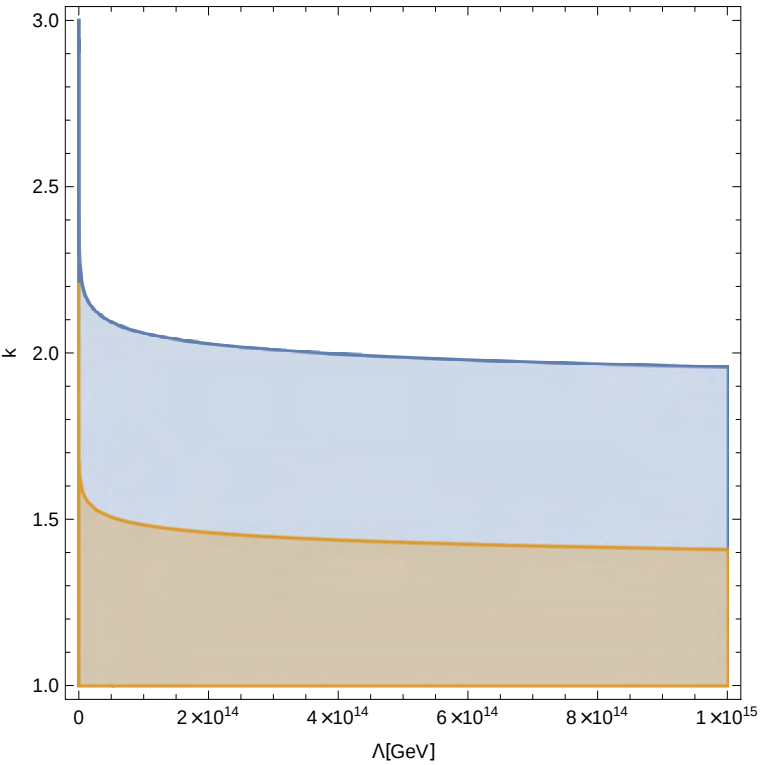

Fig. 1. The best $(k, \Lambda)$ contour parameter limits from DAMA and BOREXINO are displayed.

to non-associativity of quantum mechanics, which can be highly constrained from atomic and space physics [11]. It is worth to remark that, from the phenomenological side, VIP-2 experiment, using atomic techniques and not nuclear process measures such as in the case of BOREXINO, provides important alternative tests of other PEPV processes which do not destabilize nuclei [12].

## Acknowledgments

I would like to thank P. Belli, R. Bernabei and A. Marciano for our many exciting discussions on these fascinating aspects.

The DAMA/LIBRA experiment has been collecting data deep underground in the Gran Sasso National Laboratory (LNGS) in its phase2 to further investigate the Dark Matter (DM) particles of the Galactic halo. The first data release of DAMA/LIBRA–phase2 corresponds to 6 full annual cycles for an exposure of 1.13 ton × yr. The data confirm the evidence of a signal that meets all the requirements of the model independent DM annual modulation signature at 9.5 $\sigma$ C.L. in the energy region (1-6) keV. Considering the previous data collected by DAMA/NaI and by DAMA/LIBRA–phase1 in 2-6 keV, the achieved C.L. for the full exposure (2.46 ton × yr) is 12.9 $\sigma$.

*Keywords*: Dark matter; low background NaI(Tl) scintillators; model-independent annual modulation signature.

## 1. The DAMA/LIBRA–phase2

The DAMA/LIBRA experiment has been carried out with the aim to investigate the DM particles in the Galaxy by exploiting the DM annual modulation signature. The detector consists of 25 ultra low background NaI(Tl) detectors for an exposed mass of about 250 kg. It is the successor of the pioneer DAMA/NaI set-up[1–13] and it has been taking data in two phases: the first one, called DAMA/LIBRA-phase1[1,14–30] and the present DAMA/LIBRA-phase2[30–32]. This last phase is the result of an upgrade of the experiment in which all the photomultipliers (PMTs) were replaced by second generation Hamamatsu R6233MOD PMTs, having higher quantum efficiency and lower background with respect to those used in phase1[19,33]. The commissioning of the experiment was successfully performed in 2011, allowing the achievement of the software energy threshold at 1 keV.

The DM annual modulation signature is due to the Earth's revolution around the Sun which is moving in the Galaxy. Because of the Earth and Sun velocities

*Also: Dip. Ingegneria Civile e Ingegneria Informatica, Università "Tor Vergata", Rome, Italy.
†Also: University of Jinggangshan, Ji'an, Jiangxi, China.

composition in the Galactic frame, a larger flux of DM particles crossing the Earth is expected around $\simeq$ 2 June, while a smaller one is expected around $\simeq$ 2 December. The DM signal must satisfy simultaneously many requirements: the rate must contain a component modulated as a cosine function (1), with period of one year (2), and phase peaked around $\simeq$ 2 June (3); this modulation should be present only in a well-defined low energy range, where DM particle induced events can be present (4); it applies only to those events in which just one detector of many actually "fires" (*single-hit* events), since the DM particle multi-interaction probability is negligible (5); in the region of maximal sensitivity the modulation amplitude must be $\simeq 7\%$ for usually adopted halo distributions, but it can be larger (even up to $\simeq 30\%$) for some cases (6). Many DM candidates, interaction types and scenarios can be explored. Only systematic effects or side reactions accounting for the measured modulation amplitude and satisfying all the peculiarities of the signature could mimic it, but none is available[1,3–5,14–17,20,24,25,30].

## 2. The results

The commissioning of DAMA/LIBRA–phase2 occurred in 2011 and that year was dedicated to preliminary studies[19]; the full annual cycles of DAMA/LIBRA–phase2 considered for the DM annual modulation analysis are six (exposure of 1.13 ton×yr). The cumulative exposure, including the former DAMA/NaI and DAMA/LIBRA–phase1, is 2.46 ton×yr. The same procedures already adopted for the DAMA/LIBRA–phase1[1,14–17] have also been exploited in the analysis of DAMA/LIBRA–phase2[30–32].

Many analyses have been performed on the data to study the peculiarities expected from the DM annual modulation signature. Here just some results and examples will be reported. More details have been addressed in Ref. 30–32. As example, in Figure 1 the residual rates of the *single-hit* scintillation events measured in the former DAMA/LIBRA–phase1 and the new DAMA/LIBRA–phase2 are reported; the data are from 2 keV, the software energy threshold of DAMA/LIBRA–phase1, up to 6 keV. The residual rates are calculated from the measured rate of the *single-hit* events after subtracting the unmodulated part (see e.g. Refs. 1,4,5,15–17). The null modulation hypothesis is rejected at very high C.L. by $\chi^2$ test: $\chi^2/d.o.f. = 199.3/102$, corresponding to a P-value $= 2.9 \times 10^{-8}$. The residual rates versus time for 1 keV energy threshold are reported in Ref. 30–32. The *single-hit* residual rates shown in Figure 1 and those of DAMA/NaI have been fitted with the function: $A\cos\omega(t - t_0)$, considering a period $T = \frac{2\pi}{\omega} = 1$ yr and a phase $t_0 = 152.5$ day (June $2^{nd}$) as expected by the DM annual modulation signature. The $\chi^2/d.o.f.$ is equal to 113.8/138 and a modulation amplitude $A = (0.0102 \pm 0.0008)$ cpd/kg/keV is obtained[30]. If the period and the phase of the signal are kept free in the fit, the achieved C.L. for the full exposure (2.46 ton × yr) is 12.9 $\sigma$; the modulation amplitude of the *single-hit* scintillation events is: $(0.0103 \pm 0.0008)$ cpd/kg/keV, the measured phase is $(145 \pm 5)$ days and the measured period is $(0.999 \pm 0.001)$ yr, all these values are well in agreement with those expected for DM particles.

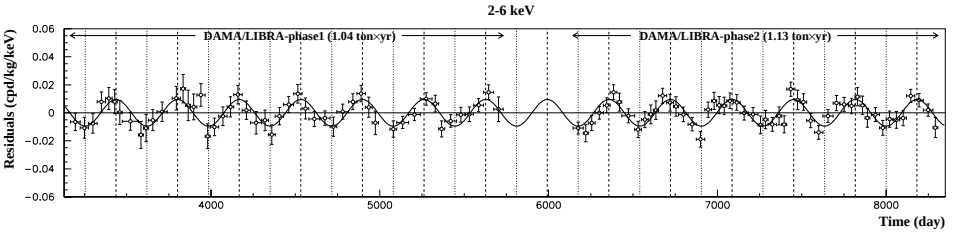

Fig. 1. Residual rate for *single-hit* scintillations measured by DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 in the (2–6) keV energy interval. The superimposed curve is the cosinusoidal functional forms $A\cos\omega(t-t_0)$ with a period $T=\frac{2\pi}{\omega}=1$ yr, a phase $t_0=152.5$ day (June $2^{nd}$) and modulation amplitude, $A$, equal to the central value obtained by best fit on the data points of DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2. The residual rates versus time for 1 keV energy threshold are reported in Ref. 30–32.

The DAMA/LIBRA–phase2 data confirm the evidence of a signal satisfying all the requirements of the model independent DM annual modulation signature. No systematics or side reactions have been found able to mimic the exploited DM signature (i.e. to account for the whole measured modulation amplitude and to simultaneously satisfy all the requirements of the signature).

Other analyses, not shown here, exclude the presence of any background modulation in the energy regions above 6 keV. For example, the measured rate integrated above 90 keV, $R_{90}$, as a function of the time has been analysed [1,17,30]; similar conclusion are also obtained considering data in other energy regions.

Among other performed analyses, a further investigation on DAMA/LIBRA–phase2 data was done – as in the previous DAMA/NaI and DAMA/LIBRA–phase1 experiments [1,5,15–17] – by applying to the *multiple-hit* residual rate[a] the same hardware and software procedures used to acquire and to analyse the *single-hit* ones. Since the probability that a DM particle interacts in more than one detector is negligible, a DM signal is expected only in the *single-hit* residual rate. Therefore, by comparing *single-hit* and *multiple-hit* results is equivalent to compare the cases of DM particles beam-on and beam-off. In this way a further test is possible on the background behaviour in the same energy range in which the positive effect is observed. Figure 2 shows the residual rates of the *single-hit* scintillation events of DAMA/LIBRA–phase2, as collected in a single cycle, and the residual rates of the *multiple-hit* events, in the (1–6) keV energy range. A clear modulation, satisfying all the peculiarities of the DM annual modulation signature, is present in the *single-hit* events, while the fitted modulation amplitude for the *multiple-hit* residual rate is well compatible with zero: $(0.0004\pm0.0004)$ cpd/kg/keV. Thus, again evidence of annual modulation with the proper peculiarities of the exploited signature is present in the *single-hit* residuals (events class to which the DM particle induced events belong), while it is absent in the *multiple-hit* residual rate (event class to which only background events belong).

[a]Multiple-hit is an event with a deposition of energy in coincidence in more than one detector.

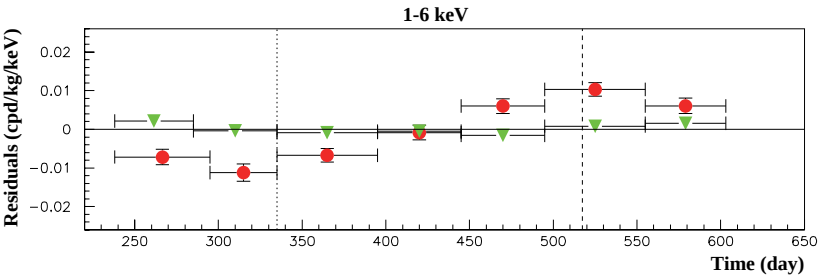

Fig. 2. Experimental residual rates of DAMA/LIBRA–phase2 *single-hit* events (circles), class of events to which DM events belong, and for *multiple-hit* events (filled triangles), class of events to which DM events do not belong. Data were considered as collected in a single annual cycle; in both cases the same hardware and software procedures have been applied. The time scale is the same as the previous DAMA papers for consistency [1,5,15–17]. The experimental points present the errors as vertical bars and the widths of the associated time bins as horizontal bars.

In conclusion, no background that can mimic the exploited DM signature, simultaneously accounting for the measured modulation amplitude and satisfying all the peculiarities of the signature, has been found or suggested by anyone throughout some decades thus far (see e.g. in Ref. 1,14–17,20,25,30)[b].

The annual modulation measured at low energy can also be highlighted by studying as a function of energy the modulation amplitude, $S_m$, obtained by analyzing the events with the maximum likelihood method and fixing $T = 1$ yr and $t_0 = 152.5$ day. The modulation amplitudes as a function of the energy for the whole data sets: DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 (total exposure 2.46 ton×yr) are plotted in Figure 3; the data below 2 keV refer only to the DAMA/LIBRA–phase2 exposure (1.13 ton×yr). It can be deduced that positive signal is present in the (1–6) keV energy range, while $S_m$ values compatible with zero are present just above. All this confirms the previous analyses. The test of the hypothesis that the $S_m$ values in the (6–14) keV energy range have random fluctuations around zero yields $\chi^2$ equal to 19.0 for 16 $d.o.f.$ (upper tail probability of 27%).

[b]Considering some remarks recently appeared in literature, any hypothetical effect due to environmental He diffusion inside the PMTs can be excluded, e.g., by considering the following arguments: i) the PMTs are kept in HP nitrogen 5.5 atmosphere the gas being continuously fluxed through the apparatus ($\simeq$ 250 liters / hour); thus no helium accumulation process can take place (typical characteristic time for accumulation of helium in PMTs through glass, considering the permeability of materials is $\simeq$ 1 year). An estimation of helium concentration within the DAMA shield is less than $5 \times 10^{-11}$ ppm; thus any hypothetical effect due to He-correlated events is negligible; ii) any migration of helium into PMT would cause their irreversible continuous degradation which would be clearly seen over time and this is not observed in the DAMA data. e.g. the Dark Noise of the PMTs goes from 40 to 500 Hz and tends to improve over time on the contrary of what it is expected by He migration inside PMTs; iii) the PMTs used in DAMA/LIBRA-phase2 and DAMA/LIBRA-phase1 are different with different voltage values on the first dynode; this should have produced different modulation amplitudes in the two phases; this has not been observed.

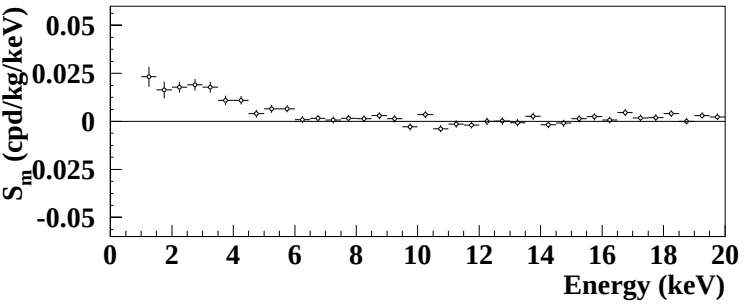

Fig. 3. Modulation amplitudes, $S_m$, for the whole data sets: DAMA/NaI, DAMA/LIBRA–phase1 and DAMA/LIBRA–phase2 (total exposure 2.46 ton×yr) above 2 keV; below 2 keV only the DAMA/LIBRA-phase2 exposure (1.13 ton × yr) is available and used. The energy bin $\Delta E$ is 0.5 keV. A modulation is evident in the lowest energy interval, and only $S_m$'s compatible with zero are present just above. In particular, the $S_m$ have random fluctuations around zero in (6–20) keV energy region with $\chi^2$ equal to 42.6 for 28 *d.o.f.* (upper tail probability of 4%); see text for comments.

For the case of (6–20) keV energy interval $\chi^2/d.o.f. = 42.6/28$ (upper tail probability of 4%). The obtained $\chi^2$ value is rather large due mainly to two data points, whose centroids are at 16.75 and 18.25 keV, far away from the (1–6) keV energy interval. The P-values obtained by excluding only the first and either the two points are 11% and 25%.

As already done for the other data releases[1,15–17,28], the observed annual modulation effect has been verified to be well distributed in all the 25 detectors.

No modulation has been found in any possible source of systematics or side reactions; therefore, cautious upper limits on possible contributions to the DAMA/LIBRA measured modulation amplitude have been obtained (see Ref. 3–5,15–17,20,25). They do not account for the measured modulation amplitudes, and also are not able to simultaneously satisfy all the many requirements of the signature. Similar analyses were also performed for the DAMA/NaI data[4,5].

## 3. Conclusions

The long-standing annual-modulation evidence observed by the DAMA is model-independent and it can be compatible with a wide set of DM scenarios.

Preliminary results recently reported by other experiments using NaI(Tl) detectors have not enough sensitivity to be comparable with the annual modulation evidence reported by DAMA. They require longer data taking and further developments. Both the negative results and all the possible positive hints, achieved so-far in the field, can be compatible with the DAMA result in many scenarios.

To efficiently disentangle among at least some of the many possible candidates and scenarios the lowering of the energy threshold below 1 keV is important. In this context related R&D's have been founded and are in progress.

# Investigation of rare processes with high purity germanium detectors

Matthias Laubenstein*

*Istituto Nazionale di Fisica Nucleare, Laboratori Nazionali del Gran Sasso*
*Via G. Acitelli 22, I-67100 Assergi (AQ), Italy*
**E-mail: matthias.laubenstein@lngs.infn.it*

The exceptional sensitivity and high resolution of high purity germanium detectors in gamma-ray spectrometry and their use in underground laboratories has increasing application because of the important science and technology that they allow to be studied. In fundamental physics their application is focussed on rare phenomena, e.g. double beta decay, rare nuclear decays and Dark Matter search. In the past years there has been a growing number of underground measurements also in other fields such as environmental monitoring, surveillance of nuclear activities, benchmarking of other physical techniques, Life Science and material selection for equipment which require materials with extremely low levels of radioactivity. This report describes the state of the art in underground gamma-ray spectrometry with high purity germanium detectors. Various applications in underground laboratories are presented.

*Keywords*: Germanium detectors; ultra low background; material screening; underground physics.

## 1. Introduction

In the underground laboratories all over the world many experiments are probing different aspects of the standard model of particle physics and beyond to very high precision.[1] Especially two fields of phenomena in the low energy region are explored, the investigation of the nature of dark matter search on the one hand, and of the neutrino on the other. The exceptional sensitivity and high resolution of high purity germanium detectors makes them a natural candidate for being used as detector. Over the last decade there have been at least seven collaborations in the field of Dark Matter search (CDEX-10[2], CDMS[3], COGENT[4], EDELWEISS[5], MALBEK[6], SuperCDMS[7], and TEXONO[8]) and five in the field of neutrino studies, especially checking whether it is a Majorana particle or not and its mass by searching for the neutrinoless double beta decay ($0\nu\beta\beta$ decay) (GERDA[9], LEGEND[10], and MAJORANA[11]) and measuring the coherent elastic neutrino-nucleus scattering (COHERENT[12], and CONUS[13]). The dark matter experiments are searching directly for interactions of Dark Matter particle candidates (nuclear recoils) and for possible oscillations of this signal if present. The experiments searching for the $0\nu\beta\beta$ decay in the isotope $^{76}$Ge have achieved exceptionally low background levels and the next generation of experiments will be able to explore completely the region of inverted mass hierarchy for neutrinos.

Nevertheless, there is a growing number of underground measurements also in other fields such as environmental monitoring, surveillance of nuclear activities, benchmarking of other physical techniques, Life Science and material selection

for equipment which require materials with extremely low levels of radioactivity. Various applications in underground laboratories will be presented in the following.

## 2. Ultra low-level gamma-ray spectrometry

In this paper the acronym ULGS stands for ultra low-level gamma-ray spectrometry. This means that additional measures (such as using a muon shield or an underground laboratory) have been taken compared to low-level gamma-ray spectrometry, where a detector and shield made from selected radio pure materials are used.[14] When performing ULGS with an active shield (or "veto counter" or "muon shield"), one gains a lot above ground and at shallow depth laboratories.[15] It is, however, not possible to avoid the cosmogenic activation of detector and shield so a muon shield can not completely substitute an underground location.[16]

The Italian Institute for Nuclear Physics (INFN) performs ULGS in the laboratory STELLA (STELLA is the acronym for SubTerranean Low-Level Assay)[17], which is located in the underground laboratories of the Gran Sasso National Laboratory (LNGS) at a depth of 1400 m (3800 m of water equivalent). Since from the beginning in the late 1970s material selection was done for the LNGS in its construction phase in order to select the most radio pure construction materials available at that time (1979), and later on for the experiments that were installed at the LNGS searching for very rare events under conditions of cosmic silence, i.e. in the absence of cosmic rays. The definite ULGS work started in 1990 in small scale with three high purity germanium (HPGe) detectors as an exploratory research project.[18] The usefulness of the technique led to an increase of the capacity. For the moment there are 15 HPGe-detectors in STELLA. A wide range of measurements are necessary, which led to the decision of equipping the laboratory with general purpose detectors rather than detectors specialised for a specific type of measurements. The non routine character of the work makes calculation of the detection efficiency for many types of samples a requirement. Reference samples are used whenever possible, but the general rule is that the efficiency is calculated using the Monte Carlo code Geant4[19,20].

## 3. Applications

Several interesting developments in the use of underground gamma-ray spectrometry have arisen in recent years. As described before the major achievements were in the field of fundamental physics and double beta decay in particular. As the benefits of the technique became clearer to a wider community the number of applications has grown. The examples that follow illustrate the versatility of the technique.

### 3.1. *Small samples*

For special investigations the amount of available material can be very small (only few grams). A lot can be gained using ULGS where the background is negligible

in order to extract valuable information. At the LNGS meteorite samples of few grams were measured to give important information about the exposure history of meteorite falls[21] or to verify that the investigated specimen was really originating from a fresh meteorite fall and belonged to a group of other samples already measured[22]. Furthermore also for material screening it has become ever more important to measure extremely small samples (surface mounted electronics, Silicon photomultipliers etc). The use of ULGS gives the possibility to screen even either single components[17] or larger sets of very small samples to improve the sensitivity on the single component reaching levels below $\mu$Bq per piece.

### 3.2. *Physics measurements*

The extremely ow background in ULGS combined with the use of ultra pure or extremely purified materials[23], is a very good opportunity to look for rare decays in several radionuclides of interest. At the LNGS in the past years new decays to excited levels of radioactive isotopes were discovered. It started with the discovery[24] of the $^{115}$In decay to the first excited level of $^{115}$Sn, which was later again investigated with better accuracy[25]. Further experiments on this decay are in progress to investigate possible effects due to its very low Q value of the matrix in which the $^{115}$In is implemented. Later on in a similar way the $\alpha$ decay of $^{190}$Pt to the first excited level of $^{186}$Os was detected[26]. Higher precision measurements are currently in progress. Finally very recently the decay of $^{50}$V was remeasured, aiming at the detection of the $\beta$ decay branch. Unfortunately, only the electron capture decay branch was confirmed and remeasured with high precision, whereas for the $\beta$ decay only a lower limit could be determined[27], now reaching almost the theoretical predictions[28].

### 3.3. *Method validation*

For LNGS as well as for other physics institutes it is essential to have alternative analytical techniques in order to either resolve issues or disputes relating to measurements or to do more comprehensive measurements on the whole natural decay chains of $^{238}$U and $^{232}$Th, considering parent nuclides and later on the daughter nuclides, in order to look for secular equilibrium through out the decay chains. LNGS could confirm that ULGS and ICP-MS gave the same results in many different matrices down to very low concentrations.[29]

### 3.4. *Radiopurity studies*

In order to benefit from the reduction of the background induced by cosmic rays in underground laboratories, it is essential that all materials used for constructing a detector and its shield are radio pure. STELLA has contributed to radio purity studies for all large and small scale detectors for rare events located at the LNGS. (e.g. BOREXINO neutrino detector[30], GERDA[31] and CUORE[32] detectors for double beta decay, XENON1T[33,34] detector for dark matter search).

### 3.5. *Activation*

Activated samples are most suitable samples for measurement using ULGS. The reason for this is that very often there is no interference from other radionuclides that increase the detection limit for the radionuclide of interest. This fortunate situation is either due to the fact that the activated material was selectively chosen beforehand, like in the case of flux monitors in nuclear reactors[35], or like in the case of environmental sampling after an incident involving neutron irradiation outside a controlled area[36]. Another example of ULGS measurements of activated samples involves solving discrepancies between model calculations and measurements of activation induced by the A-bomb in 1945. Komura et al. could solve the problem with $^{152}$Eu in granite by using the Ogoya underground laboratory[37] and Gasparro et al. showed that older measurements of $^{60}$Co in steel could be significantly too high[38].

## 4. Conclusions

The LNGS of the INFN host the underground ultra-low background facility STELLA. Its primary mission is to perform the material screening for the fundamental physics experiments installed in the underground laboratories. The ultra-low background of the detector systems allow for detecting extremely low radioactivity levels in materials down to the $\mu$Bq kg$^{-1}$ level. The exceptional sensitivity and high resolution of high purity germanium detectors in gamma-ray spectrometry and their use in underground laboratories has increasing application in other fields of science. A growing number of underground measurements is done in fields such as environmental monitoring, surveillance of nuclear activities, benchmarking, Life Science and material selection for experiments, which require materials with extremely low levels of radioactivity. In the future it is envisaged to further increase the performance of the ULGS systems carefully selecting the materials. Moreover, there might be further developments including using underground production and storage of Ge-crystals, transfer the technology developed for fundamental physics experiments to screening detector systems, and for special applications to use special coincidence techniques. Nevertheless for the HPGe-detectors acting as all-purpose work horses it is important to keep the system simple in order to minimise the labour cost for analyses. In the future new interesting applications making use of ULGS could turn up.

## Acknowledgments

The author expresses his gratitude towards the organisers of the XV Marcel Grossman Meeting 2018 in Rome for having been given the opportunity to present an invited talk on his work at this important and renowned conference.

# On the dynamical instability of self-gravitating systems

Giuseppe Alberti*

*Living Systems Research,*
*Roseggerstraße 27/2, A-9020 Klagenfurt am Wörthersee, Austria*
**E-mail: giuseppe.alberti@ilsr.at*

We study the dynamical stability of self-gravitating systems in presence of anisotropy. In particular, we introduce a stability criterion, in terms of the adiabatic local index, that generalizes the stability condition $< \gamma > \geq 4/3$ of the isotropic regime. Also, we discuss some applications of the criterion.

*Keywords*: Anisotropy; Dynamical Instability; Adiabatic Local Index; Gravity.

## 1. Introduction

The object of this work consists in the study of the dynamical stability in self-gravitating systems, through the deduction of a stability criterion. In particular, our aim is to obtain a criterion that extends the validity of the stability condition $< \gamma > \geq 4/3$ to the anisotropic systems.

In Sec. 2 we briefly deduce the stability criterion in Newtonian gravity whereas, in Sec. 3, we discuss some applications of the criterion in order to quantitatively check how much the presence of the anisotropy can affect the onset of the instability. In Sec. 4 we draw some conclusions.

## 2. Stability criterion in Newtonian gravity

In Newtonian gravity the pulsation equation writes (see Ref. 1)

$$\frac{\partial^2\xi}{\partial t^2}+\frac{4\xi P_r'}{r\rho}-\frac{1}{\rho}\Big[\frac{\gamma_r P_r}{r^2}(r^2\xi)'\Big]'+\frac{6(P_r-P_t)\xi}{r^2\rho}+\frac{2(P_r-P_t)\xi'}{r\rho}+\frac{2(\gamma_t P_t-\gamma_r P_r)(r^2\xi)'}{r^3\rho}=0 \tag{1}$$

where $P_r$ and $P_t$ are the radial and tangential components of the pressure tensor, respectively, $\rho$ the density, $r$ the radial coordinate, $\xi$ the Lagrangian displacement. The adiabatic local indexes $\gamma_r$ and $\gamma_t$, along the radial and the trasverse components, are given by

$$\gamma_r=\frac{\rho}{P_r}\Big(\frac{\partial P_r}{\partial\rho}\Big)_S \qquad \text{and} \qquad \gamma_t=\frac{\rho}{P_t}\Big(\frac{\partial P_t}{\partial\rho}\Big)_S\,, \tag{2}$$

where the subscript $S$ indicates that the derivatives are performed by keeping the entropy constant. Developing the calculations[2], we easily get the stability criterion

$$\mathcal{Q}=\frac{\int_0^R(\gamma_r P_r+2\gamma_t P_t)r^2dr}{\int_0^R(P_r+2P_t)\,r^2dr}\geq\frac{4}{3}\,. \tag{3}$$

In the isotropic limit the foregoing expression reduces to $\mathcal{Q}=< \gamma > \geq 4/3$.

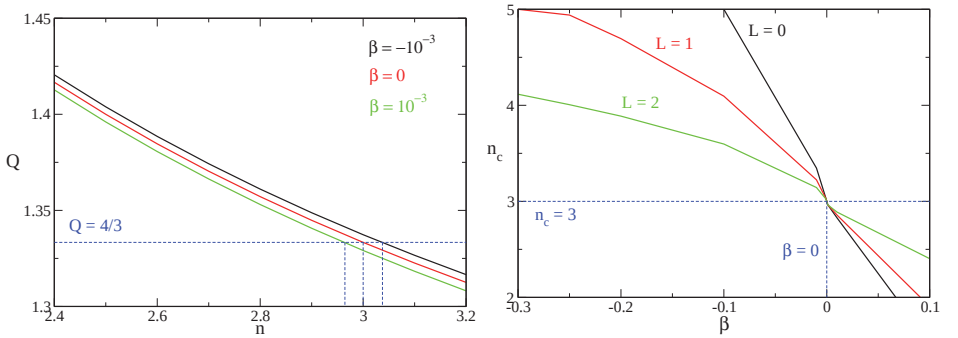

Fig. 1. **Left panel**: representation of the function $\mathcal{Q} = \mathcal{Q}(n)$ [see Eq. (3)], for $N = 2$, $L = 0$, $\beta = -10^{-3}$ (black line), 0 (red line) and $10^{-3}$ (green line). The plot shows that an unstable configuration in the isotropic limit can become stable if $\beta < 0$. Vice versa, when $\beta > 0$, a stable configuration in the isotropic limit can become unstable. **Right panel**: Critical value of the polytropic exponent $n_c$ as a function of the anisotropy parameter $\beta$, for $L = 0$, 1 and 2.

## 3. Applications

### 3.1. *Polytropes*

Let us apply Eq. (3) to the study of the stability of the polytropic models advanced by Herrera & Barreto[3]. Leaving out the details of the calculations[2], the anisotropic Lane-Emden equation writes

$$\frac{1}{\xi^2}\frac{d}{d\xi}\left(\xi^2\frac{d\theta}{d\xi}\right) = -\theta^n \mathcal{F}(\beta)\,, \tag{4}$$

where $n$ is the polytropic exponent, $\beta$ the (dimensionless) anisotropy parameter and $\mathcal{F}(\beta)$[a] is given by

$$\mathcal{F}(\beta) = 1 - \frac{\beta}{\xi^2\theta^n}\frac{d}{d\xi}\left[f(\xi)\xi^{N+1}\right]. \tag{5}$$

In the foregoing expression, the exponent $N$ and the function $f$ depend on the model. In the following, we consider $f(\xi) = (1+\xi)^L$ (with $L \in \mathbb{R}$). The isotropic Lane-Emden equation is recovered for $\beta = 0$ (implying $\mathcal{F} = 1$).

In Fig. 1 (left panel) we have represented the $\mathcal{Q}$-factor [see Eq. (3)] as a function of the polytropic exponent $n$. The diagram shows dissimilar behaviors according to the sign of the anisotropy parameter.

[a]To keep the decreasing behavior of $\theta$, we require that $\mathcal{F}(\beta) > 0$. This condition allows an upper limit for the anisotropy parameter $\beta$ (see Ref. 2).

If $\beta < 0$, which corresponds to the radial anisotropy (i.e. $P_t < P_r$, see Ref. 2), we observe a tendency towards the stability because the critical value $n_c$ of the polytropic exponent for the onset of the instability is larger than $n = 3$.[b] On the other hand, for $\beta > 0$, which corresponds to the tangential anisotropy (i.e. $P_t > P_r$), we observe that the rising of the dynamical instability is favored (from the plot, we note that $n_c < 3$).

In the right panel of Fig. 1 we have represented $n_c$ as a function of $\beta$, for three values of the exponent $L$. The plot shows that $n_c > 3$ for $\beta < 0$, in confirmation of the fact that the (presence of) radial anisotropy leads the system to the stability. If $\beta > 0$, by contrast, we find $n_c < 3$, in confirmation of the fact that the tangential anisotropy favors the rising of the instability.

### 3.2. *Anisotropic stars*

In this section we consider two models, advanced by Dev & Gleiser [5], conceived as deviations from the homogeneous model (i.e. $\rho = \rho_0$). In formulae

$$P_t = P_r + C\rho r^2 \,, \tag{6a}$$

$$P_t = P_r(1 + C\rho r^2) \,. \tag{6b}$$

In the foregoing expressions, $C$ estimates the strength of the anisotropy and can be both positive and negative, *a priori*. Similarly to the case of polytropes, $C > 0$ corresponds to the tangential anisotropy and $C < 0$ to the radial anisotropy. Integrating the equilibrium equations by using Eqs. (6a) and (6b), we obtain [5]

$$P_r = \rho_0^2 \Big( \frac{2\pi G}{3} - C \Big) (R^2 - r^2) \,, \tag{7a}$$

$$P_r = \frac{2\pi G \rho_0}{3C} \Big[ 1 - e^{C\rho_0 (r^2 - R^2)} \Big] \,. \tag{7b}$$

In the previous equations, $R$ and $G$ represent the radius of the star and the gravitational constant, respectively. Concerning the stability, for the ansatz (6a)-(7a), Eq. (3) yields $\mathcal{Q} = 2 > 4/3$, showing that the system is dynamically stable. For the ansatz (6b)-(7b), conversely, we find a more interesting situation. Eq. (3), indeed, takes the form

$$\mathcal{Q} = 1 + \frac{5}{2x^2} - \frac{15}{4x^4} + \frac{15 D_+(x)}{4x^5} \geq \frac{4}{3} \,, \tag{8}$$

where $x = R\sqrt{C\rho_0}$ and $D_+(x)$ is the Dawson function. In the limit $x \to 0$, Eq. (8) reduces to $\mathcal{Q} = 2 > 4/3$ that corresponds to the case previously analyzed. On the other hand, for $x \to +\infty$, we obtain $\mathcal{Q} = 1 < 4/3$ that corresponds to a loss of stability. Consequently, we expect to find a critical value of $x$ allowing the separation between stable and unstable configurations.

[b] $n = 3$ corresponds to the critical value in the isotropic case.

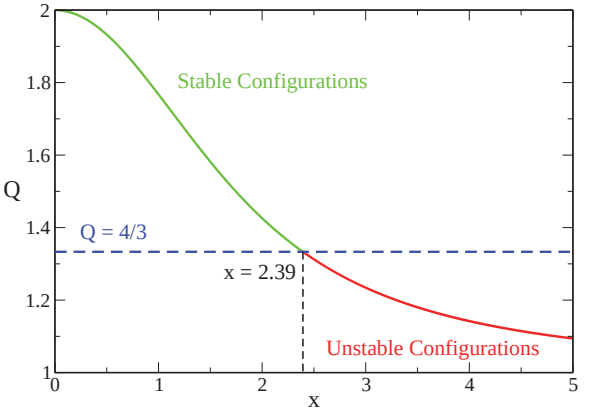

Fig. 2. Representation of the function $\mathcal{Q} = \mathcal{Q}(x)$, where $x$ is defined as $x = R\sqrt{C\rho_0}$. The plot shows the existence of a critical value $x = \bar{x}$, corresponding to the onset of the dynamical instability. Numerically we find $\bar{x} = 2.39$ or, equivalently, $\bar{C} = 5.73/(\rho_0 R^2)$.

In Fig. 2 we have represented Eq. (8) and, as we see, the existence of this critical value is confirmed. Numerically, we find that dynamical instability sets in if $x \geq \bar{x} = 2.39$, i.e. if $C \geq \bar{C} = 5.73/(\rho_0 R^2)$. It is interesting to notice that the stability of the star, rather than the anisotropy parameter, depends on the central density.

### 3.3. *Degenerate fermionic configurations*

In this section we focus on the degenerate fermionic configurations, a particular case of a more general study carried out in Ref. 6. The equation of state (EOS), in a parametric form, is

$$\rho = \frac{4\pi g m^4 \sigma^3}{3h^3}\sqrt{W^3}\left(1 + \frac{2r^2}{5r_a^2}W\right), \tag{9a}$$

$$P_r = \frac{4\pi g m^4 \sigma^5}{15h^3}\sqrt{W^5}\left(1 + \frac{2r^2}{7r_a^2}W\right), \tag{9b}$$

$$P_t = \frac{4\pi g m^4 \sigma^5}{15h^3}\sqrt{W^5}\left(1 + \frac{4r^2}{7r_a^2}W\right). \tag{9c}$$

In the foregoing expressions, $W$ is the cutoff energy (Fermi energy in this case[6]), $r_a$ the anisotropy radius, $\sigma$ the velocity dispersion and the other symbols have their usual meaning. The adiabatic local indexes $\gamma_r$ and $\gamma_t$ are given by

$$\gamma_r = \frac{5r_a^2 + 2r^2W}{7r_a^2 + 2r^2W}\,\frac{8rW^2 + 7W'(5r_a^2 + 2r^2W)}{8rW^2 + 5W'(3r_a^2 + 2r^2W)}, \tag{10a}$$

$$\gamma_t = \frac{5r_a^2 + 2r^2W}{7r_a^2 + 4r^2W}\,\frac{16rW^2 + 7W'(5r_a^2 + 4r^2W)}{8rW^2 + 5W'(3r_a^2 + 2r^2W)}, \tag{10b}$$

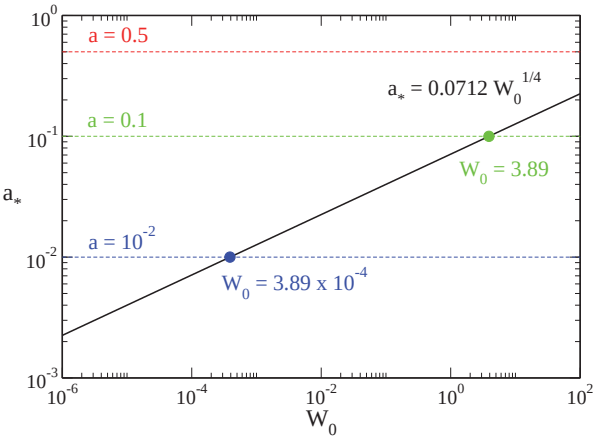

Fig. 3. Values of $a_*$ as a function of the central density $W_0$ [see Eq. (9a)]. The plot shows that, for a given value of $a$ (horizontal lines), there exists a critical value of the central density $W_0^c$ such that dynamical instabilities set in. For $a = 0.5$ (red line) we see that $W_0^c >> 1$ (the system is isotropic and thus stable) whereas, for a $a = 0.1$ (green line), we find $W_0^c = 3.89$ and for $a = 0.01$ (blue line) we have $W_0^c = 3.89 \times 10^{-4}$. This shows that $W_0^c \to 0$ for $a \to 0$ (the system is unstable).

where $W' = dW/dr$. In the isotropic limit $r_a \to +\infty$ the foregoing expressions yield $\gamma_t = \gamma_r = 5/3$. Consequently, according to Eq. (3), we get $\mathcal{Q} = 5/3 > 4/3$ confirming that, in the isotropic limit, degenerate fermionic configurations are stable[c]. Things change in the fully anisotropic regime $r_a \to 0$: we have indeed

$$\gamma_t = \gamma_r = \frac{4+7y}{4+5y}, \qquad \text{where} \qquad y = \frac{d\log(W)}{d\log(r)}. \tag{11}$$

As the reader can see, if $-4/5 < y < -4/7$, $\gamma_r$ and $\gamma_t$ are negative. In these conditions, the speed of the two sound waves along the radial and the tangential axis, given by

$$c_{sr} = \sqrt{\frac{\gamma_r P_r}{\rho}}, \quad c_{st} = \sqrt{\frac{\gamma_t P_t}{\rho}}. \tag{12}$$

become a complex number: the configuration, therefore, is unstable. This feature is a consequence of the trend of density and pressure profiles, which have become "hollow" [6].

Hollow configurations are characterized by the presence of a maximum achieved far from the center. Consequently, the profile is monotonic increasing until the maximum and monotonic decreasing from the maximum until the boundary.

A profile is hollow (and thus unstable) if, for a given value of $W_0$, the value of the anisotropy radius $r_a$ is below a critical one. To get this critical value, we compute

[c]We can also show that the EOS can be written as $P_t = P_r = P = K\rho^{5/3}$. This is the EOS of a polytrope of index $n = 3/2$ that, as it is known, represents a stable configuration (being $n = 3/2 < 3$).

$d^2\rho/dr^2 = 0$ at the center and solve for $a$. Defining the anisotropy parameter as $a = r_a/r_0$ ($r_0$ is a scaling length[6]) and indicating by $a_*$ the critical value, we have

$$a_* = \frac{r_a}{r_0}\Big|_{critical} = \frac{\sqrt[4]{W_0}}{2\pi\sqrt{5}}\,. \tag{13}$$

In Fig. 3 we have represented the function $a_* = a_*(W_0)$. According to the plot, degenerate fermionic configurations are stable if, for a given value of $W_0$, $a > a_*$ and unstable if $a \leq a_*$.

## 4. Concluding remarks

In this work we have studied the dynamical stability of anisotropic self-gravitating systems. The analysis carried out has shown that, according to the type of anisotropy, the onset of the instability is modified.

In prevalence of radial anisotropy ($P_r > P_t$), we have observed that the systems have the tendency to evolve towards stable configurations. Unstable configurations in the isotropic limit ($P_r = P_t$) can become stable. In prevalence of tangential anisotropy ($P_r < P_t$), by contrast, we have observed that the rising of the instability is favored. Stable configurations in the isotropic limit can become unstable.

In Ref. 2 we have studied the stability of other systems, such as Elliptical Galaxies.

We think that the stability criterion introduced and applied in this work represents a powerful tool for the study of the dynamical stability of a large class of astrophysical systems. The extension of the criterion to General Relativity and other applications will be adressed to forthcoming publications.

The Thomas-Fermi model is extended at finite temperature, to describe the gravitational phase transition occurring in massive fermionic systems in a general-relativistic framework. It is shown that, when a nondegenerate fermionic gas (for $N < N_{OV}$, where $N_{OV}$ is the Oppenheimer-Volkoff limit) is cooled down below a critical temperature, a condensed phase emerges and the gravitational collapse is prevented by quantum mechanics. If $N > N_{OV}$, by contrast, the system is destined to collapse towards a Black Hole because no equilibrium states exist.

*Keywords*: General Relativity; Thermodynamics; Fermions; Phase Transitions.

## 1. Introduction

The object of this work, intendend as a résumé of a previous publication[1], is to describe the occurrence of the gravitational phase transition that the Fermi gas at non-zero temperature experiences, in a general relativistic framework.

As it is known, gravitational phase transitions have been investigated since early '70s, when Hertel & Thirring[5] have shown the non-equivalence of statistical ensembles. Several steps forward have been made by Padmanabhan[7] and Chavanis[3] (for a detailed review see Ref. 4 and references therein) who have shown the occurrence of the phase transition in several systems (e.g. hard spheres,...).

In the case of fermions[3], when the system is cooled down below a critical temperature, a condensed phase emerges and the initial gaseous configuration evolves towards this condensed configuration.

Bilić & Viollier[2] firstly studied the occurrence of the gravitational phase transition in General Relativity (hereafter GR): however, they focused their attention only on a particular case. For this reason, in this work, we complete their previous investigations by describing the most general case.

The paper is organized as follows. In Sec. 2 we present the main equations. In Secs. 3 and 4 we discuss the occurrence of the phase transition in the canonical and microcanonical ensembles, respectively. In Sec. 5, finally, we draw some conclusions.

## 2. Theoretical framework

We consider a (static) self-gravitating[a] fermionic gas, formed by $N$ particles of mass $m$ at a temperature $T \neq 0$ and placed within a spherical box of dimension $R$. The equilibrium equations are given by

$$\frac{d\Phi}{dr} = -\frac{2G}{c^4}\frac{(\Phi+1)(M_r c^2 + 4\pi P r^3)}{r^2}\left(1 - \frac{2GM_r}{rc^2}\right)^{-1}, \tag{1a}$$

$$\frac{dM_r}{dr} = \frac{4\pi\epsilon r^2}{c^2}. \tag{1b}$$

with the conditions $\Phi(0) = \Phi_0$ and $M_r(0) = 0$. In the previous equations, $\Phi$ corresponds to the gravitational potential, $M_r$ represents the mass-energy contained within a sphere placed at distance $r < R$ from the center of the system ($\epsilon$ and $P$ are the mass-energy density and the pressure, respectively). The particle number $N$ is given by

$$N = N(\Phi_0) = \int_0^R 4\pi n r^2 \Big(1 - \frac{2GM_r}{rc^2}\Big)^{-1/2} dr\,, \tag{2}$$

being $n = \rho/m$ the particle number density ($\rho$ is the rest mass density). The thermodynamic analysis is performed by means of the caloric curve $T = T(E)$[b]. To this purpose, we define the following variables

$$\Lambda = -\frac{E_b R}{GN^2m^2} = \frac{(Nm - M)Rc^2}{GN^2m^2}\,, \qquad \eta = \frac{GNm^2}{k_B T R}\,. \tag{3}$$

## 3. Canonical instabilities

In this Section we discuss the case of the canonical ensemble. In Fig. 1 we have represented the occurrence of the phase transition for $R = 15\,R_{OV}$ and $N = 0.7277\,N_{OV}$ (left panel) and $R = 15\,R_{OV}$ and $N = 1.0012\,N_{OV}$[c] (right panel).

In both cases the system exhibits a phase transition because we observe the coexistence, at the same (transition) temperature ($\eta_t = 1.5722$ in the first case and $\eta_t = 1.3315$ in the second one), of several states identified by the points $P_1$, $P_2$, $P_3$ and $P_4$. The plots present different colors according to the stability of the solutions (black and green lines corresponding to stable states, red lines corresponding to unstable states). Let us consider the case $N < N_{OV}$ first.

[a] In this work we neglect the contribution of the other interactions that, in a more realistic situation, fermions certainly feel.

[b] For the details concerning the numerical procedure used to get the caloric curve see Ref. 1.

[c] $R_{OV}$ and $N_{OV}$ are the values of the radius and of the particle number at the Oppenheimer-Volkoff limit[6]. Numerically we have $R_{OV} = 9.162$ km and $N_{OV} = 8.752 \times 10^{56}$ particles.

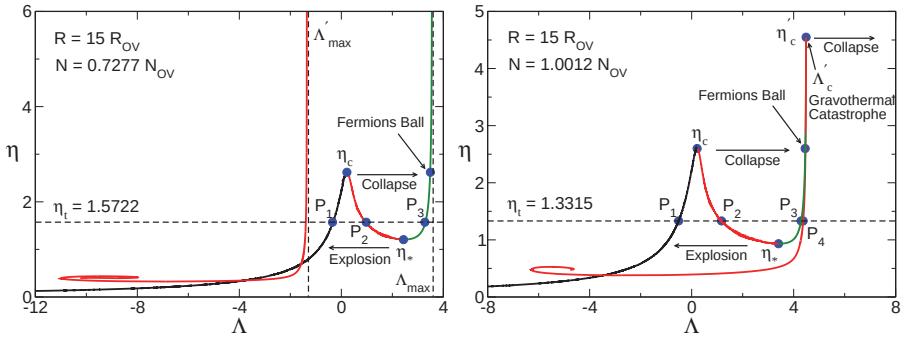

Fig. 1. Equilibrium phase diagrams for fermionic systems in GR. $\eta_t$ corresponds to the transition temperature. **Left Panel**: At the temperature $\eta_c$ the system evolves from the gaseous (black line) to the condensed phase (green line). The gravitational collapse is prevented by Pauli's exclusion principle. At the temperature $\eta_*$, the system evolves from the condensed phase to the gaseous one. The gravitational explosion is halted by the box. **Right Panel**: The condensed phase collapses towards a Black Hole at the temperature $\eta_c'$.

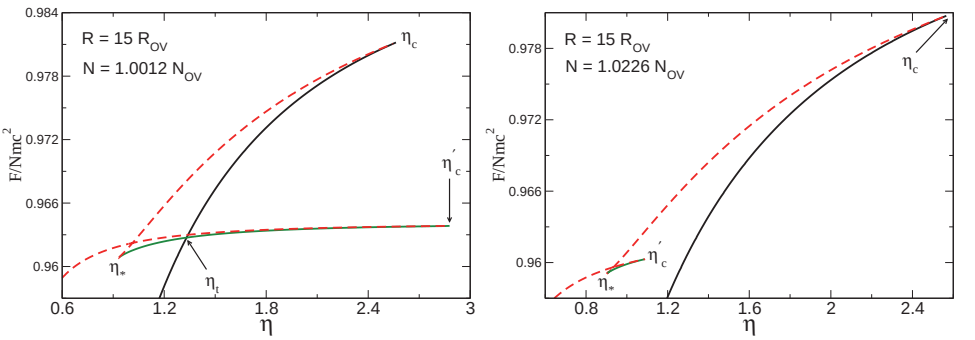

Fig. 2. Free energy as a function of the normalized inverse temperature $\eta$. **Left Panel**: The phase transition is identified by the intersection point between the gaseous (black full line) and the condensed branch (green full line). **Right Panel**: The intersection point between the gaseous and the condensed phase is missing: the phase transition is thus suppressed (the crossing point concerns unstable states).

Points $P_1$ represent the gaseous phase (black line): they are global minima of free energy (thus stable) for $\eta < \eta_t$ and local minima of free energy (thus metastable[d]) for $\eta > \eta_t$. When the temperature exceeds the critical value $\eta_c$, the gaseous phase undergoes a collapse and forms a compact object (condensed phase, green line, points $P_3$) containing all the mass. The stability of the solutions $P_3$ is inverted with respect to that of the solutions $P_1$. Consequently, the compact object represents

[d]The lifetime of metastable states can be longer than the age of the Universe. This implies that the phase transition does not occur in practice. However, metastable states can play a central role in astrophysics[4].

a stable configuration (it is a global minimum of free energy). We refer to this compact object as "fermion ball".

The condensed phase, similar to the gaseous one, evolves too. For $\eta < \eta_*$, indeed, the condensed undergoes an explosion (halted by the box). Points $P_2$, by contrast, correspond to unstable physical solutions (they are saddle points). Moreover, in this region of the diagram, the specific heat is negative (because $d\eta/d\Lambda < 0$).

Let us now turn our attention to the case $N > N_{OV}$ (right panel of Fig. 1). The difference, with respect to the former case, is represented by the presence of a second collapse (of general relativistic origin) at the temperature $\eta'_c$. In this case, the condensed phase undergoes a second collapse towards a Black Hole.

The temperature $\eta'_c$, which is a decreasing function of $N$, allows un upper limit for the extension of the condensed phase. The theory identifies a critical value of $N$, namely that corresponding to the extinction of the condensed phase and to the suppression of the phase transition[1].

The reason of this phenomenon is shown in Fig. 2. The left panel plots the free energy as a function of the (reverse) normalized temperature, for $N = 1.0012\, N_{OV}$. The phase transition is identified by the intersection point between the gaseous and the condensed phase. The right panel shows the case $N = 1.0226\, N_{OV}$. As we see, the plot does not display any intersection point between the two phases, implying that the phase transition is suppressed.

## 4. Microcanonical instabilities

Let us now discuss the microcanonical ensemble. In Fig. 3 we study the occurrence of the phase transition for $R = 179\, R_{OV}$ and $N = 3.2620\, N_{OV}$ (left panel) and $R = 179\, R_{OV}$ and $N = 4.2657\, N_{OV}$ (right panel). Similar to the canonical ensemble, the left panel of Fig. 3 shows the occurrence of the phase transition because of the coexistence, at the same (transition) energy $\Lambda_t = -0.025$, of several states identified by the points $P_1$, $P_2$, $P_3$ and $P_4$.

Points $P_1$ represent the gaseous phase (black line): they are global entropy maxima (thus stable) for $\Lambda < \Lambda_t$ and local entropy maxima (thus metastable) for $\Lambda > \Lambda_t$. When the energy exceeds the critical value $\Lambda_c$, the gaseous phase undergoes a collapse and forms a compact object (condensed phase, green line, points $P_3$) containing a fraction ($\sim 1/4$) of the total mass and surrounded by an atmosphere.

The stability of the solutions $P_3$ is inverted with respect to that of the solutions $P_1$. Consequently, the compact object represents a stable configuration (it is a global entropy maximum). We refer to this compact object as "fermion ball".

The condensed phase, similar to the gaseous one, evolves too. For $\Lambda < \Lambda_*$, it undergoes an explosion (halted by the box). Analogous to the canonical ensemble, points $P_2$ are unstable saddle points. In this region of the diagram the specific heat is negative (because $d\eta/d\Lambda < 0$).

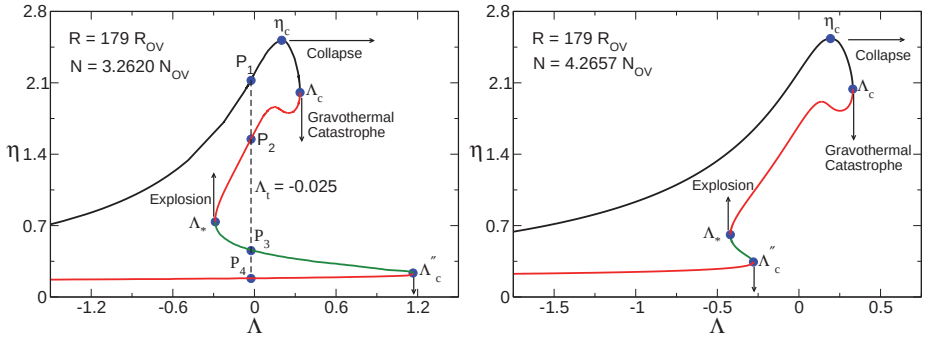

Fig. 3. Equilibrium phase diagrams for fermionic systems in GR. **Left Panel**: A phase transition from the gaseous to the condensed phase occurs at the energy $\Lambda_t$. At the energy $\Lambda_c$ the system evolves from the gaseous to the condensed phase. The gravitational collapse is prevented by quantum degeneracy. At the energy $\Lambda_*$ the system evolves from the condensed to the gaseous phase. The gravitational explosion is halted by the box. At the energy $\Lambda_c''$ the system collapses towards a Black Hole. **Right Panel**: The phase transition is suppressed.

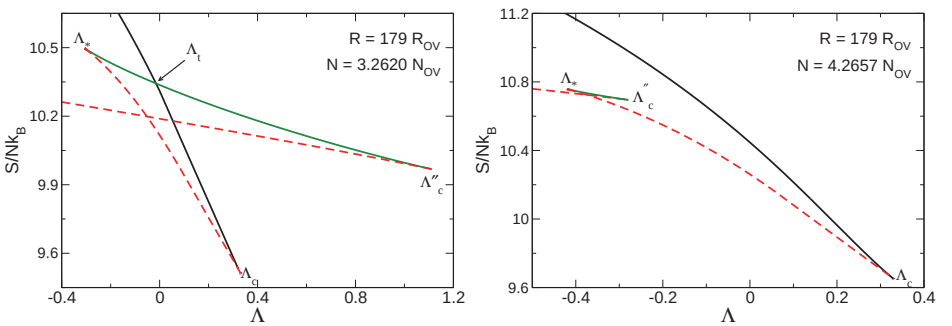

Fig. 4. Entropy as a function of the normalized energy $\Lambda$. **Left Panel**: The phase transition is identified by the intersection point between the gaseous (black full line) and the condensed branch (green full line). **Right Panel**: The intersection point between the gaseous and the condensed phase is missing, so the phase transition is suppressed (the crossing point concerns unstable states).

The novelty with respect to the non-relativistic regime[3] is the presence of a second collapse, occurring at the critical energy $\Lambda_c''$. The existence of this critical energy allows an upper limit to the extension of the condensed phase and, as a consequence, the suppression of the phase transition[1].

To better understand this phenomenon we have represented, in Fig. 4, the entropy as a function of the normalized energy $\Lambda$. The left panel shows the occurrence of the phase transition, because of the presence of a crossing point between the gaseous and the condensed phase. The right panel of Fig. 4, by contrast, does not display any crossing point between the two phases and the phase transition is thus suppressed (Fig. 3 plots the caloric curve associated).

## 5. Concluding remarks

In this work we have studied the nature of phase transitions of the Fermi gas in a general relativistic framework. The model takes both quantum mechanics and GR into account. As we have seen, the occurrence of the phase transition depends on the values of $N$ and $R$.

In the main paper[1] we have determined two critical values of the cavity radius, namely the canonical critical radius $R_{CCP} = 3.57\, R_{OV}$ and the microcanonical critical radius $R_{MCP} = 27.4\, R_{OV}$. If $R < R_{CCP}$, the system does not experience any phase transition whereas, if $R_{CCP} \leq R < R_{MCP}$, the system experiences the canonical phase transition. If $R \geq R_{MCP}$, both types of phase transition occur.

In Sec. 3 we have considered the case of the canonical phase transition. We have seen that, for $N < N_{OV}$, the result is similar to that obtained in the non-relativistic regime[3]. The result of the phase transition is, indeed, the formation of a compact object containing all the mass of the initial configuration. Things change when we consider the case $N \geq N_{OV}$, because the system exhibits a second collapse at the temperature $\eta_c'$. The result of this collapse is a Black Hole. However, if the value of $N$ is above a critical one (see Ref. 1), the phase transition is suppressed.

In Sec. 4 we have considered the case of the microcanonical phase transition. Similar to the canonical ensemble, the system exhibits a second collapse (at the energy $\Lambda_c''$) towards a Black Hole. Analogous to the canonical ensemble, we observe the phenomenon of the suppression of the phase transition.

The results obtained in this work call for further investigations. For example, the microcanonial phase transitions may be related to the onset of red-giant structure or to the Supernova phenomenon. Furthermore, to check the robustness of the model and have a first "experimental" proof of the occurrence of the phase transition, it would be interesting to perform $N$-body simulations in GR. This could represent a new challenge for Numerical Relativity.

The formation of large scale structures in the universe can be described in terms of a Schrödinger-Poisson system. This fact is justified showing that the Schrödinger-Poisson equations can be obtained as the large $N$ limit of a Newtonian $N$-body system, that, in the cosmological context, describes the evolution of dark matter halos. This result is based on the Nelson stochastic quantization, and on the Calogero conjecture. The relevance of this finding for the study of LSS is discussed.

*Keywords*: Schrödinger-Poisson equations; large tructure formation; dark matter; cosmology, $N$-body simulations.

## 1. Introduction

It is widely accepted tat the formation of large scale structures (LSS) in the universe, as superclusters, sheets and filaments[1], is shaped by collisionless Dark Matter[2] (DM), see[3] for an historical review. In the standard $\Lambda$-CDM cosmological model[4], DM is assumed to be constituted of unknown particle species that interact (almost) only gravitationally, and DM is described as a cold fluid at cosmological scales. In facts, Cold Dark Matter (CDM) is in agreement with all cosmological data, including LSS[1], CMB[5], leansing[6], BAO[7], and Supernovae[8]. Even though DM particles are still elusive, there are currently many DM candidates, and the search for DM particles is an open issue[9].

At cosmological scales above $100\,Mpc$, CDM is successfully described as a pressureless dust fluid; but this approximation fails at smaller scales. Since, at such smaller scales, the typical velocities are non-relativistic, the Newtonian limit of the Einstein equations is sufficient to describe the time evolution of massive bodies within the universe. Indeed, CDM can be described as a classical $N$-body system, in which the individual particles represent huge agglomerates of mass $M$ of elementary dark matter particles of mass $m \ll M$.

The first and most natural way to treat this $N$-body system is to resort to numerical simulations[10–14]. Such simulations show that, if the mass $M$ is much smaller than the mass scale of the structures that we want to characterize, the exact value of $M$ does not affect the LSS formation. For instance, the MILLENNIUM

simulation[10] was carried out tracing the evolution of $N \sim 10^{10}$ identical particles of mass $M \simeq 10^9 M_\odot$, where $M_\odot \simeq 2 \times 10^{30} Kg$ is the solar mass. Although the choice $M \simeq 10^9 M_\odot$ in the $N$-body simulations is fit for purpose, it is still arbitrary. However, an indication on the plausibility of this value for DM halos comes from scalar field DM models[15].

In alternative, one can describe the $N$-body dynamics statistically, by means of the phase space distribution of the bodies $f(t, x, p)$, where the evolution of $f(t, x, p)$ is given by the Boltzmann equation. Furthermore, in the case of LSS formation, $N$ is large and collisions are suppressed, so that the Boltzmann equation reduces to a Vlasov equation[16].

## 2. The Schrödinger method

The so called Schrödinger method (ScM) has been proposed[17–32] as a numerical double of the $N$-body system describing the dynamics of CDM at large cosmological scales. The ScM is based on the hypothesis that, it is possible to associate to the $N$-body system a wave function $\psi$, such that the mass density of the system is given by $\rho = M\, N\, |\psi|^2$. Such a wave function $\psi$ obeys the coupled Schrödinger-Poisson equations (SPEs)

$$\begin{aligned} i\hbar \partial_t \psi &= -\tfrac{\hbar^2}{2a(t)M} \Delta\psi + MV\,\psi\,, \\ \Delta V &= 4\pi G\,\rho\,, \end{aligned} \tag{1}$$

where $V$ is the Newtonian potential, $\rho$ is the DM density, $M$ is the mass of the DM halos, $a(t)$ is a scale factor introduced to take into account the expansion of the universe, and $\hbar$ is a free parameter. The Newtonian potential $V$ is determined through the Poisson equation in (1). The form of the DM density used to run cosmological simulations in[17–32] is $\rho = (M\,|\psi|^2 - \rho_{crit})/a(t)$, where $\rho_{crit}$ is a parameter representing a *comoving critical density of the universe*, although some authors assume $\rho_{crit} = 0$, so that the SPEs reduce to the Schrödinger-Newton equation[33]. However, since we are not interested in discussing the explicit form of the DM density, we will use the generic expression $\rho$. Furthermore, here we are only focused on the validity of the ScM approach, and this is not related to the expansion of the universe, thus hereafter we set $a(t) = 1$.

The SPEs can be viewed as the non-relativistic limit of the Klein-Gordon and Dirac equations. In this case $\hbar$ coincides with the Planck constant $\sim 10^{-34} J\,s$, and numerical solutions of the SPEs point towards ultralight DM particles of mass $m \sim 10^{-23} eV$. However, when the SPEs is interpreted as a numerical double of the $N$-body system of DM halos, $M$ is huge and $\hbar$ is merely a free parameter chosen at will, that determines the phase space resolution in the ScM. To ensure the match with $N$-body simulations one must require $\hbar/M \sim 10^{-4} Mpc \cdot c$, so that $\hbar$ is huge comparison with the Planck constant.

### 2.1. *The Nelson stochastic quantization and the Calogero conjecture*

The agreement between the numerical simulations of DM dynamics based on the $N$-body Newtonian systems (when the bodies have the mass of DM halos, and $\hbar$ is a free parameter) and those based on the SPEs, is usually accepted as an empirical fact[17–32]. However, a deeper view on the relation between the ScM and the $N$-body DM system has been recently proposed in[34], where it has been argued that the SPEs can be obtained as the large $N$ limit of the Newtonian $N$-body system. This result is based on the so called Nelson stochastic quantization and on the Calogero conjecture, as resumed below.

To begin with, let us recall briefly the basis of the Nelson stochastic quantization[35]. Let us consider the classical trajectory of a particle by

$$M\,\ddot{\vec{x}} = -\vec{\nabla}\phi + \vec{B}(t) \tag{2}$$

where $-\vec{\nabla}\phi$ represents all the conservative forces, and $\vec{B}(t)$ is a random force with zero mean, representing a small random noise.

Nelson has shown[36] that, under these hypothesis, the motion of the particle can be described by means of a stochastic process, and the probability distribution $f(x)$ of the particle can be expressed as $f(x) = |\psi|^2$, in terms of a wave function $\psi$ satisfying the Schrödinger equation

$$i\hbar\partial_t\psi = -\tfrac{\hbar^2}{2M}\Delta\psi + \phi\,\psi\,. \tag{3}$$

In this picture the quantum behavior of the dynamics of the particle is induced by the random field $\vec{B}(t)$.

At this point, one can question about the nature of the random force $\vec{B}(t)$. One possibility, conjectured by Calogero[37], is that, in an $N$-body system with Newtonian interactions, $\vec{B}(t)$ is the resultant of the gravitational interactions of each particle with all the other particles, and its random behavior comes from the fact that the classical dynamics of a $N$-body system is chaotic. Exploiting this idea, Calogero has shown that the order of magnitude of the induced Planck constant is[37]

$$\hbar \sim M^{5/3}G^{1/2}(N/ < \rho >)^{1/6}\,, \tag{4}$$

where $N$ and $M$ are the number and the mass of the bodies, $< \rho >$ is the average density of the system, and $G$ the gravitational constant.

Indeed, due to the mechanism conjectured by Calogero, any particle in the $N$-body system undergoes a stochastic gravitational noise due to the classical gravitational interaction with all the other particles, which plays the role of the stochastic random noise $\vec{B}(t)$ in (2). Thus, the dynamics of each particle of the system can be described in terms of a wavefunction $\psi$ solution of (3), where $\hbar$ is given by (4). At that point, one can express the wavefunction of the entire system using the Hartree-Fock approximation, so that the number density of the $N$-body system will be $n(x) = N\,|\psi|^2$. This is the analog of the derivation of the famous Gross-Pitaevskii

equation[38] for a Bose-Einstein condensate by means of the Hartree-Fock approximation, see[39]. Finally, the potential in (3) is $\phi = M\,V$, where $V$ is the gravitational potential solution of the Poisson equation $\Delta V = 4\pi G\rho$, where $\rho = M\,n(x)$. Therefore, based on these arguments, one understands why the dynamics of an $N$-body system in the large N limit is well described by the SPEs (1).

Since the dynamics of DM at large scales is described by huge agglomerates of DM halos interacting via Newtonian potentials, the hypothesis at the basis of the Nelson quantization and of the Calogero conjecture are satisfied. This implies that the evolution of DM can be described statistically by means of the SPEs. The stochastic background responsible for the Nelson quantization is given, as in the Calogero conjecture, by the gravitational interaction between the DM halos, and its stochastic character is due to the chaotic behavior of the $N$-body dynamics. This explains the equivalence of numerical simulations of DM dynamics based on SPEs and $N$-body systems.

What is more, the Calogero conjecture also allows to estimate the order of magnitude of the effective Planck constant in (1). In facts, there is perfect agreement between the empirical value of $\hbar$ used in SPEs, and that obtained by Calogero estimate (4). For instance, in the case of the Millennium simulation[10], the $N$-body problem is solved for $N \simeq 10^{10}$ particles of mass $M \simeq 10^9 M_\odot$ where $M_\odot \simeq 2 \times 10^{30} Kg$ is the solar mass. Using $< \rho > \simeq 3H_0^2/8\pi G \simeq 4 \times 10^{-26} Kg/m^3$, where $H_0 \simeq h^{-1} \times 100 \times km/sMpc$, and $h \simeq 0.73$ is the Hubble constant, equation (4) gives $\hbar \simeq 2 \times 10^{66} Kg\,m^2/s$. This value corresponds to a ratio $\hbar/M \simeq 10^{-4} Mpc\,c$ in the range of values used in numerical simulations, e.g. $\hbar/M \sim 10^{-4} Mpc\,c$ in[28,30] or $\hbar/M \sim 10^{-6} Mpc\,c$ in[29,31].

## 3. Conclusions

In conclusion, the validity of the Schrödinger method as $N$-body double stays in the fact that the $N$-body dynamics is well described in terms of the SPEs in the large N limit. This is due to the the stochastic quantization induced by the random gravitational background produced by the N bodies, as in the Calogero conjecture. When applied to LSS formation, this gives a further argument in support of the validity of the Schrödinger method for the DM dynamics at cosmological scales. Moreover, this derivation of the SPEs is the first known realistic application of the Nelson quantization and of the Calogero conjecture.

# Self–gravitating particles, entropy, and structure formation

Andrew J. Wren*

*London, United Kingdom*
* *E-mail: andrew.wren@ntlworld.com*

I outline a kinetic theory model of gravitational collapse due to a small perturbation. This model produces a pattern of entropy destruction in a spherical core around the perturbation, and entropy creation in a surrounding halo. Core–halo patterns are ubiquitous in the astrophysics of gravitational collapse, and are found here without any of the prior assumptions of such a pattern usually made in analytical models. Motivated by this analysis, I outline a possible scheme for identifying structure formation via data from observations or a simulation. This might aid exploration of hierarchical structure formation, supplementing the usual density–based methods for highlighting astrophysical and cosmological structure at various scales.

*Keywords*: Kinetic theory; Gravitational collapse; Entropy; Structure formation.

## 1. Introduction and Motivation

Many astrophysical contexts see gravitational collapse leading to structure formation. A simple model of gravitational collapse can be constructed based on the virial theorem, with an artificial division between a central core and surrounding halo.[1] Entropy rises within the halo, with at least a relative entropy decrease in the shrinking core. If we further assume that the core's density profile scales with its radius $R$, then its phase space volume varies like $R^{3/2}$ and it is easily seen that there is an absolute fall in entropy within the core.

Note that there may, at least in principle, be two distinguishable entropy–related effects: entropy transport from one volume element to another; and entropy creation/destruction. The distinction is somewhat arbitrary in the artificial virial theorem model just discussed. In kinetic theory treatments however, entropy creation is separately identifiable, and arises only from collisional effects.

This note is based on a full account in Ref. 2. I outline how to construct a kinetic theory model of gravitational collapse allowing analytical description of entropy creation (Sec. 2). A core–halo pattern emerges as a result (Sec. 3). This suggests an approach to identifying structure in simulations and observations (Sec. 4).

## 2. Outline of the Model

The model consists of a small central perturbation to an underlying uniform distribution of self–gravitating particles. Via the well–known "Jeans swindle," a system with a finite number of particles $N$ in a bounded volume can be used to model a uniform arrangement of particles which is unbounded in extent, and so stable if unperturbed.[1]

The perturbation evolves under truncated zeroth and first order BBGKY equations for the evolution of the distribution function (DF) and the correlation function. Write $f_0, f_1$ for the underlying and perturbation DFs, similarly $g_0, g_1$ for the

correlation functions, and set $\mathbf{a}_{1,2}$ to be $N$ times the acceleration of a particle at $1 = (\mathbf{x}_1, \mathbf{v}_1)$ due to a particle at $2 = (\mathbf{x}_2, \mathbf{v}_2)$. The full first order equation for the DF's evolution is[3]

$$\frac{\partial f_1(1)}{\partial t} + \mathbf{v}_1 \cdot \frac{\partial f_1(1)}{\partial \mathbf{x}_1} + \int \mathbf{a}_{1,2}\, f_1(2)\, \mathrm{d}(2) \cdot \frac{\partial f_0(1)}{\partial \mathbf{v}_1} = -\frac{1}{N} \frac{\partial}{\partial \mathbf{v}_1} \int \mathbf{a}_{1,2}\, g_1(1,2)\, \mathrm{d}(2), \quad (1)$$

where the right–hand side gives the "collisional" effects of two–body interactions.

Both $f_0$ and $f_1$ are assumed to have initial Maxwellian velocity distributions, with parameter $\sigma$, and a typical scale for the system is then given[1] by the "Jeans wave number," $k_\mathrm{J} = \sqrt{4\pi G m n}/\sigma$, where $m$ is the (identical) mass of each particle, $n$ is the average number density, and $G$ is Newton's gravitational constant. The model is valid for the beginning of gravitational collapse — the initial period during which the perturbation remains small.

The entropy creation rate comes entirely from collisional effects, and its density at $\mathbf{x}_1$ is

$$\left( \frac{\partial S_{\mathbf{x}_1}}{\partial t} \right)_{\text{creation}} = \int \ln\left[ f(1) \right] \frac{\partial}{\partial \mathbf{v}_1} \cdot \int \mathbf{a}_{1,2}\, g(1,2)\, \mathrm{d}(2)\, \mathrm{d}^3\mathbf{v}_1, \quad (2)$$

where $f = f_0 + f_1$ and $g = g_0 + g_1$. It is useful to coarse grain the entropy, both because it enables progress to be made with analytical calculations, and because identification of structure typically implies focusing on only a range of scales.

The approach of Ref. 2 coarse grains by choosing a parameter $\beta \ll 1$, and then in applying Eq. (2) considering only wave numbers $k < \beta k_\mathrm{J}$. Furthermore, Ref. 2 focuses on only the "asymptotically dominant" part of the DF, correlation, and entropy creation — the part that soon comes to grow fastest.

## 3. Result: a Core–Halo Pattern

I briefly describe the approach of Ref. 2 to calculating the resulting asymptotically–dominant coarse–grained (acg) entropy creation rate, and in particular its dependence on the distance $r$ from the initial central perturbation. Let $S^\circ_\mathrm{acg}$ be the acg entropy created within a sphere of radius $r$ in the time $t$ since the initial perturbation was introduced. For large $N$, Eq. (1)'s collisional term is highly suppressed, and, at leading order in $1/N$, we can ignore it in calculating the contribution of the DF to the first order correlation equation. The resulting equations can then be solved to give, to leading order in $1/N$, perturbation size $\epsilon$, and $\beta$,

$$\frac{\partial^2 S^\circ_\mathrm{acg}}{\partial t\, \partial r} = \frac{2 k_\mathrm{J}^2\, \sigma\, \mathrm{e}^{3 k_\mathrm{J} \sigma t}}{9\pi^2 \beta} \left( \frac{\epsilon N}{n B} \right)^2 \hat{S}^\circ_\mathrm{acg}(k_\mathrm{J} \beta r)\,, \quad (3)$$

with $B = 4\pi/(k_\mathrm{J}\beta)^3$ being the volume of a sphere associated with the coarse–graining scale, and $\hat{S}^\circ_\mathrm{acg}$ is a function shown in Fig. 1. Note that Eq. (3) shows the entropy creation rate's "shell density", expressing the entropy creation on a shell of radius $r$ around the initial perturbation.

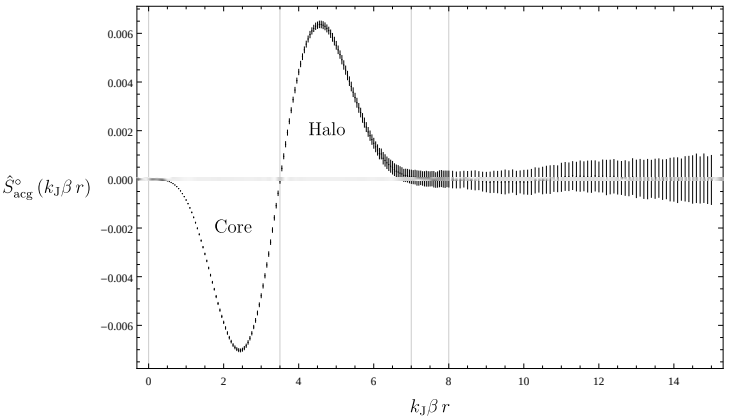

Fig. 1. The entropy–creation pattern function $S^{\circ}_{\mathrm{acg}}$, calculated by numerical integration of an analytical expression. The error bars show integration error estimates. Adapted from fig. 2 of A core–halo pattern of entropy creation in gravitational collapse, A. J. Wren, MNRAS, **477** (2018).

Entropy destruction occurs in a "core" around the central perturbation, with, at leading order, equal (see Ref. 2) and opposite entropy creation in a "halo" extending for a finite radius beyond that core, as shown in Fig. 1. The physical scale for the core–halo pattern depends on the coarse–graining parameter $\beta$: the coarser the graining, the bigger the pattern's physical scale. Entropy destruction (resp. creation) corresponds to collisional relaxation (resp. "de–relaxation") of the perturbation.

A core–halo pattern of gravitational collapse, well known from simulations and observations, is generally set "by hand" in analytical models. As far as the author has been able to determine, this is the first time an analytical kinetic theory model has produced a core–halo pattern.

## 4. Structure Formation in Simulations and Observations

It is well known that the Universe has a multi–scale hierarchical structure, in which core–halo patterns are ubiquitous. The identification of observed or simulated astrophysical structure typically involves considering features of especially high or low densities, in physical space, or phase space. There is no unambiguous definition of structure in this context, which can result in different methods giving different results — for example, in identifying sub–haloes near the centre of dark matter haloes (see Ref. 4), in major halo mergers (see Ref. 5) and in classifying elements of the cosmic web (see Ref. 6). This suggests that complementary methods for identifying structure, or structure formation, may be helpful.

Given data from observations or a simulation, the above analysis suggests we might construct a coarse–grained particle DF and correlation function, which then could give the entropy creation rate from Eq. (2). The pattern of coarse–grained

entropy creation might then give a way to identify structure formation, presumably associated with volumes of relatively lower entropy creation.

A key step is extracting a correlation function from the data. There are various methods for doing this.[7] At least in the kinetic theory model of Sec. 2, the correlation between two particles is small compared with their joint DF. In calculating correlation functions from data, this would imply a need to identify the difference between two quantities of relatively similar size.[7]

This means that robust identification of entropy creation, and hence structure formation, may need rather precise data. The outlook for data of sufficient precision is perhaps encouraging with the development of ever more powerful computer simulations, and the availability of detailed phase space observations from, for example, *Gaia*.[8]

**Acknowledgements**

My thanks to the anonymous referee of Ref. 2 for suggesting more physical discussion should be included, which prompted me to develop Sec. 4's scheme.

Contrary to Cartesian vortexes, Newtonian point masses do not have internal structures and inside thermal energies. The Hamilton kinetic energy demonstrates independent variables for ordered translations and Umov's inside heat-chaos. The sum of these indivisible energies obeys the Lorentz transformations, while their difference drives adaptive self-organization of mechanical systems. The simplified Newtonian model with one consolidated degree of freedom for energies of order and chaos can be replaced by the Cartesian world paradigm. The latter can be learned quantitatively in high and higher schools due to Umov's thermomechanics for inertial heat and de Broglie's thermodynamics of the isolated particle.

*Keywords*: Inside Variables; Adaptive Nonlocality; Chaos-Order Self-Organization.

## 1. Umov's inertial heat

It is almost impossible to understand the nonlocal laws of quantum mechanics when primary education is based on Newton's point masses in empty space, and not on continuous distributions of Cartesian matter-extensions. High school students should learn the basic principles of Descartes and Newton alternatives before they begin formal calculations in the simplest approximation of point mechanical bodies. At the very beginning it is important to understand that "no theory is completely correct", and "experiments can only falsify theories, not confirm them" [1]. In particular, the Newton model erroneously supports independent conservations of mass and energy, while Einstein's relativistic formalism requires only a single conservation of energy, including thermal parts. Teachers of physics should also not conceal Kuhn's metaphysical ideas, such as "Einstein's theory is not merely a more complex version of Newton's (point masses)" and "there is no coherent direction of ontological development".

Cartesian mechanics of 'matter-extension' was developed by Nikolay Umov [3] quantitatively for the slow transfer of continuous energy densities long before the Lorentz transformations and Special Relativity. In 1873, Umov assigned to each mass $m$ the inside energy variable $kmc^2$ and pioneered in the inertial properties of heat after light emission/absorption. The modern relativistic theory can specify the Umov kinematic coefficient $k$ as the Fitzgerald-Lorentz contraction

factor $\sqrt{1-\beta^2} \Rightarrow k$. That time Umov estimated this variable for nonrelativistic ($\beta^2 \equiv v^2/c^2 \ll 1$) energy flows as $1/2 \leq k = (1-0.5\beta^2) \leq 1$. Today it is clear that the Umov's inside energy corresponds to the Lagrange function $L = -mc^2\sqrt{1-\beta^2}$ in the full Hamilton energy $E \equiv -L + \mathbf{v}\cdot\mathbf{P} = mc^2/\sqrt{1-\beta^2}$. The latter does not vanish in the co-moving frame of references, $E_o \equiv mc^2 \neq 0$, and obeys the Lorentz transformation rules,

$$E_o = \frac{E - \mathbf{vP}}{\sqrt{1-\beta^2}}, \quad \mathbf{P}_o = \frac{\mathbf{P} - E\mathbf{v}}{\sqrt{1-\beta^2}} = 0. \tag{1}$$

Hence the Hamiltonian structure of kinetic energies,

$$E = E_o\sqrt{1-\beta^2} + \mathbf{vP} = E_o\sqrt{1-\beta^2} + \frac{\beta^2 E_o}{\sqrt{1-\beta^2}} \equiv \frac{E_o}{\sqrt{1-\beta^2}}, \tag{2}$$

has two virtual (immeasurable) parts of different origins. The first part, $E_o\sqrt{1-\beta^2}$, is the Lagrange (1788) - Umov (1873) energy of inside heat-chaos and the second part, $\mathbf{vP}$, is the Hamilton (1833) energy of ordered spatial translations. Changes of the sum of this kinetic energy can be measured in practice. Newtonian mechanics with one degree of freedom for the summary kinetic energy (2) is well formulated for direct tests and mathematical descriptions of 'how' bodies move. But mechanics without inside degrees of freedom never explains 'why' free bodies move (or gravitate) in their closed system and 'what' burned Hiroshima.

In Umovian mechanics of inertial heat, the inside energy variable $E_o\sqrt{1-\beta^2}$ decreases with increasing Hamilton energy of ordered translations $\mathbf{vP} = \beta^2 E_o/\sqrt{1-\beta^2}$. From our Cartesian point of view, every gravitating body tends to a relativistic equipartition of its kinetic energies of inside chaos and external translational order. The principle of equipartition of relativistic kinetic energies behind the observed mechanical motion [4] forms the non-Newtonian ontology of thermomechanics and frees Einstein's adaptive dynamics from the thermal death problem.

Internal heat or latent degree of kinematic freedom cannot be reasonably introduced by the point mass model. Consequently, the inside chaos variable fundamentally distinguishes the Cartesian paradigm of 'matter-extension' from the empty space concept of Newton [5,6]. Indeed, the point particle of Newton has only kinematic degrees of freedom for spatial translations, while the continuous Cartesian vortex contains elementary internal energy even in the co-moving system. Planck-Laue relativistic cooling $Q(\beta^2) = E_o\sqrt{1-\beta^2} \approx (mc^2 - mv^2/2 - mv^4/8c^2 - ...)$ of thermal energy $E_o \equiv Q_o$ (or inside inertial heat) and Hamilton heating $p_i v^i \equiv H(\beta^2) + L(\beta^2) = E_o/\sqrt{1-\beta^2} - E_o\sqrt{1-\beta^2} \approx (mv^2 + mv^4/2c^2 + ...)$ due to ordered translations reiterate together pro-Newtonian changes $\Delta[Q(\beta^2) + p_i v^i] = \Delta(mv^2/2 + 3mv^4/8c^2 + ...)$ of the summary kinetic energy at the low speed limit of Cartesian transport.

## 2. Cartesian interpretation of relativistic thermomechanics

The slow spatial motion of a Cartesian extended body is primarily the energy transfer of the volume integral, $Q_o(1-\beta^2/2)$, over ordered densities of Umov's

inside chaos. The concomitant fraction of the translational kinetic energy $Q_o\beta^2$ is considered a small correction of inside thermal chaos due to the ordered spatial movement of chaotic densities. The Cartesian transport of two competing energies from chaos and order formally corresponds to the Newtonian transport of constant mass $Q_o/2c^2$ plus one variable energy $Q_o\beta^2/2$. Newton had no idea about the inside degree of kinematic freedom and modeled measurable changes $[Q_o(1-\beta^2/2)+Q_o\beta^2]-Q_o = Q_o\beta^2/2$ of the total kinetic energy through one constant coefficient $Q_o/2c^2 \equiv m/2$.

It is important to teach that the kinematic cooling of Umov-Planck-Laue $Q/Q_o = \sqrt{1-\beta^2} \approx 1-\beta^2/2$ of mechanical bodies coincides with a decrease in the frequency-energy $\hbar\omega/\hbar\omega_o = \sqrt{1-\beta^2} \approx 1-\beta^2/2$ of a quantum particle in wave dynamics. This cooling originates from the kinematic time dilation in the Lorentz transformations. Therefore, Cartesian thermomechanics of non-empty space with the inside heat-chaos of Umov, relativistic dynamics of the rest mass-energy of Einstein, the particle-wave dualism of quantum mechanics and the thermodynamics of the isolated particle of de Broglie have the common temporological nature. Such coherent convergence of nonlocal Cartesian mechanics with quantum mechanics of elementary material distributions encourages high school teachers to discuss Umov's thermomechanics of inertial inside energies in parallel with the Newtonian simplifications of reality. High and higher schools should start teaching inside variables of the Hamilton energy in the available nonrelativistic[3] and relativistic[7] terms. Then students can be prepared to understand the spatial transport of quantum energy and accept the $\hbar$-randomness[8] of the nonlocal Cartesian world.

# How history and philosophy of science can inform teaching and learning of general relativity in upper secondary school

Magdalena Kersting

*Department of Physics, University of Oslo,*
*Postboks 1048, Oslo, 0316, Norway*
**E-mail: magdalena.kersting@fys.uio.no*
*www.mn.uio.no/fysikk/english/people/aca/magdak*

Science educators have to move beyond traditional content-focused instruction to teach concepts of Einsteinian physics. This work presents a design-based research project that introduced general relativity (GR) to upper secondary school students in Norway. The educational approach invited students to explore the historical development and philosophical aspects of GR within a digital learning environment. Results based on focus group interviews show that students were particularly motivated by such an approach because it emphasised the cultural and social relevance of physics and it linked GR to their previous knowledge of physics. Employing history and philosophy of science in the service of physics education can serve as a successful approach to making GR more accessible to young learners.

*Keywords*: Physics Education; History & Philosophy of Science; General Relativity.

## 1. Context and Background

Few scientific discoveries have had a bigger impact on our understanding of the universe than GR. Einstein's revolutionary theory of gravity did not only herald a new scientific age but fostered a new interest in the philosophy of space and time as well. Yet, despite its scientific, philosophical, and technological importance, GR and other topics of Einsteinian Physics[1] lack from most school curricula around the world. This work presents a design-based research project that introduced GR to upper secondary physics students in Norway.[2] The educational approach invited students to explore the historic development and philosophic aspects of GR within a digital learning environment. Research suggests that history and philosophy of science (HPS) can be fruitful in teaching and learning of physics: HPS perspectives can foster awareness of the nature of science and they help to promote deeper understanding of scientific ideas.[3] This work aims to study how such approaches might foster understanding of and motivation for GR.

## 2. History and Philosophy in General Relativity Education

Science educators promote the use of HPS as a fruitful teaching strategy in learning domains where students have to fundamentally revise their understanding of space and time.[4] This strategy can be traced back to Einstein who was guided by the wish to understand the intrinsic value of physics when developing his theories of relativity:[5] The physicist wished for the human mind to understand the reality of nature. Indeed, by presenting a new view towards space, time, and gravity, GR invites students to view reality from a new philosophical viewpoint. This philosophic

perspective can be complemented with historic approaches to teaching physics. According to Einstein, knowledge of the history of physics is important because it emphasises connections between a new theory and its rich environment:

> To use a comparison, we could say that creating a new theory is not like destroying an old barn and erecting a skyscraper in its place. It is rather like climbing a mountain, gaining new and wider views, discovering unexpected connections between our starting point and its rich environment. But the point from which we started out still exists and can be seen, although it appears smaller and forms a tiny part of our broad view gained by the mastery of the obstacles on our adventurous way up.[6]

In the next sections, this work explores how HPS can inform teaching and learning of GR in upper secondary schools. This exploration is guided by the following research question: **How can a historic and philosophic approach to teaching and learning of Einsteinian Physics foster understanding of and motivation for GR?**

## 3. Theoretical Framework and Methodology

To bridge the gap between educational research and the reality of physics classrooms, methods of design-based research informed the design and development of a digital learning environment about GR.[7] The goal was to find workable ways of making GR accessible at the upper secondary school level. In line with the iterative nature of the design-based research framework, two rounds of field studies were conducted - one in spring 2016 and one in spring 2017. In total, eleven physics classes in five upper secondary schools in Norway participated in the trials. To gain insight into students' experiences with the digital learning resources, the author of this paper conducted seven semi-structured focus group interviews with 5 to 8 participants per group and 46 students (18-19 years) in total. The teachers chose the students to allow for a balance of gender and to include both stronger and weaker students. The interviews were based on an interview guide that included the design of the learning activities, the use of history and philosophy, and challenges and motivation in the learning domain of GR. The interviews were transcribed and analysed using thematic analysis.[8] The themes of the thematic analysis focused on the use of history and philosophy; the individual codes unpacked students' motivation, interests, and challenges.

## 4. Results and Design Examples

In the focus group interviews, students expressed their curiosity towards learning about GR at the high school level and without advanced calculations. Students had a general expectation that the topic would be difficult and they showed respect towards Einstein's achievement. At the same time, they were looking forward to

learning more about relativistic ideas such as gravitational waves that they had encountered in popular culture and in the news before. Generally, the findings show that students approved of an HPS approach in GR education. Four factors turned out be particularly motivating or insightful for the participating students:

(1) Einstein is a popular figure in contemporary culture and students mentioned repeatedly that they enjoyed learning more about Einstein. The learning environment presented Einstein as a real person who struggled to find a new theory of gravity. Being able to follow some of these struggles helped students to identify with Einstein. One student in the interview expressed that relating to Einstein's reasoning helped him to understand GR more qualitatively:

**Student**: *You got into the same reasoning that made Einstein and his friend, it's the same that got into the thoughts of them that resonate within me a bit as well. That you could use this knowledge in a somehow different way than to calculate.*

(2) Physics was presented as an important part of our cultural heritage with social relevance for our daily lives. Students liked to get a broader and more comprehensive perspective on physics and to make connections to the society as a whole. In particular, they appreciated to learn that physics is an ongoing endeavour and that physicists do not have answers to everything.

(3) Students learned that physics was a modern field that has more to offer than just textbook knowledge. Many students appreciated these insights into perspectives of modern researchers as the following excerpt shows:

**Interviewer**: *So do you feel you have learned something?*
**Student**: *Yes, I think it was really nice that you got, like, the perspective of recent scientists who made their new discoveries so that you get a bit more recent perspectives. Because it is a bit easy to think that physics is just somehow in the book at school.*

(4) Finally, the historic contextualisation helped students to link new ideas in GR to their knowledge of classical physics and to their previous experiences. Students appreciated to be able to follow the reasoning that led to GR; this presentation helped them to understand why a theory actually works as the following excerpt from an interview illustrates:

**Interviewer**: *So you mentioned this historic approach. [...] What do the others think about it?*
**Student 1**: *I think it was good.*
**Student 2**: *But that it became clear why it is like that. And it is good that they explained how they ended up there, why it is actually like that.*

**Student 3**: *Yes, it gets maybe easier to make connections. Or the theories up to now, if you get, somehow, you know a bit about the history and what happened before. And you get something you think - because you think the history is fascinating - you make better connections this way than just getting the theory or the formula straight into your face without any evidence for understanding why it came out like that.*

**Student 4**: *And if you also learn about how they reached this, then it can be easier to understand why it actually works.*

The findings from the focus group interviews informed revisions of the learning environment that took place over the course of two consecutive years in 2016 and 2017. These revisions led to a series of activities that draw on historic events and philosophic questions (Figures 1-3). The learning environment *General Relativity* is accessible at the Norwegian open-access learning platform Viten: www.viten.no/relativity

Fig. 1. The learning environment contrasts the first experimental confirmation of GR to the recent breakthrough in gravitational wave astronomy. Students get to explore the gravitational bending of light observerd during the solar eclipse in 1919 and they can move between newspaper headlines from 1919 and 2016.

## 5. Discussion and Conclusion

Science educators have to move beyond traditional content-focused instruction to teach concepts of Einsteinian physics. This work explored how perspectives of history and philosophy of science can inform teaching and learning of GR at the upper secondary school level. Specifically, this work presented a design-based research project that invited students to explore the historic development and philosophic aspects of GR within a digital learning environment[2]. Previous research suggests

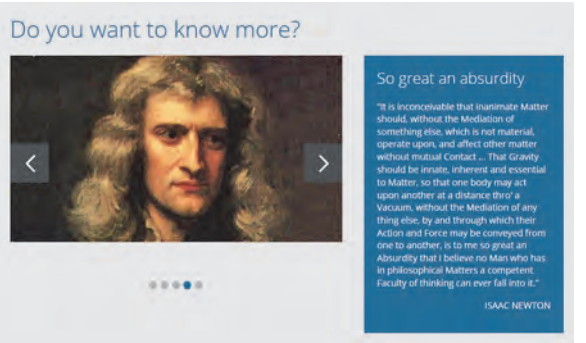

Fig. 2. Newton felt uncomfortable with the mysterious force of gravity that exhibits the principle of action at a distance. In a letter to a colleague, Newton called the gravitational force a 'great absurdity'.

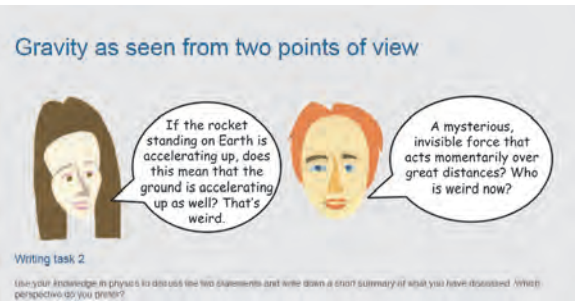

Fig. 3. In a discussion task, students are asked to discuss the epistemological implications of Einstein's and Newton's interpretation of gravity.

that HPS approaches can be an effective way to help students revise their understanding of space and time in line with relativistic ideas[4,9]. Findings of this study shift the focus away from novel conceptualisations of space and time towards more personal and societal aspects of GR: Guided by the question of how an HPS approach to teaching and learning of GR might foster understanding of and motivation for GR, the findings show that students were motivated by the presentation of Einstein as a real and struggling person instead of an all-knowing genius. Moreover, students appreciated perspectives that emphasised the cultural and social relevance of physics. Being able to gain insights into modern researchers' perspectives and seeing that there are still many unresolved questions in physics was another motivating factor. HPS perspectives did not only foster motivation among students; the historic contextualisation of GR helped students to link relativistic concepts to their previous knowledge of physics. The findings thus support an observation by Einstein that awareness of the history of physics can facilitate deeper understanding of physics[6]. In conclusion, the findings of this work suggests that employing history

and philosophy of science in the service of physics education can serve as a successful approach to making GR more accessible to learners at the upper secondary school level.

# Teaching Einsteinian concepts in the first years of Italian secondary school: some preliminary results

Matteo Luca Ruggiero*

*IIS Russell-Moro-Guarini, Corso Molise 58, Torino Politecnico di Torino, Corso Duca degli Abruzzi 24, Torino, Italy and INFN, Sezione di Pisa, Italy*
**E-mail: matteo.ruggiero@polito.it*

As a matter of fact, modern physics is not taught in the majority of secondary schools; however, recent researches suggest that there are several advantages in introducing modern physics early in school. This is, for instance, the approach of the Einstein-First project. In the context of this approach, we report here some preliminary results of an intervention in the first year of Italian secondary school.

*Keywords*: Einsteinian physics; relativity; teaching modern physics.

## 1. Introduction

Einstein's theory of General Relativity (GR) has had a renewed popularity due to recent discoveries, such as the observations of gravitational waves signals by interferometers[1], which also proved the existence of black holes, and the reconstruction of a black hole shadow[2]. These discoveries have had a widespread impact on the non-specialist public: indeed, they have been presented as "events" by the scientific community, and the results have been shared with great success in the media. These scientific events testify a renewed interest in science which could perhaps stimulate new enrollments in Science, Technology, Engineering and Mathematics (STEM) subjects: as a matter of fact (see e.g. Refs. 3, 4, 5) recent analyses show a decline of interest among students in these disciplines. The detection of gravitational waves required an enormous scientific endeavour in order to build and operate the interferometers such LIGO and VIRGO; the detection process exploits the quantum behavior of light and, consequently, we may say that these discoveries are a beautiful example where the two great theories of XX century are used together to discover the ultimate secrets of Nature. Notwithstanding the great interest in the new discoveries also among teenagers, who have a privileged and frequent access to the internet and social media, we notice that modern physics, i.e. Quantum Mechanics (QM) and GR are usually out of school curricula, except for some outline in the last year of secondary schools. The Italian education system makes no exception: in fact, in the syllabi for secondary school[a] the word "Einstein" appears just one time, in the syllabus of schools leaving qualification in scientific studies, while the word "quantum mechanics" is totally absent: the syllabus ends with the "wave nature of light, as postulated by De Broglie" and the "uncertainty principle". As a consequence, the great majority of students are completely unaware of the physical principles on which are based not only the recent discoveries but also their

[a]Indicazioni Nazionali, MIUR (2010): https : //tinyurl.com/indicazioni − nazionali

mobile phones and tablets. Teaching modern physics in view of its application in technology could help to motivate students: on one hand, this is important to face the decline in STEM enrollment and, on the other hand, this can help to shorten the distance between citizens and science, in order to have more awareness in political choices connected with scientific issues. Recent research has suggested that it is possible and also effective to introduce modern physics early in schools: the Einsten-First project[6–8] aims at introducing the basic ideas of modern physics from an early age, i.e. starting from primary school. The introduction of the language and the concepts of modern understanding of space, time, matter and radiation at early age could prevent conceptual conflicts between Newtonian physics and Euclidean geometry, that are commonly taught at school, and the completely different world view of modern physics. According to the latter, Euclidean geometry is just a good approximation in regions where the space-time curvature is small; similarly, space and time are quite different from the absolute entities of Newtonian physics, but they are woven into the fabric of space-time, which is a "living" thing according to the famous J.A. Wheeler quotation: *spacetime tells matter how to move, matter tells spacetime how to curve*. So, if the concepts of modern physics can be learnt from an early age, there will be no conflict associated to the transition from the classical to the modern paradigm of physics. Moreover, an early introduction of the fundamental ideas of modern physics can help also those students that will not study modern physics at secondary or tertiary level to have an understanding of the physics principles which current technology is based on. Of course, this new approach does not suggest to completely abandon the paradigm of classical physics, because it is important to understand many phenomena; it is rather suggested that classical physics can be introduced *after* learning the modern physics paradigm or, at least, its language and basic concepts. This paper reports the results of a short intervention, according to the approach of the Einstein-first project, in the first year of Italian secondary school, aimed at introducing some basic ideas of GR.

## 2. The context and the intervention

The intervention involved students in the first year of "ITES Russell-Moro" in Torino, a secondary school leaving qualification in economics. Students in this school are taught science (physics, Earth science, biology and chemistry) during the first two years only. In particular, physics is taught during the first year and its curriculum includes Newtonian mechanics, thermology and electricity. Modern physics is completely out of the syllabus, so that students leave this school without any knowledge of the XX century physics and its applications. In particular, 46 students, aged 14-16, from three classes took part in the intervention. It is important to emphasize that during the year, students were not taught Newton law of gravitational interaction: they only studied weight as a force. The development of the intervention, which consisted in four 1-hour lessons during four days for each class, is described in details below.

Fig. 1. Triangles on a flat (left) and curved surface (right).

Fig. 2. The space-time simulator. Frames on the left show the path of two steel balls on the flat surface of the simulator, which corresponds to propagation in vacuum: the two balls move along straight lines. Frames on the right show the path of the two steel balls on the curved surface of the simulator, around masses: the two balls undergo a deflection with respect to the vacuum case. This is a simple model of gravitational deflection.

**DAY 1.** Students were asked to answer a pre intervention questionnaire, which is an Italian translation of the one already used by the Einstein-First collaboration in the interventions described in[6,8]; we just removed questions about the quantum nature of matter and light, since these subjects were not discussed during the intervention. The key ideas we focused on are the non Euclidean features of geometry, that are important to describe the current model of space-time, and the way distant bodies interact. The relevant questions are:

Q1: Can parallel lines ever meet? Circle Yes or No. Please give reasons for your answer.

Q2: Can the sum of the angles in a triangle be different from 180 degrees? Circle Yes or No. Please give reasons for your answer.

After compiling the questionnaire, students were asked to measure the perimeter and the sum of the internal angles of triangles on a sheet of paper (see Figure 1, left).

**DAY 2.** Students were asked to draw triangles on the surface of balloons (using sticky tape to draw "straight" lines) and, then, to measure their perimeter and the sum of internal angles (see Figure 1, right). Moreover, they had to draw a plot of the sum of internal angles as a function of the perimeter.

**DAY 3.** Students were involved in activities at the "space-time simulator". Actually, models and analogies prove useful to introduce the concepts of modern physics and they are developed and successfully tested by the Einstein-First project. In particular, the space-time simulator is a table with a stretch lycra sheet, which

creates a visual representation of the curvature of space-time in presence of masses (see Figure 2). Using steel or billiard balls, the simulator allows to visualize the connection between mass and curvature. A ball moves along a straight line if no other masses are present on the sheet, while its path is curved in presence of other masses: in analogy, a mass move along a geodesic in space-time, that is a straight line if space-time is flat; in presence of other masses the ball moves along a curved geodesic. Moreover, it is manifest that the lycra sheet deformation is proportional to the masses on it. The simulator allows to visualize the action at distance between masses, which is explained in terms of curvature (see Figure 3). In summary, the space-time simulator enables to perform numerous experiments that simulate what is observed in the Universe, such as, for instance, planetary motion, tidal effects, gravitational deflection of light. Indeed, what is really visualised is the interplay between masses and the lycra sheet deformation, which can be described in terms of spatial curvature. Accordingly, the space-time simulator might be misleading, since in the Universe curvature is refereed both to the space and *time* dimensions. For instance, free fall in curved space-time can be explained as a consequence of the warping of time (see Ref. 9 and references therein). That being said, in our intervention the space-time simulator was used as an analogy, and it proved useful to emphasize the non Euclidean features of surfaces.

Fig. 3. The space-time simulator and action ad distance: the simulator can be used to simulate action at distance, since moving one ball over the lycra sheet provokes a deformation and, hence, the motion of the other ball.

**DAY 4.** After a brief summary of the activities performed, with emphasis on the common idea linking them (curvature of surfaces) and a short description of the analogy with what really happens in the Universe (planetary motion, tidal effects, gravitational deflection of light), students were asked to answer the post intervention questionnaire. In the latter we added a question, motivated by the experiments performed at the space-time simulator (see Figure 3):
QX: The gravitational attraction force is effective only when the two bodies are close to each other. Circle Yes or No. Please give reasons for your answer.

## 3. Analysis of the results

In Figure 4 we report the analysis of the answers to the questions Q1 and Q2. As for Q1 “Can parallel lines ever meet?”, before the intervention *all students* answered

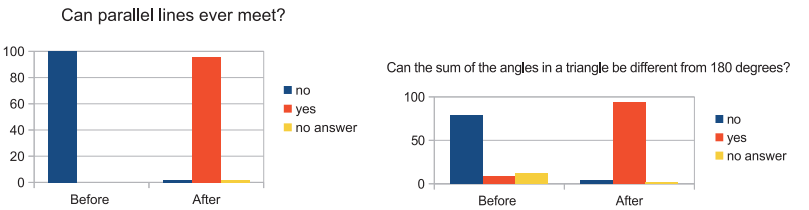

Fig. 4. Distributions of the answers Q1 (left) and Q2 (right) before and after the intervention

NO, which is an expected results: Euclidean geometry is based on the parallel postulate and students are taught that two lines are parallel if they *never* meet. However, during the intervention students experimented that things are quite different if the surface is curved, such as on a balloon; furthermore, the analogy with what happens on the surface of the Earth was discussed during the intervention. After the intervention, the number of students who answered YES is about 95%; it is relevant that in the reasons they mentioned the role of the surface: "on curved surfaces, such as the Earth, they can meet". Things are quite similar for Q2 "Can the sum of the angles in a triangle be different from 180 degrees?" Before the intervention about the 79% of students answered that the sum cannot be different from 180 degrees; 9% said that the sum can be different and the rest (12 %) did not answer. In this case, the percentage of students who said that the sum needs to be 180 is lower than 100% reported in Q1: we have to consider that perhaps some of them did not remember this rule of Euclidean geometry. After the intervention, those who say that the sum can be different from 180 degrees are about 94%, which is similar to the result of Q1. In the motivations they say "it depends on the surface", "it depends on the triangle", "it depends on the perimeter"; the latter motivations rely on to fact that they analyzed the mathematical relationship between the perimeter and the sum of internal angles on the balloons. As for the extra question QX "The gravitational attraction force is effective only when the two bodies are close to each other", 54% of the students correctly answered that bodies interact at distance; in the motivations they correctly point out that "masses influence each other even though they are not close", thus revealing that they correctly understood the mutual character of interaction, which has been emphasized during the experiment with the space-time simulator. The other students (46%) did not believe that interaction between distant bodies is possible, notwithstanding the experiments at the space-time simulator. Actually, the ideas of secondary schools students about action at distance were investigated in the past (see e.g. Ref. 10), and evidence was found that in order to realize the abstract notion of action at distance students need a connection: for instance, between a falling object and the Earth, they consider air as a medium that creates a connection. Also, their ideas about forces acting at distance are guided by the notion of a support: for instance,

objects at rest or moving horizontally are supported by other objects, and these supports prevent them by falling. Moreover, students are not concerned with mutual interactions, rather they think of the Earth that attracts the apple, or the Sun that attracts the Earth, thus emphasizing a dominant role in the interaction: a much higher level of abstraction is needed to understand gravitation as an interaction between any two bodies at any distance in space. Indeed, there is the possibility that even though students correctly understood the experiments with two masses on the space-time simulator, they thought that, in any case, masses are not "far away" on the simulator and they were not able to generalize their observations to a more abstract situation of truly distant objects. In conclusion, in this intervention we focused on the non Euclidean features of curved surfaces and, using the space time simulator, we described by analogy what happens in curved space-time. As a result of the intervention, the great majority of students was able to understand that the properties of Euclidean geometry are not true on curved surface. The analogue model at the space-time simulator enabled us also to introduce the concept of action at distance, which was correctly understood by more than one half of the sample. The results of the intervention are positive, if we consider the context and the students' attitude: of course further interventions on different contexts, with a larger number of students and with more educational content are needed to evaluate the effectiveness of this approach.

Motivating the students to study General Relativity from many points of view is a key for success in teaching GR. The risk of flattening GR to its mathematical contents is continuously present in the secondary school as well as in the undergraduate studies of Physics.

*Keywords*: History of Science, General Relativity, Philosophy of Science.

## 1. Motivations: from wave optics to quantum behavior

Most of Italian students do not choose STEM curricula after school. Among the reasons there is a lack of experimental activities especially for the last year of physics in the High Schools. An approach to Quantum Physics is recommended through spectroscopy, thanks to the wave-particle behavior of the photon, the availability of a LASER and the simplicity of many diffraction experiments. This not help to understand how interference and diffraction phenomena have been studied before the advent of LASER. The Michelson Interferometer was used to study the vectorial composition of the light with the orbital Earth velocity, or the cosmic ether existence. The result was that the modulus of velocity c was conserved, while the direction followed the vectorial composition traditional rule (Andrei, et al. 2014; Sigismondi, 2008).

Nevertheless the historical process through selection rules and suspected extraterrestrial elements like Helium and Coronium is also important. Quantum Mechanics verifies the Heisemberg principle for the matter, the diffraction of light is already the Heisemberg principle for photons (Vavilov, 1959).

At the Italian Ministry for Education a course in Spectroscopy is already organized for the high school teachers http://ls-osa.uniroma3.it/documents/98 (2018) but the general vision given by the historical perspective is still lacking. The selection rules found in spectroscopy $\Delta L, \Delta m = 0, \pm 1, \pm 2$...were interpreted later as permitted quantum gaps, and their violations as 'prohibited rules' upon which many fundamental discoveries have been done (e.g. 21 cm line of neutral Hydrogen and all galactic structure). The 'rarity' of some transition were obtained directly from quantum mechanics density function, as tunnel effect.

## 2. Gravitational waves and interferometry

In General Relativity the interferometers of Michelson e Morley (1881-1887) have been adapted to gravitational waves in LIGO/VIRGO experiments using

the same principles and the same geometry. The interference of Michelson experiment http://adsabs.harvard.edu/abs/1882USNAO...1..109M (1882) and http://adsabs.harvard.edu/abs/1887SidM....6..306M (1887) was realized with white light, a situation which is different from monochromatic LASER light, and much closer with the first experiences on diffraction made by the Jesuit father Francesco Maria Grimaldi in 1648, with very tiny Fresnel shadows occurring for the interplay between Planck's black body photons distribution and Fresnel integrals for each wavelength. Similarly at Mount Wilson Observatory the interference between the stellar light received at opposite parts of the diameter of the 100 inches reflecting Hooker telescope (the technological marvel of its time) permitted the evaluation of the stellar diameter of Betelgeuse and the first stellar surface images. (S. Metchev (2013) in http://www.astro.sunysb.edu/metchev/PHY517_AST443/solar_diameter.pdf and M. Richmond http://spiff.rit.edu/richmond/occult/bessel/bessel.html (2018))

Also this interferometer can be realized and studied at school, as in 2018 at Pescara Galilei Lyceum. The utilization of Magneto Optical Filter in Gravitational Waves detection was proposed by the late Alessandro Cacciani (1937-2007) (P. Rapex, 2008).

## 3. Relativistic light bending

Other effects like light gravitational bending are very difficult to be observed, even if the GAIA astrometry satellite is now able to measure it at 180 degrees from the Sun and the major planets (Crosta and Mignard, 2005). The gravitational light bending can be simulated only by the analogy photon-glass ball on the elastic carpet made by lycra, with a big mass at the center. This similarity (used e.g. at Rome 3 University, Physics dept.) is not completely satisfying because of the photon is massless. The apparatus is good for showing N-body simulations with friction, to show e.g. the onset of King profiles in galactic clusters... in a few seconds, instead of billions of years.

This effect shows clearly the difference from Newtonian and Einstein gravity upon light (sir James Jeans, The Growth of Physical Sciences, 1948). Unless it is not evident form Mitchell 1780 approach of escape velocity, which gives correctly the value of Schwarszschild Radius, but considers light gravitating as matter, even if we know the photon is massless.

The great project Gravity Probe B on the Lense-Thirring effect of Earth's frame dragging is also far from experimental level without using analogies (Ruffini and Sigismondi, 2002). The Solar figure, spherical within few parts in a million, was measured by Dicke (Damiani et al., 2007) to assess the possibility of a scalar-tensorial theory beyond Einstein and now is measured to understand the physics of solar secular variability, so important for our climate (Sigismondi, 2011 and 2005).

## 4. General Relativity and the view of the World

General Relativity was important to the view of the World as much as Quantum Physics. Bertrand Russell (1974) was one of the most relevant divulgators of Einstein's theory, he contributed to spread the basis of Special and General Relativity, but the relevance of the new cosmological view of the World is left too often to the University specialistic studies, to avoid also to fall into 'unpleasant metaphysical questions'. While right these questions can drive more students to STEM. The continuum model of the Universe has been the same at all times, in order to agree with cosmological expansion a continuum creation is required, which is not against the physical laws. This last part, being not comprised, is not present in textbooks like M. Parotto, E. L. Palmieri, il Globo Terrestre e la sua Evoluzione, Zanichelli Bologna 2017. The 'unpleasant metaphysical questions' are indeed more stimulating than *increasing precision for saying anything about the truth* [Martin Heidegger]. Russell in this respect says that 'the consequences of Relativity are neither grandiose nor surprising as believed' (p. 218-219). The differences between classical and relativistic physics are usually very small, and the mass of 4 weights of 1 Kg is smaller than 4 Kg, but the evidence of this effect of the equivalence of mass - binding energy in percentage four nuclei of H are lighter (0.7% less) than one nucleus of He. Russell explains that events instead of coordinates are the essence of Relativity, and the action [Energy*time] is its natural unit of measure (p. 156-7). The action which fulfilled some aesthetic, almost theological principle of symmetry with Maupertuis, Lagrange and Laplace, and become crucial in Quantum Mechanics with Planck constant in 1900 (J. Jeans, Il Cammino della Scienza, Bompiani, 1953, p. 318-328).

## 5. Cosmology, a new science with proper identity after Einstein

With Einstein the Physical Cosmology was born, because the Universe's behavior was comprised as a consequence of the matter's distribution Peebles, Principles of Physical Cosmology, 1990). The Galileian idea of same physics on the Earth and across all Universe reached in this way its maximum extent. Einstein by introducing the Cosmological Constant and later Hoyle, Bondi and Gold (Dubois and Fuezfa, 2019), and finally Hawking and Hartle tried to obtain a static or stationary Universe, conceptually not different from Aristotle's one, while Lemaitre proposed an evolutionary Universe, finding the observational proofs. The hot big bang theory was confirmed by the Cosmic Background Radiation discovery (1965) even if Zeldovich (1965) theorized a cold one, based upon Fermi energy (Aguirre, 1999).

## 6. Ether and eternity of the Universe from Aristotle to Hawking

The role of Cosmic Ether, object of the studies of Michelson and Morley, is now played by the Dark Energy, which behaves exactly as the Cosmological Constant, and produces an accelerating Universe. Framing philosophically the Physical

Fig. 1. Y. B. Zeldovich and Pope John Paul II.

Cosmology helps the students, also the ones far from STEM, to understand the present debate on the view of our World. Comparing the theories of expanding Universe, eternal Universe, oscillating Universe with the ancient ones, made by Aristotle and object of a condemnation by Etienne Tempier bishop of Paris in 1277, is also important. Instead of blocking science this act stimulated it, because always Christianity has considered God as Creator. He is not a lier and the man can know Him from Revelation, but also from the Creation itself (as S. Thomas of Aquinus few years before Etienne Tempier taught in Paris University). 'God does not play with dices' used to say Einstein and this debate is nowadays extremely far from the current main stream. [Alessandro Giostra http://www.upra.org/evento/pierre-duhem-la-nascita-della-scienza-nel-mondo-occidentale-cristiano/]

The beginning of science and the possibility of confutation for a theory According to Pierre Duhem (Système du Monde, 1913-58), the act of Etienne Tempier was the starting point of the modern science. The construction of the theory, moreover, is based upon some principles, and the speed of light in vacuum-the veritable "celeritas"- cannot be surpassed. The recent (2011) debate of OPERA results in Gran Sasso National Laboratories and CERN of Geneva can be studied in this optics. Provided this frame, there are plenty of motivations to know the essence of General Relativity and its contribution to the view of our World.

Einstein did know well that only one contradictory fact on the speed of light in vacuum would destroy all General Relativity theory. This characteristic of a scientific theory is the Fälschungsmöglichkeit, possibility of confutation, theorized by Karl Popper.

Nowadays we are facing more and more with dogmatic theories like the anthropogenic global warming or the OGM vs organic food with respect to human health or the gender theory on the sexual differentiation induced by the environment and the cultural background... whatever fact has an explanation pro that theory, and no disproofs are possible, and we are in a scientific, post-galileian era. This note may appear unappropriated either in a scientific congress either in the school, but the paralysis of autonomous thinking starts from the school and spread to all parts of the society. If the most influential theory of Physics is subjected naturally to the possibility of confutation, why there should be theories that cannot be falsified? A theory since Ptolemy and before is a representation of the reality, which can be changed with a better one, when it is available.

Fig. 2. The cover of "Sozein ta Phainomena" of Pierre Duhem.

# Lie point symmetries of the geodesic equations of the Gödel's metric

Fatma Al-Kindi and Muhammad Ziad*

*Department of Mathematics, College of Science, Sultan Qaboos University, AlKhoudh, Muscat, Sultanate of Oman*

**E-mail: mziad@squ.edu.om*

Lie point symmetries of the geodesic equations of the Gödel's metric are found. These form a ten dimensional Lie algebra. The Lie algebra contains a maximal seven-dimensional solvable sub-algebra. It also contains five dimensional subalgebra of isometries of the metric. The isometries are used to reduce the order of the geodesic system by one. The time-like trajectories of the Gödel's metric are then derived and their graphs in the $(r, \phi)$ plane are displayed showing some interesting features of the dynamics in this universe.

*Keywords*: Lie Symmetries; Isometries; Geodesic Equations.

## 1. Introduction

Systems of ordinary differential equations frequently appear in applied sciences and engineering, and most of the time finding their solution appears a big challenge. Theory of continuous groups via Lie point symmetries provides an alternate approach for finding solutions of such systems.[1–3] Finding Lie point symmetries (using Einstein summation convention)

$$X = \xi(x, y^i)\frac{\partial}{\partial x} + \eta^i(x, y^i)\frac{\partial}{\partial y^i} \tag{1}$$

of a system of $k$ second order ordinary differential equations

$$H^a(x, y^i, \dot{y}^i, \ddot{y}^i) = 0, \quad a, i = 1, .., k, \tag{2}$$

means finding the general solution $\xi(x, y^i)$ and $\eta^i(x, y^i)$ of the determining equations obtained from the symmetry condition[2]

$$\hat{X}(H) = 0, \tag{3}$$

where $\hat{X}$ is the extension of the symmetry operator $X$ written as

$$\hat{X} = \xi(x, y^i)\frac{\partial}{\partial x} + \eta^i(x, y^i)\frac{\partial}{\partial y^i} + (\eta^i)'(x, y^i)\frac{\partial}{\partial \dot{y}^i} + (\eta^i)''(x, y^i)\frac{\partial}{\partial \ddot{y}^i}, \tag{4}$$

and $(\eta^i)'$ and $(\eta^i)''$ are obtained from the extension formula given by

$$(\eta^i)^{(n)} = \frac{d(\eta^i)^{(n-1)}}{dx} - (y^i)^{(n-1)}\frac{d\xi}{dx}. \tag{5}$$

Determining equations obtained from eq. (3) appear as identities in the derivatives of dependent variables, thus they split into $k$ systems of linear partial differential equations in the functions $\xi$ and $\eta^i$ which are to be solved simultaneously.
Gödel's metric in a cylindrical coordinate system $(t, r, \phi, z)$, where $t < \infty$, $0 \leq r \leq \infty$, $0 \leq \phi \leq 2\pi$, $-\infty < z < \infty$, given by

$$ds^2 = a^2 \left( [dt + \sqrt{2} \sinh^2 r d\phi]^2 - dr^2 - dz^2 - \sinh^2 r \cosh^2 r d\phi^2 \right), \tag{6}$$

ascertain the geodesic equations

$$\ddot{t} + \frac{4 \sinh r}{\cosh r} \dot{t}\dot{r} + \frac{2\sqrt{2} \sinh^3 r}{\cosh r} \dot{r}\dot{\phi} = 0, \tag{7a}$$

$$\ddot{r} + 2\sqrt{2} \sinh r \cosh r \dot{t}\dot{\phi} - \sinh r \cosh r (1 - 2 \sinh^2 r) \dot{\phi}^2 = 0, \tag{7b}$$

$$\ddot{\phi} - \frac{2\sqrt{2}}{\sinh r \cosh r} \dot{t}\dot{r} + \frac{2}{\sinh r \cosh r} \dot{r}\dot{\phi} = 0, \tag{7c}$$

$$\ddot{z} = 0, \tag{7d}$$

where dot over head the variables $t$, $r$, $\phi$ and $z$ denote the derivatives with respect to the arc length parameter $s$. The solution of these equations have been a topic of interest to many researchers following different approaches.[4–6] The Killing vectors from these symmetries are singled out to reduce the order of the system. In the following section, the Lie point symmetries of the system are found along with the analysis of the resulting Lie algebra. In section 3 we use the Killing vectors to reduce the order of the system. The solution of the system is then achieved and a graphic representation of the geodesics is given.

## 2. Lie point symmetries of the geodesic system

Applying the second prolongation of the symmetry generator of the system (7) produces four determining equations, which give a system of seventy PDEs. The solution of this system then gives the components of the infinitesimal generator $X$ which appears to be

$$\xi = c_1 s + c_2 z + c_3, \tag{8}$$

$$\eta^1 = -\sqrt{2} \tanh r \, (c_4 \sin \phi - c_5 \cos \phi) + c_7, \tag{9}$$

$$\eta^2 = c_4 \cos \phi + c_5 \sin \phi, \tag{10}$$

$$\eta^3 = -\frac{2 \cosh^2 r - 1}{\sinh r \cosh r} \, (c_4 \sin \phi - c_5 \cos \phi) + c_6, \tag{11}$$

$$\eta^4 = c_8 s + c_9 z + c_{10}. \tag{12}$$

This provides a basis of the Lie algebra given by

$$X_1 = s\frac{\partial}{\partial s},\ X_2 = z\frac{\partial}{\partial s},\ X_3 = \frac{\partial}{\partial s},$$
$$X_4 = -\sqrt{2}\tanh r\sin\phi\frac{\partial}{\partial t} + \cos\phi\frac{\partial}{\partial r} - \frac{2\cosh^2 r - 1}{\sinh r\cosh r}\sin\phi\frac{\partial}{\partial\phi},$$
$$X_5 = \sqrt{2}\tanh r\cos\phi\frac{\partial}{\partial t} + \sin\phi\frac{\partial}{\partial r} + \frac{2\cosh^2 r - 1}{\sinh r\cosh r}\cos\phi\frac{\partial}{\partial\phi},$$
$$X_6 = \frac{\partial}{\partial\phi},\ X_7 = \frac{\partial}{\partial t},\ X_8 = s\frac{\partial}{\partial z},\ X_9 = z\frac{\partial}{\partial z},\ X_{10} = \frac{\partial}{\partial z}, \tag{13}$$

forming a ten-dimensional Lie algebra $L_{10}$ which is neither solvable nor nilpotent. It is trivial to identify the Nöether gauge symmetries which appear to be $X_3,\ X_4,\ X_5,\ X_6 + \frac{\sqrt{2}}{2}X_7,\ X_7,\ X_8,\ X_{10}$ in eqs. (13). The maximal solvable subalgebra is given by

$$L_7 = \left\langle X_1 + X_9,\ X_1 - X_9,\ X_2,\ X_3, X_6 + \tfrac{\sqrt{2}}{2}X_7,\ X_7,\ X_{10}\right\rangle \subset L_{10}. \tag{14}$$

## 3. Reduction of the order of the system

One can use Cartan's theory,[2] according to which there exists a first integral, $X_a\dot{x}^a$ for each symmetry generator $X = \xi_a\partial_a$ obtained in eqs. (13) which satisfies the equations of Killing[2]

$$X_{a;b} + X_{b;a} = 0. \tag{15}$$

It is straight forward to check that the symmetry generators $X_i$ where $i = 4, ..., 7, 10$ satisfy eqs. (15). The corresponding first integrals are given by

$$a = -\sinh r\cosh r\sin\phi\left[2\sqrt{2}\dot{t} + \dot{\phi}(2\sinh^2 r - 1)\right] - \dot{r}\cos\phi, \tag{16}$$
$$b = \sinh r\cosh r\cos\phi\left[2\sqrt{2}\dot{t} + \dot{\phi}(2\sinh^2 r - 1)\right] - \dot{r}\sin\phi, \tag{17}$$
$$c_1 = \sqrt{2}\dot{t}\sinh^2 r + \dot{\phi}\sinh^2 r(\sinh^2 r - 1), \tag{18}$$
$$c_2 = \dot{t} + \sqrt{2}\sinh^2 r\dot{\phi}, \tag{19}$$
$$c_\circ = -\dot{z}, \tag{20}$$

where $a, b, c_\circ, c_1$ and $c_2$ are arbitrary constants. The tangent vector $\dot{x}^a$ and the associated underlying curve $x^a(s)$ are said to be timelike if and only if $g_{ab}\dot{x}^a\dot{x}^b > 0$. Fixing $g_{ab}\dot{x}^a\dot{x}^b = 1$ yields

$$\left(\dot{t} + \sqrt{2}\sinh^2 r\dot{\phi}\right)^2 - \sinh^2 r\cosh^2 r\dot{\phi}^2 - \dot{r}^2 = 1 + c_\circ^2 \equiv c_3 \tag{21}$$

or

$$c_2\dot{t} + c_1\dot{\phi} - \dot{r}^2 = c_3. \tag{22}$$

The sign of the term $\dot{t} + \sqrt{2}\sinh^2 r\dot{\phi}$ and hence of $c_2$ may be defined to identify the future or past directions of the tangent vector $\dot{x}^a$. One may be interested

in exploring $x^a(s)$ which are timelike and whose tangent vector fields are future directed. Thus necessarily we require $c_2 > 0$, whereas $c_3 > 0$ from eq. (21).

Eqs. (16)-(22) give explicit expression of $\dot{x}^a$ reducing the system as

$$\dot{t} = c_2 \left[1 - \frac{2\sinh^2 r}{\cosh^2 r}\right] + \frac{\sqrt{2}c_1}{\cosh^2 r}, \tag{23a}$$

$$\dot{\phi} = \frac{\sqrt{2}c_2}{\cosh^2 r} - \frac{c_1}{\sinh^2 r \cosh^2 r}, \tag{23b}$$

$$\dot{r}^2 = c_2^2 - c_3 - \left(\frac{\sqrt{2}c_2 \sinh r}{\cosh r} - \frac{c_1}{\sinh r \cosh r}\right)^2, \tag{23c}$$

$$\dot{r} = -\left(a\cos\phi + b\sin\phi\right). \tag{23d}$$

Using the transformation $u = \sinh^2 r$, and letting

$$4(c_2^2 + c_3) = \varepsilon^2, \quad \frac{(c_2^2 + 2\sqrt{2}c_1c_2 - c_3)}{2(c_2^2 + c_3)} = \alpha, \quad \frac{c_1^2}{(c_2^2 + c_3)} = \beta^2, \tag{24}$$

eq. (23c) can be written as

$$\dot{u}^2 = -\varepsilon^2(u^2 - \alpha u + \beta^2), \tag{25}$$

where $c_2^2 + c_3 > 0$ as $c_3 > 0$. The latter equation gives

$$u(s) = \alpha + \sqrt{\alpha^2 - \beta^2}\cos(\varepsilon s + s_\circ) = \sinh^2 r. \tag{26}$$

Now using eq. (26) in eqs. (23a)-(23b) after simplification one gets the time-like trajectories in the Gödel universe as

$$\begin{aligned}(t, r, \phi, z) = \Bigg(&\sqrt{2}\tan^{-1}\left(\sqrt{\frac{\alpha+1-\sqrt{\alpha^2-\beta^2}}{\alpha+1+\sqrt{\alpha^2-\beta^2}}}\tan\left(\sqrt{c_2^2+c_3}s + \frac{s_\circ}{2}\right)\right) - c_2 s + t_\circ,\\ &\sinh^{-1}\sqrt{\alpha + \sqrt{\alpha^2-\beta^2}\cos(\varepsilon s + s_\circ)},\\ &\tan^{-1}\left(\frac{\left(\sqrt{\frac{\alpha+1-\sqrt{\alpha^2-\beta^2}}{\alpha+1+\sqrt{\alpha^2-\beta^2}}} - \sqrt{\frac{\alpha-\sqrt{\alpha^2-\beta^2}}{\alpha+\sqrt{\alpha^2-\beta^2}}}\right)\tan\left(\sqrt{c_2^2+c_3}s + \frac{s_\circ}{2}\right)}{1 + \sqrt{\frac{\alpha+1-\sqrt{\alpha^2-\beta^2}}{\alpha+1+\sqrt{\alpha^2-\beta^2}}}\sqrt{\frac{\alpha-\sqrt{\alpha^2-\beta^2}}{\alpha+\sqrt{\alpha^2-\beta^2}}}\tan^2\left(\sqrt{c_2^2+c_3}s + \frac{s_\circ}{2}\right)}\right) + \phi_\circ, -c_\circ z + z_\circ\Bigg).\end{aligned} \tag{27}$$

For specific values of the constants $\alpha$ and $\beta$ given in eqs. (24) one can find the extrema of $u(s)$. Putting $\dot{u}(s) = 0$ of eq. (25) gives

$$u^2 - 2\alpha u + \beta^2 = 0, \tag{28}$$

which yields

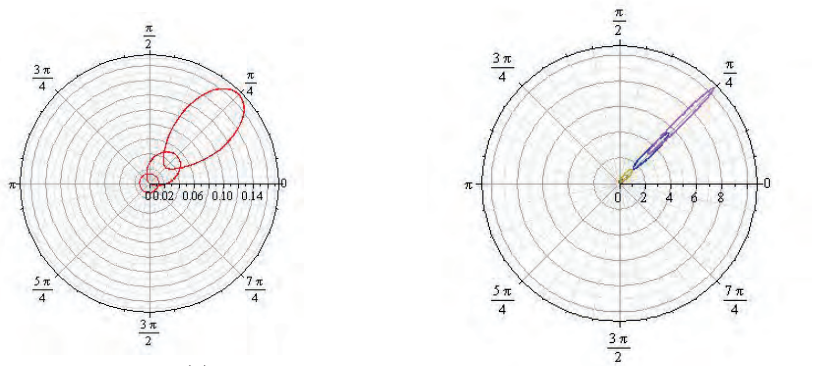
$$u(s) = \alpha \pm \sqrt{\alpha^2 - \beta^2}. \tag{29}$$

So $u(s)$ attains its maximum at $u(s) = \alpha + \sqrt{\alpha^2 - \beta^2}$ and its minimum at $u(s) = \alpha - \sqrt{\alpha^2 - \beta^2}$.

For $c_{1min} = \dfrac{-\sqrt{2}c_2 \pm \sqrt{c_2^2 + c_3}}{2}$, $\alpha^2 - \beta^2 = 0$, which means that $u(s) = \alpha$ is constant and the graph in $(u, \phi)$ plane is a circle with radius equal to $\alpha$. In this case

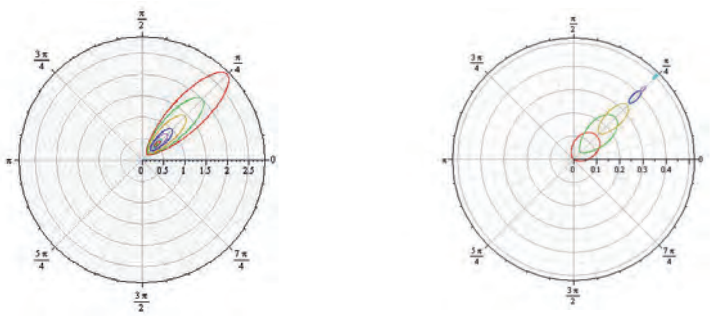
$$0 < u(s) < \frac{-1 + \sqrt{2}}{2}. \tag{30}$$

For $c_1 > c_{1min}$ the trajectories appear to be ellipses stretching and tending to be a line as $c_1 \to \infty$. If $c_3 \to c_2^2$ the ellipses shrinks and tends to be a point. Figures below illustrates the above analysis.



(a) (b)

Fig. 1. Trajectories in $(y, \phi)$ plane with increasing $c_1$, and $c_2, c_3$ are fixed.



(a) (b)

Fig. 2. (a) Trajectories with $c_1$ and $c_2$ are fixed, $0 < c_3 < c_2^2$. (b) Trajectories with $c_1$ is increasing as $c_3 \to c_2^2$.

## 4. Conclusion

It is known that a system of $n$ $kth$-order ODEs admitting a $kn$-dimensional transitive solvable Lie sub algebra, is solvable by quadratures.[2] In our case the system of four coupled ODEs admits a seven dimensional solvable sub-algebra, thus this result can not be applied for the reduction of the system. Other well known procedure is given by the Cartan theory according to which, if a system of ODEs admits a set of Killing vectors, then one obtains first integrals of the system corresponding to these Killing vectors.[2] In the present situation, the Gödel's metric serves as the Lagrangian of the system, which admits five Killing vectors and correspondingly gives five first integrals of the system given by eqs. (16)-(20). This led to a solution of the system in parametric form $x^a(s)$, $a = 1..4$ given by eq. (27). The graphs of the trajectories in $(r, \phi)$-plane for all possible values of the parameters appearing in the solution are also given at the end.

The Schwarzschild-de Sitter/Kottler geometry is the unique spherical solution of the vacuum Einstein equations with positive cosmological constant. Putative alternatives in the literature are shown to either solve different equations or to be the SdSK solution in disguise. No-hair and cosmic no-hair come together in a new simultaneous theorem for SdSK in the presence of an imperfect fluid.

*Keywords*: Schwarzschild-de Sitter, no-hair, cosmic no-hair.

## 1. Introduction

The Jebsen-Birkhoff theorem of general relativity (GR) states that the Schwarzschild geometry is the unique vacuum, spherical, asymptotically flat solution of the Einstein equations

$$G_{ab} \equiv R_{ab} - \frac{1}{2}\, g_{ab} R = 0\,. \tag{1}$$

The theorem is no longer true if matter is present, but what if a cosmological constant $\Lambda$ is included? The Einstein equations change to $G_{ab} = -\Lambda g_{ab}$. It is straightforward to extend the proof of the Jebsen-Birkhoff theorem to this case. In particular, *for $\Lambda > 0$, the Schwarzschild-de Sitter/Kottler (SdSK) geometry is the unique solution,*

$$ds^2 = -\left(1 - \frac{2m}{R} - H^2 R^2\right) dT^2 + \frac{dR^2}{1 - \frac{2m}{R} - H^2 R^2} + R^2 d\Omega^2_{(2)} \tag{2}$$

*(where $H = \sqrt{\Lambda/3}$).*

This fact is not mentioned in modern GR textbooks, even though de Sitter space is extremely important for inflationary and dark energy cosmology [1] and, for $\Lambda < 0$, anti-de Sitter space is fundamental for string theories and the AdS/CFT correspondence. A proof of the generalized Jebsen-Birkhoff theorem for $\Lambda \neq 0$ can be found in Synge's 1960 textbook.[2] A recent proof in null coordinates has

appeared in[3]. Complicated proofs appear in[4–7]. The proof in spherical coordinates is a very simple extension of the standard textbook proof of the Jebsen-Birkhoff theorem.[11] However, there is confusion in the literature: purported alternatives to SdSK have been reported, which would violate the theorem. More general solutions with FLRW "background" in the presence of matter do not seem to reduce to SdSK when the "background" becomes de Sitter. Enter modified gravity: there are claims that polytropic stars in $f(R)$ and scalar-tensor gravity cannot be matched to SdSK. If they are interesting for cosmology, these theories contain a time-dependent $\Lambda$. Perhaps SdSK is not the correct solution to match internal solutions to—the situation is unclear. It does not help if the situation is unclear even in GR, which is what we clarify here.

## 2. Putative Alternatives to SdSK

Here we compare putative alternative geometries to SdSK, using the areal radius as the radial coordinate.

### 2.1. *Abbassi-Meissner proposal*

It is claimed that an alternative to SdSK is the Abbassi-Meissner solution[8–10]

$$ds^2 = -f(t,r)dt^2 + \frac{\mathrm{e}^{2Ht}}{f(t,r)}\,dr^2 + \mathrm{e}^{2Ht}r^2 d\Omega^2_{(2)}\,, \tag{3}$$

where $H = \sqrt{\Lambda/3}$, $m = \text{const.}$, and

$$f(t,r) = h(t,r) + \sqrt{h^2(t,r) + H^2 r^2 \mathrm{e}^{2Ht}}\,, \tag{4}$$

$$h(t,r) = \frac{1}{2}\left(1 - H^2 r^2 \mathrm{e}^{2Ht} - \frac{2m}{r}\,\mathrm{e}^{-Ht}\right). \tag{5}$$

Let us change to the areal radius $R = \mathrm{e}^{Ht}r$ instead of $r$, and to the new time $T$ defined by

$$dT = dt + \frac{2HRdR}{A_0\left(A_0 + \sqrt{A_0^2 + 4H^2R^2}\right)}\,, \tag{6}$$

where

$$A_0(R) = 1 - \frac{2m}{R} - H^2R^2 = 2h(0,R)\,. \tag{7}$$

The line element becomes diagonal and locally static

$$ds^2 = -A_0(R)dT^2 + \frac{2}{A_0(R) + \sqrt{A_0^2(R) + 4H^2R^2}} \cdot \left[1 + \frac{2H^2R^2}{A_0\left(A_0 + \sqrt{A_0^2 + 4H^2R^2}\right)}\right] dR^2 + R^2 d\Omega^2_{(2)}\,, \tag{8}$$

and it is clearly not SdSK. It solves the field equations $G_{ab} = -\Lambda g_{ab} + T_{ab}$ with a radial flow.[11]

### 2.2. *Non-rotating Thakurta solution*

The Thakurta solution of GR[12] is conformal to Kerr and describes a rotating black hole embedded in a FLRW universe. The non-rotating, spherical subcase is the late time limit of generalized McVittie solutions[13] and it is also the $\omega \to \infty$ limit of a class of Brans-Dicke perfect fluid solutions describing inhomogeneous universes found by Ref. 14. The non-rotating Thakurta line element is

$$\begin{aligned} ds^2 &= a^2(\eta)\left[-\left(1-\frac{2m}{r}\right)d\eta^2 + \frac{dr^2}{1-2m/r} + r^2 d\Omega^2_{(2)}\right] \\ &= -\left(1-\frac{2m}{r}\right)dt^2 + \frac{a^2 dr^2}{1-2m/r} + a^2 r^2 d\Omega^2_{(2)}\,, \end{aligned} \tag{9}$$

where $a(\eta)$ is the scale factor of the FLRW "background". Changing coordinates to $(t, r) \to (T, a(t)r)$ with

$$dT = \frac{1}{F}\left(dt + \frac{HRdR}{A^2 - H^2R^2}\right)\,, \tag{10}$$

$$A(t,R) = 1 - \frac{2m}{r} = 1 - \frac{2M}{R}\,, \qquad M \equiv ma(t)\,, \tag{11}$$

the line element becomes

$$ds^2 = -\left(1 - \frac{2M}{R} - \frac{H^2R^2}{1-\frac{2M}{R}}\right)F^2 dT^2 + \frac{dR^2}{1-\frac{2M}{R} - \frac{H^2R^2}{1-2M/R}} + R^2 d\Omega^2_{(2)} \tag{12}$$

(where $F$ is an integrating factor) and it solves the field equations $G_{ab} = -\Lambda g_{ab} + q_a u_b + q_b u_a$, where $q^c$ (with $q^c u_c = 0$) describes a purely spatial radial flow.

### 2.3. *Castelo Ferreira metric*

The Castelo Ferreira line element[15] is

$$\begin{aligned} ds^2 = &-\left[1 - \frac{2m}{R} - H^2R^2\left(1-\frac{2m}{R}\right)^{\alpha}\right]dt^2 + \frac{dR^2}{1-\frac{2m}{R}} - 2HR\left(1-\frac{2m}{R}\right)^{\frac{\alpha-1}{2}} dtdR \\ &+R^2 d\Omega^2_{(2)} \end{aligned} \tag{13}$$

with $\alpha, m$ constants and $H = H(t)$. The coordinate change

$$dT = \frac{1}{F}\left(dt + \frac{HRdR\left(1-\frac{2m}{R}\right)^{\frac{\alpha-1}{2}}}{1-\frac{2m}{R} - H^2R^2\left(1-\frac{2m}{R}\right)^{\alpha}}\right) \tag{14}$$

turns the line element into

$$\begin{aligned} ds^2 = &-\left[1 - \frac{2m}{R} - H^2R^2\left(1-\frac{2m}{R}\right)^{\alpha}\right]F^2 dT^2 \\ &+\frac{dR^2}{1-\frac{2m}{R} - H^2R^2\left(1-\frac{2m}{R}\right)^{\alpha}} + R^2 d\Omega^2_{(2)}\,. \end{aligned} \tag{15}$$

One can choose the background to be de Sitter space, then one obtains the non-rotating Thakurta solution if $\alpha = -1$ and the SdSK solution if $\alpha = 0$. However, the general Castelo Ferreira metric is not SdSK.

## 3. A Simultaneous No-Hair/Cosmic No Hair Theorem

The Jebsen-Birkhoff no-hair theorem states that the Schwarzschild solution is generic; the cosmic no-hair theorem states that de Sitter space is generic. Then, does a simultaneous no-hair/cosmic no-hair theorem exist, stating that SdSK is generic in some sense?

One can write any spherical metric as

$$ds^2 = -A^2(t,R)dt^2 + B^2(t,r)dR^2 + R^2 d\Omega^2_{(2)} \tag{16}$$

without loss of generality. Now one needs some assumptions about the matter content. In the previous examples of putative SdSK solutions, a common ingredient was the imperfect fluid stress-energy tensor

$$T_{ab} = (P+\rho)\, u_a u_b + P g_{ab} + q_a u_b + q_b u_a \,, \quad u_c u^c = -1 \,, \quad q_c u^c = 0 \,, \tag{17}$$

so we assume 1) this $T_{ab}$ with barotropic and constant equation of state $P = w\rho$, with $w = \text{const.}$; 2) spherical symmetry; 3) the solution of $G_{ab} = -\Lambda g_{ab} + 8\pi T_{ab}$ is asymptotically de Sitter: there is a de Sitter-like cosmological horizon of radius $R_H$ and the solution reduces to SdSK as $R \to R_H$.

The Einstein equations become

$$\frac{\dot{B}}{BR} = 4\pi T_{01} \,, \tag{18}$$

$$A^2 \left( \frac{2B'}{B^3 R} - \frac{1}{B^2 R^2} + \frac{1}{R^2} \right) = \Lambda A^2 + 8\pi T_{00} \,, \tag{19}$$

$$\frac{2A'}{AR} - \frac{B^2}{R^2} + \frac{1}{R^2} = -\Lambda B^2 + 8\pi T_{11} \,, \tag{20}$$

$$\frac{A'B}{A} - B' - \frac{RB^2\ddot{B}}{A^2} + \frac{R\dot{A}\dot{B}B^2}{A^3} - \frac{RA'B'}{A} + \frac{RA''B}{A}$$
$$= \left(-\Lambda R^2 + 8\pi T_{22}\right) \frac{B^3}{R} \,. \tag{21}$$

The fluid 4-velocity and energy flux density are

$$u_\mu = (-|A|, 0, 0, 0) \,, \qquad q_\mu = \left(0, B^2 q, 0, 0\right) \,, \tag{22}$$

while the stress-energy tensor is

$$T_{00} = A^2 \rho \,, \qquad T_{01} = -|A| B^2 q \,, \tag{23}$$

$$T_{11} = B^2 P \,, \qquad T_{22} = \frac{T_{33}}{\sin^2\theta} = R^2 P \,, \tag{24}$$

where $T_{01} > 0$ and $q < 0$ correspond to radial inflow.

In the case of inflow $q < 0$ we have

$$(B^2)^{\cdot} = -8\pi|A|B^4 Rq > 0\,, \tag{25}$$

therefore $B^2 = g_{11}$ increases with time. Assuming the metric coefficients to be continuous and differentiable, there are then two possibilities:

- either $B^2(t,R) \to +\infty$ for any fixed $R$ as $t \to +\infty$, or
- $B^2(t,R)$ has an horizontal asymptote as $t \to +\infty$.

Consider the first case. The apparent horizons are located by

$$\nabla^c R \nabla_c R = 0 \quad \leftrightarrow \quad 1/B^2 = 0. \tag{26}$$

If $B^2 \to +\infty$ as $t \to +\infty$ or as $t \to t_{max}$, then at late times all points of space (at any $R < R_H$) lie arbitrarily close to an apparent horizon. This situation is familiar in cosmology: it corresponds to a phantom universe ending in a Big Rip singularity at $t_{max}$ and the apparent horizon shrinks around a comoving observer as the cosmic expansion super-accelerates. This phantom asymptotics contradict the assumption of de Sitter asymptotics and we discard this case.

In the other case in which $B^2(t,R) \to B_0^2(R)$ as $t \to +\infty$, we have $\dot{B} \to 0$ as $t \to +\infty$. Then the radial flow $q \to 0$ as $t \to +\infty$. Differentiate the (0,0) Einstein equation to obtain

$$8\pi\dot{\rho} = \frac{2}{R}\left(\frac{B'}{B^3}\right)^{\cdot} - \frac{1}{R^2}\left(\frac{1}{B^2}\right)^{\cdot} \to 0 \quad \text{ as } \; t \to +\infty\,. \tag{27}$$

Then the equation of state $P = w\rho$ yields $\dot{P} \to 0$ as $t \to +\infty$. The (2,2) (or (3,3)) equation gives

$$8\pi\dot{P} = \frac{2}{R}\left(\frac{A'}{AB^2}\right)^{\cdot} + \frac{1}{R^2}\left(\frac{1}{B^2}\right)^{\cdot} \approx \frac{2}{RB^2}\left(\frac{A'}{A}\right)^{\cdot} \to 0 \tag{28}$$

as $t \to +\infty$, then $A^2$ also becomes time-independent, and the metric becomes static. To make progress, use the covariant conservation equation $\nabla^b T_{ab} = 0$ for the imperfect fluid, obtaining

$$\begin{aligned} &u_a u^b \nabla_b (P+\rho) + [(P+\rho)\, u_a + q_a]\, \nabla^b u_b \\ &+ [(P+\rho)\, u_b + q_b]\, \nabla^b u_a + \nabla_a P + u^b \nabla_b q_a + u_a \nabla^b q_b = 0\,. \end{aligned} \tag{29}$$

Projecting onto the time direction $u^a$ and using $u^a \nabla_b u_a = 0$ leads to

$$-\dot{\rho} - (P+\rho)\, \nabla^b u_b + u^a q^b \nabla_b u_a + u^a u^b \nabla_b q_a - \nabla^b q_b = 0\,. \tag{30}$$

At late times $q^c$ and $\dot{\rho}$ disappear from this equation, leaving $(P+\rho)\, \nabla^b u_b \simeq 0$. In general $\nabla^b u_b \neq 0$ (this quantity reduces to $3H > 0$ for large $r$) and we are left with $P + \rho \to 0$ as $t \to +\infty$. Either the fluid reduces to a pure $\Lambda$ (then the vacuum uniqueness theorem for SdSK holds trivially), or else both $\rho$ and $P = w\rho$ become subdominant and $\Lambda$ dominates. In this case the solution also reduces to SdSK.

In the case of outflow $q > 0$, one has instead $(B^2)^{\cdot} = -8\pi|A|B^4Rq < 0$; since $B^2$ is bounded from below by zero and it decreases as $t \to +\infty$, it must have an horizontal asymptote with $B^2(t, R) \to B_0^2(R)^+$ as $t \to +\infty$. Then $\dot{B} \to 0$ and $q \to 0$ and we repeat the reasoning done for $q < 0$ from here.

A special case is that of a perfect fluid $q^a = 0$; then $T_{01} = 0$ and the (0,1) equation gives $B = B(R)$. It is then straightforward to prove that it must be $P = -\rho$ and that SdSK is the unique solution.[16]

## 4. Conclusions

A generalized Jebsen-Birkhoff theorem holds for $\Lambda \neq 0$ but, although its proof is straightforward, it does not appear in modern GR textbooks. In particular, for $\Lambda > 0$, SdSK is the unique spherical vacuum solution. Putative alternatives to SdSK in this situation are either non-vacuum solutions or SdSK in disguise. Going beyond the vacuum case, we have proved a simultaneous no-hair and cosmic no-hair theorem in the presence of $\Lambda$ and a radial purely spatial heat flow. Further generalization to other forms of matter will be pursued in the future.

# Higher dimensional conformal-$U(1)$ gauge/gravity black holes

Seyed Hossein Hendi[1,2*]

[1] *Physics Department and Biruni Observatory, College of Sciences, Shiraz University, Shiraz 71454, Iran*
[2] *Research Institute for Astronomy and Astrophysics of Maragha (RIAAM), P.O. Box 55134-441, Maragha, Iran*

Motivated by quantum nature of gravitating black holes, higher dimensional exact solutions of conformal gravity with an abelian gauge field is obtained. It is shown that the obtained solutions can be interpreted as singular black holes.

## 1. Introduction

Considering the quantum effects in gravitational interaction, one may find that the higher-curvature modification of general relativity is inevitable. However, in order to have a physically ghost free theory of higher-curvature modifications, some special constraints should be applied. Fortunately, there are known higher-curvature interesting renormalizable actions with no ghosts under certain criterion. As an interesting example, we can regard the so-called Conformal Gravity (CG), which is defined by the square of the Weyl tensor [1, 2].

The CG is an interesting theory of modified general relativity with a remarkable property which is sensitive to angles, but not distances. In other words, it is invariant under local stretching of the metric which is called the Weyl transformation, $g_{\mu\nu}(x) \to \Omega^2(x) g_{\mu\nu}(x)$. It has been shown that CG is useful for constructing supergravity theories [3, 4] and can be considered as a possible UV completion of gravity [5–7]. It may be also arisen from twister-string theory with both closed strings and gauge-singlet open strings [8]. Moreover, CG can be appeared as a counterterm in $adS_5/CFT_4$ calculations [9, 10]. In addition to the motivations mentioned above, solving the dark matter and dark energy problems are two of the most important and interesting motivations of studying CG theory [7].

Since CG is renormalizable [5, 11] and the requirement of conformal invariance at the classical level leads to a renormalizable gauge theory of gravity, it seems interesting to consider black holes in CG which permits a consistent picture of black hole evaporation [12]. The first attempt to obtain the spherically symmetric black hole solutions in four dimensions has been done by Bach [13], and then, Buchdahl has considered a particular case of the conformal solutions in [14]. It is worthwhile to mention that the 4-dimensional solution of Einstein gravity is a solution of CG as well. In addition, it has been shown that the Einstein solutions can be obtained by considering suitable boundary condition on the metric in CG [15, 16].

CG can also be introduced in higher dimensions ($D > 4$), straightforwardly [17]. Nevertheless, unlike the 4-dimensional case, CG does not admit Einstein trivial

*email address: hendi@shirazu.ac.ir

solutions in higher dimensions. This nontrivial behavior is due to the fact that in contrast to the 4-dimensional action, the Kretschmann scalar $R^{\alpha\beta\gamma\delta}R_{\alpha\beta\gamma\delta}$ contributes dynamically in the higher dimensions [18]. Such a nontrivial behavior motivates one to investigate higher dimensional CG black hole solutions.

The outline of this paper is as follows. In the next section, we give a brief review on neutral and charged black holes of CG in 4-dimensional spacetime. We also construct $D$-dimensional topological static black hole solutions of CG gravity in the presence of generalized Maxwell theory. We finish our paper with some concluding remarks.

## 2. Four-dimensional exact solutions

At the first step, we consider a four-dimensional conformal action as

$$\begin{aligned} I_G &= -\alpha \int d^4x\sqrt{-g}C_{\lambda\mu\nu\kappa}C^{\lambda\mu\nu\kappa} \\ &\equiv -2\alpha \int d^4x\sqrt{-g}\left[R^{\mu\nu}R_{\mu\nu} - \frac{1}{3}(R^{\alpha}{}_{\alpha})^2\right], \end{aligned} \tag{1}$$

where the Weyl conformal tensor is

$$\begin{aligned} C_{\lambda\mu\nu\kappa} &= R_{\lambda\mu\nu\kappa} + \frac{1}{6}R^{\alpha}{}_{\alpha}\left[g_{\lambda\nu}g_{\mu\kappa} - g_{\lambda\kappa}g_{\mu\nu}\right] \\ &\quad - \frac{1}{2}\left[g_{\lambda\nu}R_{\mu\kappa} - g_{\lambda\kappa}R_{\mu\nu} - g_{\mu\nu}R_{\lambda\kappa} + g_{\mu\kappa}R_{\lambda\nu}\right]. \end{aligned} \tag{2}$$

Variation of action (1) with respect to the metric tensor leads to the following equation of motion

$$\begin{aligned} &W^{\mu\nu} = 2C^{\mu\lambda\nu\kappa}{}_{;\lambda\kappa} - C^{\mu\lambda\nu\kappa}R_{\lambda\kappa} = \\ &\frac{1}{2}g^{\mu\nu}(R^{\alpha}{}_{\alpha})^{;\beta}{}_{;\beta} + R^{\mu\nu;\beta}{}_{;\beta} - R^{\mu\beta;\nu}{}_{;\beta} - R^{\nu\beta;\mu}{}_{;\beta} - 2R^{\mu\beta}R^{\nu}{}_{\beta} \\ &+\frac{1}{2}g^{\mu\nu}R_{\alpha\beta}R^{\alpha\beta} - \frac{2}{3}g^{\mu\nu}(R^{\alpha}{}_{\alpha})^{;\beta}{}_{;\beta} + \frac{2}{3}(R^{\alpha}{}_{\alpha})^{;\mu;\nu} + \frac{2}{3}R^{\alpha}{}_{\alpha}R^{\mu\nu} - \frac{1}{6}g^{\mu\nu}(R^{\alpha}{}_{\alpha})^2 = 0. \end{aligned} \tag{3}$$

It was shown that the static spherically symmetric solution of conformal gravity in four dimensions can be written as

$$ds^2 = -f(r)dt^2 + \frac{dr^2}{f(r)} + r^2d\Omega^2, \tag{4}$$

where $d\Omega^2$ is the line element of a 2−sphere, $S^2$, and the metric function is [14]

$$f(r) = c_0 + \frac{d}{r} + \frac{c_0^2 - 1}{3d}r - \frac{1}{3}\Lambda r^2. \tag{5}$$

It is clear that for nonvanishing $\Lambda$, Eq. (5) is not a solution of Einstein gravity, while as long as $\Lambda = 0$, the metric becomes identical to the Schwarzschild solution of Einstein gravity. It is worth mentioning that although $\Lambda$ plays the role of the cosmological constant, it is arisen purely as an integration constant and is not put in the action by hand. Such a constant cannot be added to the action of CG because it would introduce a length scale and hence break the conformal invariance.

In order to add an action of matter, we should take care of its conformal transformation to keep the theory be conformally invariant. Fortunately, the Lagrangian of Maxwell theory is conformal invariant in four dimensions and we can add it to the gravitational sector of conformal theory as an appropriate matter field.

So, we can consider the static charged adS solutions of conformal$-U(1)$ gravity in four dimensions [13]. The appropriate action is

$$I = \alpha \int d^4x\sqrt{-g}\left(\frac{1}{2}C^{\mu\nu\rho\sigma}C_{\mu\nu\rho\sigma} + \frac{1}{3}F^{\mu\nu}F_{\mu\nu}\right), \tag{6}$$

where the unusual sign in front of the Maxwell term comes from the so-called critical gravity, which is necessary to recover the Einstein gravity from conformal gravity in IR limit. The static topological solution is found in [19] the same as Eq. (5) with the following gauge potential one form

$$A = -\frac{Q}{r}dt, \tag{7}$$

which leads to the following metric function [19]

$$f(r) = c_0 + \frac{d}{r} + c_1 r - \frac{1}{3}\Lambda r^2. \tag{8}$$

In order to have consistent solutions, three integration constants $c_0$, $c_1$, and $d$ should obey an algebraic constraint

$$3c_1 d + \varepsilon^2 + Q^2 = c_0^2, \tag{9}$$

where $\varepsilon = 1, -1, 0$ denotes spherical, hyperbolic, and planar horizons, respectively. Therefore, the metric function takes the following compact form

$$f(r) = c_0 + \frac{d}{r} + \frac{c_0^2 - \varepsilon^2 - Q^2}{3d}r - \frac{1}{3}\Lambda r^2. \tag{10}$$

## 3. Higher dimensional solutions

Here, we are going to generalize the conformal action of $U(1)$-gauge/gravity coupling in higher dimensions. As we know, the Maxwell action does not enjoy the conformal invariance properties in higher dimensions, and therefore, the higher dimensional solutions in CG cannot be produced in the presence of Maxwell field (and also the other electrodynamic fields that are not conformal invariant in higher dimensions).

So, we should consider a generalization of linear Maxwell action to the case that it respects the invariance of conformal transformation. To do so, we take into account the power Maxwell nonlinear theory, which its Lagrangian is a power of Maxwell invariant, $(-F_{\mu\nu}F^{\mu\nu})^s$. It is a matter of calculation to show that the power Maxwell action enjoys the conformal invariance, for $s = D/4$ ($D =$ dimension of spacetime) [20]. In other words, it is easy to show that as long as $s = D/4$, the energy-momentum tensor of power Maxwell invariant theory is traceless [20].

Regarding the mentioned issues, we find that the suitable action of higher dimensional conformal $U(1)$-gauge/gravity action can be written as

$$I = \frac{1}{16\pi}\int d^D x\sqrt{-g}\left(C^{\mu\nu\rho\sigma}C_{\mu\nu\rho\sigma} + \beta(-F^{\mu\nu}F_{\mu\nu})^{\frac{D}{4}}\right). \tag{11}$$

Hereafter, we can regard a higher dimensional static spacetime and look for exact solutions with black hole interpretation. Variation of this action with respect to the metric tensor $g_{\mu\nu}$ and the Faraday tensor $F_{\mu\nu}$ leads to the following field equations

$$\begin{aligned}\mathbf{E}_{\rho\sigma} &= \left(\nabla^\mu\nabla^\nu + \frac{1}{2}R^{\mu\nu}\right)C_{\rho\nu\mu\sigma} + \frac{\beta}{8}\left[g_{\rho\sigma}(-F^{\mu\nu}F_{\mu\nu})^{\frac{D}{4}} + D(-F^{\mu\nu}F_{\mu\nu})^{\frac{D}{4}-1}F_{\sigma\delta}F_{\rho}{}^{\delta}\right]\\ &= 0,\end{aligned} \tag{12}$$

$$\partial_\rho\left[\sqrt{-g}(-F^{\mu\nu}F_{\mu\nu})^{\frac{D}{4}-1}F^{\rho\sigma}\right] = 0. \tag{13}$$

Since we are looking for topological black hole solutions of mentioned field equations, we express the metric of a $D$-dimensional spacetime as follows

$$ds^2 = -f(r)dt^2 + f^{-1}(r)dr^2 + r^2 d\Sigma^2_{k,D-2}, \tag{14}$$

where $k$ denotes spherical ($k = 1$), hyperbolic ($k = -1$), and planar ($k = 0$) horizons of the $(D-2)$-dimensional manifold with the following line element

$$d\Sigma^2_{k,D-2} = \begin{cases} d\Omega^2_{D-2} = d\theta_1^2 + \sum\limits_{i=2}^{D-2}\prod\limits_{j=1}^{i-1}\sin^2\theta_j d\theta_i^2 & k=1 \\ d\Xi^2_{D-2} = d\theta_1^2 + \sinh^2\theta_1\left(d\theta_2^2 + \sum\limits_{i=3}^{D-2}\prod\limits_{j=2}^{i-1}\sin^2\theta_j d\theta_i^2\right) & k=-1 \\ dl^2_{D-2} = \sum\limits_{i=1}^{D-2} d\theta_i^2 & k=0 \end{cases}, \tag{15}$$

in which $d\Omega^2_{D-2}$ is the standard metric of a unit $(D-2)$-sphere, $d\Xi^2_{D-2}$ is the metric of a $(D-2)$-dimensional hyperbolic plane with unit curvature, and $dl^2_{D-2}$ is the flat metric of $R^{D-2}$.

Using this metric and a radial gauge potential ansatz $A_\mu = -qr^{(2s-D+1)/(2s-1)}\delta^0_\mu$, one can find the nonzero components of the theory as follows

$$\begin{aligned}\mathbf{E}_{tt} &= 2D_3r^4f(r)f^{(4)}(r)+D_3\left[rf'(r)+4D_{5/2}f(r)\right]r^3f'''(r)\\&+\left[\frac{D_3}{2}r^2f''(r)+\left(2D^2D_{23/2}+85D_{102/85}\right)f(r)+D_3D_4\left(\frac{3rf'(r)}{2}+k\right)\right]r^2f''(r)\\&-\left[3D_{10/3}D_3rf'(r)+\left(4D^2D_{49/4}+187D_{228/187}\right)f(r)+5kD_3D_{16/5}\right]rf'(r)\\&+2\left(2D^2D_{23/2}+84D_{99/84}\right)f^2(r)-4k\left(D^2D_{12}+45D_{54/45}\right)f(r)-2D_3^2k^2\\&-\frac{D_1}{2}r^4\beta(1-2s)\left(\frac{\sqrt{2}q(2s-D_1)}{(2s-1)r^{(D-2)/(2s-1)}}\right)^{2s},\end{aligned}\tag{16}$$

$$\begin{aligned}\mathbf{E}_{rr} &= D_3\left[2f(r)-rf'(r)\right]r^3f'''(r)-D_3\left[\frac{r^2}{2}f''(r)-3D_{10/3}f(r)+D_4\left(\frac{3}{2}rf'(r)+k\right)\right]\\&\times r^2f''(r)+D_3\left[3D_{10/3}rf'(r)-9D_{28/9}f(r)+5kD_{16/5}\right]rf'(r)\\&+2D_3^2\left[3f^2(r)-4kf(r)+k^2\right]+\frac{D_1}{2}r^4\beta(1-2s)\left(\frac{\sqrt{2}q(2s-D_1)}{(2s-1)r^{(D-2)/(2s-1)}}\right)^{2s},\end{aligned}\tag{17}$$

$$\begin{aligned}\mathbf{E}_{\theta\theta} &= D_3r^4f(r)f^{(4)}(r)+D_3\left[rf'(r)+2D_3f(r)\right]r^3f'''(r)\\&+\left[\frac{D_3}{2}r^2f''(r)+\left(D^2D_{13}+52D_{66/52}\right)f(r)+D_3D_4\left(\frac{3rf'(r)}{2}+k\right)\right]r^2f''(r)\\&-\left[3D_{10/3}D_3rf'(r)+\left(2D^2D_{29/2}+121D_{156/121}\right)f(r)+5kD_3D_{16/5}\right]rf'(r)\\&+2\left(D^2D_{13}+51D_{63/51}\right)f^2(r)-2k\left(D^2D_{14}+57D_{72/57}\right)f(r)-2D_3^2k^2\\&+\frac{D_1D_2}{4}r^4\beta\left(\frac{\sqrt{2}q(2s-D_1)}{(2s-1)r^{(D-2)/(2s-1)}}\right)^{2s},\end{aligned}\tag{18}$$

in which we used $D_i = D-i$ for convenience and prime refers to $d/dr$. However, we will use common $D-i$ in indices and powers for clarity of equations. Solving Eqs. (16)-(18), and keeping in mind that $s = D/4$, we can obtain the metric function for $D \geq 5$ as follows

$$f(r) = k - \frac{C_1}{r^{D-3}} - \frac{\beta\mu q^{D/2}}{C_1}r + C_2r^2,\tag{19}$$

where $C_1$ and $C_2$ are two integration constants, and $\mu = 2^{(D-4)/4}\left(D_2D_3\right)^{-1}$ is a dimensionful constant. Interestingly, we see that although the field equations are too complicated, the solutions are quite simple. It is noticeable to mention that the solution to $D = 4$ is given by (10) when we set $\beta = -2/3$ in (11), but it cannot be obtained by using the field equations (16)-(18). Therefore, the four-dimensional spacetime has one more integration constant compared to the other dimensions. In order to obtain a compact form of the metric function to be valid for all dimensions, one can consider a special case $c_0 = \varepsilon$ of the four-dimensional metric function (10).

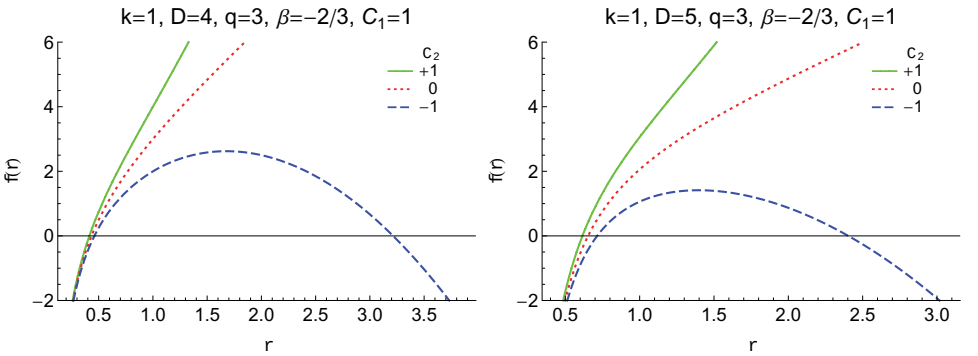

Fig. 1. The metric function versus radial coordinate. Positive $C_2$ corresponds to asymptotic adS solutions whereas the negative sign belongs to dS ones. In addition, for zero value of this parameter, the asymptotic behavior of these solutions are neither flat nor (a)dS. This is correct until the factor of $r$ in the metric function (19) is a nonzero value.

In this situation, the metric function of $D \geq 4$ is given by (19) and the field equations (16)-(18) can be used for $D = 4$ as well. We should note that since we considered a special case, $c_0 = \varepsilon$, the 4-dimensional solution given in (19) is also a solution of the field equations of (6).

Having solutions at hand, we are in a position to check that these solutions can be considered as a black hole or not. To do so, we first look for the singularities of the solutions. By calculating the Kretschmann scalar

$$R^{\lambda\tau\rho\sigma}R_{\lambda\tau\rho\sigma} = 2DD_1C_2^2 - \frac{4D_1D_2C_2\beta\mu q^{D/2}}{C_1 r} + \frac{2D_2^2\beta^2\mu^2q^D}{C_1^2r^2} + \frac{D_1D_2^2D_3C_1^2}{r^{2(D-1)}}, \quad (20)$$

one can easily find that the metric (14) with the metric function (19) has an essential singularity at the origin ($\lim\limits_{r\to 0}\left(R^{\lambda\tau\rho\sigma}R_{\lambda\tau\rho\sigma}\right) = \infty$). In addition, Fig. 1 shows that this singularity can be covered with an event horizon, and therefore, we can interpret the solution as a singular black hole.

## 4. Conclusions

Motivated by the importance of higher dimensional spacetime in high energy physics, we have constructed the conformal-$U(1)$ gauge/gravity black hole solutions in $D \geq 4$. Since higher-dimensional solutions in CG cannot be produced in the presence of Maxwell field (and also the other electrodynamic fields that are not conformal invariant in higher dimensions), we have used a class of nonlinear electrodynamics $(-F_{\mu\nu}F^{\mu\nu})^s$ (which enjoys the conformal invariance properties in higher dimensions as $s = D/4$) to obtain black hole solutions. In addition, we have seen that the obtained solutions enjoy an essential singularity at the origin and they can be considered as black holes.

Quadratic Gravity is one of the modified theories of gravity; its action contains additional terms quadratic in Riemann tensor and its contractions. We study Kundt metrics, defined geometrically by admitting non-expanding, non-twisting and non-shearing null geodesic congruence, in the framework of Quadratic Gravity. We examine the special cases, namely the *pp*-waves and VSI spacetimes. Equations of geodesic deviation are calculated to provide means of physical interpretation.

*Keywords*: Quadratic Gravity; Kundt spacetimes; Geodesic deviation.

## 1. Introduction

Despite many successes of general relativity, including the prediction of gravitational waves that were directly detected nearly four years ago, even such brilliant theory has its limits. Attempts to solve problems of general relativity (e.g., quantization, inflation, dark matter and energy) involve modifying the action.[1] Our focus is on the so-called Quadratic Gravity (QG), where the action contains additional terms that are quadratic combinations of Riemann tensor and its contractions

$$S = \int \left(\tfrac{1}{\kappa}(R - 2\Lambda) + \alpha\, R^2 + \beta\, R_{ab}^2 + \gamma(R_{abcd}^2 - 4R_{ab}^2 + R^2)\right) \sqrt{-g}\, \mathrm{d}^D x\,. \qquad (1)$$

The vacuum field equations derived from this action are then

$$\begin{aligned}&\tfrac{1}{\kappa}\left(R_{ab} - \tfrac{1}{2}R\, g_{ab} + \Lambda\, g_{ab}\right) + 2\alpha\, R\left(R_{ab} - \tfrac{1}{4}R\, g_{ab}\right) + (2\alpha + \beta)(g_{ab}\Box - \nabla_a\nabla_b)R\\ &+2\gamma\left(R\, R_{ab} - 2R_{abcd}\, R^{cd} + R_{acde}\, R_b^{\ cde} - 2R_{ac}R_b^{\ c} - \tfrac{1}{4}g_{ab}(R_{cdef}^2 - 4R_{cd}^2 + R^2)\right)\\ &+\beta\Box\left(R_{ab} - \tfrac{1}{2}R\, g_{ab}\right) + 2\beta\left(R_{abcd} - \tfrac{1}{4}g_{ab}R_{cd}\right) R^{cd} = 0\,. \qquad (2)\end{aligned}$$

We can easily see that for $\alpha = \beta = \gamma = 0$, we get famous Einstein's general relativity. In general, Eq. (2) contains second order derivatives of the Ricci scalar and tensor, which implies the fourth order derivatives of the metric. A special case of QG is Gauss–Bonnet theory ($\alpha = 0 = \beta$), that belongs to so called Lovelock's gravity.[2] Our aim is to study spacetimes known in general relativity, which are defined by purely geometrical properties independent of the specific field equations. Metric describing such spacetimes can then be considered as an ansatz and inserted into the QG field equations to observe restrictions on the metric functions and differences between QG and classic general relativity.

Specific representative of such spacetimes is the Kundt family whose line element can be written as[3–5]

$$\mathrm{d}s^2 = g_{pq}(u,x)\,\mathrm{d}x^p\mathrm{d}x^q + 2g_{up}(r,u,x)\,\mathrm{d}u\,\mathrm{d}x^p - 2\mathrm{d}u\,\mathrm{d}r + g_{uu}(r,u,x)\,\mathrm{d}u^2\,. \qquad (3)$$

Its *geometric definition* is that it admits non-expanding, non-twisting, and non-shearing null geodesic congruence. The optically privileged vector field generating the congruence is $\boldsymbol{k} = \partial_r$, where $r$ is an affine parameter along the congruence. The spacetime is foliated by the null surfaces $u = \text{const.}$, to which $\boldsymbol{k}$ is orthogonal (and tangential). The transverse $(D-2)$-space: $u = \text{const.}$ and $r = \text{const.}$ is described by the metric $g_{pq}(u, x)$, where $x \equiv x^k$, $k = 2, \ldots D-1$ are coordinates covering the transverse space. For simplicity, we will study Kundt metrics with $g_{up} = 0$, i.e., without so-called gyratons, that describe spinning null fluid.[6,7]

To algebraically classify these spacetimes, the Weyl tensor projected on a null tetrad $\boldsymbol{k}, \boldsymbol{l}, \boldsymbol{m}_i$ can be employed. These (invariant) projections are called Weyl scalars. Spacetime can be classified based on the number of Weyl scalars, sorted by their boost weights, that can be set to zero. Details on the algebraic classification can be found, e.g., in Refs. 8, 9. In Table 1, we list conditions for algebraic types of the Kundt metric.[10]

Table 1. Conditions for algebraic types of the Kundt metric (with $g_{up} = 0$)

| Type | Necessary and sufficient conditions[a] |
|---|---|
| II(ad) | $g_{uu} = -\frac{{}^S R(u,x)}{(D-2)(D-3)}\, r^2 + c(u,x)\, r + d(u,x)$ |
| II(bd) | ${}^S R_{pq} = \frac{1}{D-2}\, g_{pq}\, {}^S R$ |
| II(cd) | ${}^S C_{mpnq} = 0$ |
| III | II(abcd) |
| III(a) | ${}^S R_{,p} = 0 \quad$ and $\quad c_{,p} = \frac{2}{D-3}\, g^{mn} g_{m[n,u||p]}$ |
| III(b) | $g_{p[m,u||q]} = \frac{1}{D-3}\, g^{os} \left( g_{pm} g_{o[s,u||q]} - g_{pq} g_{o[s,u||m]} \right)$ |
| N | III(ab) |
| O | $g^{os} g_{o[s,u||p]||q} + \frac{1}{2(D-2)}\, {}^S R\, g_{pq,u} = \frac{g_{pq}}{D-2}\, g^{mn} \left( g^{os} g_{o[s,u||m]||n} + \frac{1}{2(D-2)}\, {}^S R\, g_{mn,u} \right)$ <br> $d_{||pq} + g_{pq,uu} - \frac{1}{2} g^{os} g_{op,u} g_{sq,u} - \frac{1}{2}\, c\, g_{pq,u}$ <br> $= \frac{g_{pq}}{D-2}\, g^{mn} \left( d_{||mn} + g_{mn,uu} - \frac{1}{2} g^{os} g_{om,u} g_{sn,u} - \frac{1}{2}\, c\, g_{mn,u} \right)$ |

*Note*: [a] The symbol "$||$" denotes spatial covariant derivative ($d_{||pq} = d_{,pq} - \Gamma^m_{pq}\, d_{,m}$).

## 2. Field Equations

We insert the (non-gyratonic) Kundt metric into the QG field equations and observe the conditions they impose upon the metric functions. Firstly, we look at general Kundt metric, but our main focus will be on more special cases. Results for the simpler case of the Gauss–Bonnet gravity can be found in Refs. 10, 11.

### 2.1. *General case*

The $rr$-component $(2\alpha + \beta)\, g_{uu,rrrr} = 0$ implies that either $(2\alpha + \beta) = 0$ or $g_{uu}$ is at most cubic in $r$, so it can be written as $g_{uu} = a\, r^3 + b\, r^2 + c\, r + d$, where $a, b, c, d$ are functions of $u$ and the transverse coordinates $x^p$. These functions will be constrained by the following components of the field equations.

The $rp$-component is $(2\alpha+\beta)\, g_{uu,rrrp}=0$. For $(2\alpha+\beta)\neq 0$, it implies that $a_{,p}=0$, so that $a=a(u)$.

The remaining components $(ru, pq, up, uu)$ get more complicated, and longer, therefor we will not show them here. They can be found for example in Ref. 10. The equations give relations between the functions $a, b, c, d$ and the metric $g_{pq}$.

### 2.2. *pp-waves with constant spatial curvature*

One of the most common examples of the Kundt spacetimes are plane-fronted waves with parallel rays, or *pp*-waves, see e.g., Ref. 12. They are defined as spacetimes admitting a covariantly constant vector field $\boldsymbol{k}=\partial_r$, which implies that the metric is $r$-independent. In the non-gyratonic case, we have

$$\mathrm{d}s^2 = g_{pq}(u,x)\,\mathrm{d}x^p\mathrm{d}x^q - 2\mathrm{d}u\,\mathrm{d}r + g_{uu}(u,x)\,\mathrm{d}u^2\,. \tag{4}$$

For further simplification, we assume that the transverse space is of a constant curvature, which means that its Riemann and Ricci tensors (denoted ${}^{S}R_{pqmn}$ and ${}^{S}R_{pq}$) are related to the Ricci scalar ${}^{S}R$ by

$${}^{S}R_{pqmn} = \frac{{}^{S}R}{(D-3)(D-2)}\,(g_{pm}g_{qn}-g_{pn}g_{qm})\,, \quad {}^{S}R_{pq} = \frac{{}^{S}R}{D-2}\,g_{pq}\,. \tag{5}$$

The $rr$, $rp$ and $up$-components of the field equations are satisfied identically. The $ru$ and $pq$-components give a quadratic equation for the scalar curvature ${}^{S}R$ with two solutions

(a) Trivial solution

$${}^{S}R=0 \Rightarrow g_{pq}=\delta_{pq}, \quad \Lambda=0\,. \tag{6}$$

(b) Non-trivial solution

$${}^{S}R = -\frac{1}{2\kappa}\,\frac{(D-2)(D-3)}{(D-2)(D-3)\alpha+(D-4)(D-5)\gamma+(D-3)\beta} = 4\Lambda_0\,. \tag{7}$$

Since ${}^{S}R$ is constant, necessarily $g_{pq,u}=0$.

For both cases (6), (7), the $uu$-component can be written as

$$k\Delta g_{uu} + \beta\Delta\Delta g_{uu} = 0\,, \tag{8}$$

where the constant $k$ differs for the two solutions mentioned above

$$\text{(a) } k=\kappa^{-1}\,, \quad \text{(b) } k=\frac{(D-3)\beta-2(D-4)\gamma}{\omega\kappa}+\frac{(D-2)(D-3)^2\beta}{2\omega^2\kappa^2}\,,$$
$$\omega \equiv (D-2)(D-3)\alpha+(D-4)(D-5)\gamma+(D-3)\beta\,. \tag{9}$$

This means that we need to solve Helmholtz-like equation for $g_{uu}$ [13]

$$\Delta g_{uu} + \frac{k}{\beta}\,g_{uu} = f\,, \qquad \text{where} \qquad \Delta f = 0\,. \tag{10}$$

The interesting fact is that it is possible to find solution of (10) that does not solve $\Delta g_{uu} = 0$, so such a solution does not exist in Einstein's general relativity.

From Table 1, we see that the non-trivial solution (b) is of type II(bcd), and the non-zero Weyl scalars are

$$\Psi_{2S} = \frac{{}^{S}R}{(D-1)(D-2)}\,, \qquad \Psi_{4^{ij}} = \left[-\frac{1}{2}g_{uu||pq} + \frac{g_{pq}}{2(D-2)}\Delta g_{uu}\right] m_i^p\, m_j^q\,. \quad (11)$$

### 2.3. *VSI spacetimes*

The definition of VSI spacetimes[14] is that all scalar curvature invariants of all orders vanish. Their (non-gyratonic) line element has the form

$$\mathrm{d}s^2 = \delta_{pq}\,\mathrm{d}x^p\mathrm{d}x^q - 2\mathrm{d}u\,\mathrm{d}r + \big(c(u,x)\,r + d(u,x)\big)\mathrm{d}u^2\,, \quad (12)$$

so $g_{uu}$ is at most linear in $r$. The $rr$, $rp$, $ru$, $pq$-components are satisfied identically, the only non-trivial components are $up$ and $uu$. The $up$-component implies $(1/\kappa)c_{,p} + \beta\Delta c_{,p} = 0$, which in general relativity ($\beta = 0$) restricts $c = c(u)$.

The $uu$-component gives two constraints with respect to $r$, namely

$$\Delta\left(\tfrac{1}{\kappa}c + \beta\Delta c\right) = 0 \quad \text{and} \quad \Delta\left[-\tfrac{1}{\kappa}d + \beta\left(2c_{,u} - \tfrac{1}{2}c^2 - \Delta d\right)\right] = 0\,. \quad (13)$$

Looking at Table 1, we observe that VSI spacetimes are of type III(b) with non-zero scalar components of the Weyl tensor

$$\Psi_{3T^i} = -m_i^p\frac{D-3}{2(D-2)}c_{,p}\,,$$
$$\Psi_{4^{ij}} = -\frac{1}{2}m_i^p\, m_j^q\left[r\left(c_{||pq} - \frac{g_{pq}}{D-2}\Delta c\right) + d_{||pq} - \frac{g_{pq}}{D-2}\Delta d\right]. \quad (14)$$

## 3. Geodesic Deviation

Possible way of physical and geometrical interpretation of spacetimes is to investigate local effects of curvature on freely falling test particles.[15,16] Such particles move along geodesics and due to the gravitational field, they can move closer or further away from each other. Let us have a geodesic congruence with central geodesic $\gamma(\tau)$. Its tangent vector $\boldsymbol{u}$ is a four-velocity of the particle moving along geodesic. The vector separating geodesics in the congruence is $\boldsymbol{Z}$. The equation of geodesic deviation then takes the form

$$\frac{\mathrm{D}^2 Z^a}{\mathrm{d}\tau^2} = R^a{}_{bcd}\,u^b\,u^c\,Z^d\,. \quad (15)$$

We choose an orthonormal frame $\boldsymbol{e}_{(a)}$ with $\boldsymbol{e}_{(0)} = \boldsymbol{u}$. The round brackets denote tetrad indices. The projection of Eq. (15) on spatial tetrad vectors becomes

$$\ddot{Z}^{(i)} = R^{(i)}{}_{(0)(0)(j)}Z^{(j)}, \quad i,j = 1,\dots D-1\,. \quad (16)$$

In the Kundt case $\boldsymbol{u} = \dot{r}\,\partial_r + \dot{u}\,\partial_u + \dot{x}^p\,\partial_p$ and the vector $\boldsymbol{e}_{(1)}$ is defined as $\boldsymbol{e}_{(1)} = \sqrt{2}\,\tilde{\boldsymbol{k}} - \boldsymbol{u}$, where $\tilde{\boldsymbol{k}} = 1/(\sqrt{2}\,\dot{u})\,\partial_r$. We call it longitudinal direction. The remaining vectors $\boldsymbol{e}_{(i)}$, $i = 2,\dots D-1$, are called transverse directions.

### 3.1. *Geodesic deviation for pp-waves*

The equations of geodesic deviations for *pp*-waves (with $g_{up} = 0$) are

$$\begin{aligned}\ddot{Z}^{(1)} &= 0\,,\\ \ddot{Z}^{(i)} &= \Big(\tfrac{1}{2}\dot{u}^2\left(g_{uu||pq} + g_{pq,uu} - \tfrac{1}{2}g^{os}g_{op,u}\,g_{sq,u}\right)m_i^p\,m_j^q \\ &\qquad +2\dot{u}\,g_{m[p,u||n]}m^m_{(i}\,m^p_{j)}\,\dot{x}^n - {}^{S}R_{mpnq}m_i^m m_j^n\,\dot{x}^p\dot{x}^q\Big)Z^{(j)}\,.\end{aligned} \tag{17}$$

These were calculated without any use of field equations. Due to the absence of the terms $R^{(1)}_{\ (0)(0)(i)}$, the effect of the waves on particles is only transverse, i.e., in the $\boldsymbol{e}_{(i)}$ directions. Unlike general relativity, the deformations caused by the waves are not always traceless. Since it is possible to choose a frame where $\dot{x}^i = 0$, the conditions for the waves to be traceless become

$$g^{pq}\left(g_{uu||pq} + g_{pq,uu} - \tfrac{1}{2}g^{os}g_{op,u}g_{sq,u}\right) = 0\,. \tag{18}$$

If we now restrict ourselves to the QG and transverse space with constant curvature, the equations simplify into

$$\ddot{Z}^{(1)} = 0, \tag{19}$$

$$\ddot{Z}^{(i)} = \left(\tfrac{1}{2}\dot{u}^2\,g_{uu||pq}m_i^p\,m_j^q + \frac{{}^{S}R}{(D-2)(D-3)}g_{pq}\big(g_{kl}\,\dot{x}^p\,\dot{x}^k\,m_i^q\,m_j^l - \dot{x}^p\,\dot{x}^q\,\delta_{ij}\big)\right)Z^j,$$

and the waves are traceless when $\Delta g_{uu} = 0$, which corresponds to the solution of general relativity. If we solve Eq. (10) for $g_{uu}$, we can insert the resulting metric component into Eq. (19).

### 3.2. *Geodesic deviation for VSI-spacetimes*

For the VSI spacetimes (12), the equations of geodesic deviation are

$$\begin{aligned}\ddot{Z}^{(1)} &= \tfrac{1}{2}\dot{u}\,c_{,p}\,m_j^pZ^{(j)},\\ \ddot{Z}^{(i)} &= \tfrac{1}{2}\dot{u}\,c_{,p}\,m_i^pZ^{(1)} + \left(\tfrac{1}{2}\dot{u}^2\,g_{uu||pq}m_i^p\,m_j^q + m^p_{(i}m^q_{j)}\dot{u}\,\dot{x}^k\,c_{,p}\,g_{qk}\right)Z^{(j)}\,.\end{aligned} \tag{20}$$

We can see that in general, there is a longitudinal effect due to the term $1/2\,\dot{u}\,c_{,p}$. This would be impossible in general relativity, because of $c_{,p} = 0$.

## 4. Conclusion

We studied Kundt spacetime in QG by an explicit analyses of the constraints imposed by the field equations. We investigated the special cases, the *pp*-waves and VSI spacetimes, and obtained solutions that are not allowed in general relativity. The equations of geodesic deviation shown that the effect of *pp*-waves is always transverse, but *generally not traceless* and the VSI spacetimes cause *longitudinal effect*. Both effects are not possible in general relativity.

Double field theory promotes the T-duality of closed string theory to a manifest symmetry, thus leading to a new perspective on the geometry experienced by stringy probes. In this contribution, we discuss the mathematical structure underlying the symmetries of double field theory, thus defining a DFT algebroid. We trace its origins in a large Courant algebroid defined over a doubled geometry, and show that after imposing a section condition the DFT algebroid reduces to a canonical Courant algebroid, as expected in generalized geometry.

*Keywords*: Differential Geometry; String Duality; Courant Algebroid; Supergravity.

## 1. Motivation and goal

Finding the ultimate theory that would describe quantum gravitational phenomena remains an open problem today. Nevertheless, theoretical arguments suggest that the geometry of quantum gravity should depart from Riemannian geometry.

One possible direction which goes beyond Riemannian geometry is the generalized geometry proposed by Ref. 1, see also Ref. 2 and Ref. 3. In generalized geometry one considers extensions of the tangent bundle over a smooth spacetime manifold; in the simplest case, the tangent bundle is extended by the cotangent bundle. From a physical perspective, we are familiar with the physics on the tangent bundle $TM$ of a manifold $M$, whose sections are vector fields which are closed under the Lie bracket and generate diffeomorphisms. In generalized geometry, there is a symmetry group $O(d,d)$, where each $d$ represents separately the rank of the tangent and cotangent bundles, and it contains not only diffeomorphisms but also 2-form gauge transformations. This highlights the relation to closed string theory, whose massless sector indeed includes the graviton and the 2-form Kalb-Ramond $B$-field.

On the other hand, double field theory (DFT) incorporates T-duality (or rather $O(d,d;\mathbb{R})$) as a manifest symmetry of a field theory which is based on a doubled space (Refs. 4, 5, 6, 7, 8). T-duality is a symmetry in string theory that relates the momentum modes of strings propagating in a compact space to their winding modes in a dual compact space. Promoting T-duality to a symmetry in field theory

comes with the cost of imposing a section condition, or strong constraint, that effectively reduces the doubled geometry to a half-slice. For instance, the standard supergravity frame in DFT is obtained by dropping all dependence on the dual winding coordinates of the doubled geometry, thus resulting in the standard low-energy action of the NS-NS (Neveu-Schwarz) sector of string theory in $d$ dimensions.

Understanding better the structure and the geometry of string duality is motivated at a conceptual level through the connections to the geometry of quantum gravity that we already mentioned, and also with regard to the implications of string theory for cosmology, where the winding modes included in DFT could play a crucial role. This is the case in the cosmological scenario of Ref. 9, which is recently explored from the point of view of DFT too, see e.g. Ref. 10.

In this contribution, our goal is to explain the mathematical structure which underlies the symmetries of double field theory. We shall show that this is an algebroid that lies in a certain precise way in between two Courant algebroids over different base manifolds. This contribution is based on Ref. 11.

## 2. Courant algebroid

A Courant algebroid is a quadruple $(E, [\cdot,\cdot]_E, \langle\cdot,\cdot\rangle, \rho)$ comprising the following, see Ref. 12. $E \to M$ is a vector bundle over a smooth manifold $M$, equipped with a binary operation $[\cdot,\cdot]_E : \Gamma(E) \otimes \Gamma(E) \to \Gamma(E)$ on its sections, and a symmetric $C^\infty(M)$-bilinear, non-degenerate form $\langle\cdot,\cdot\rangle : \Gamma(E) \otimes \Gamma(E) \to C^\infty(M)$ which takes smooth sections of the bundle and returns a function. Finally, a bundle map $\rho : E \to TM$, called the anchor, maps from $E$ to the tangent bundle $TM$.

What turns this quadruple to a Courant algebroid is a set of five properties. The first one is a Jacobi identity

$$[[A,B]_E,C]_E + cyclic = \tfrac{1}{3}\,\mathcal{D}\langle[A,B]_E,C\rangle + cyclic\ , \tag{1}$$

which tells us that for any smooth sections $A, B, C \in \Gamma(E)$, the Jacobiator of the binary operation is exact with respect to the differential operator $\mathcal{D} : C^\infty(M) \to \Gamma(E)$ which is defined by $\langle\mathcal{D}f, A\rangle = \frac{1}{2}\,\rho(A)f$, for functions $f \in C^\infty(M)$. The second property is a Leibniz rule

$$[A, fB]_E = f[A,B]_E + (\rho(A)f)B - \langle A,B\rangle\mathcal{D}f\ . \tag{2}$$

Moreover, the anchor is a homomorphism of bundles, $\rho[A,B]_E = [\rho(A),\rho(B)]$, and the image of the derivation $\mathcal{D}$ is in the kernel of the anchor, $\rho\circ\mathcal{D} = 0$, or equivalently $\langle\mathcal{D}f, \mathcal{D}g\rangle = 0$. Lastly, a compatibility condition for the bracket and bilinear form, the analog of ad-invariance of the Killing form of a Lie algebra, reads as

$$\rho(C)\langle A,B\rangle = \langle[C,A]_E + \mathcal{D}\langle C,A\rangle, B\rangle + \langle A, [C,B]_E + \mathcal{D}\langle C,B\rangle\rangle\ . \tag{3}$$

When we consider the generalized tangent bundle $E = TM \oplus T^*M$, its sections are generalized vectors $V + \lambda$, formal sums of a vector $V \in \Gamma(TM)$ and 1-form

$\lambda \in \Gamma(T^*M)$. The standard Courant bracket,

$$[V+\lambda, V'+\lambda']_E = [V,V'] + \mathcal{L}_V\lambda' - \mathcal{L}_{V'}\lambda - \frac{1}{2}d(i_V\lambda' - i_{V'}\lambda) \ , \tag{4}$$

is an antisymmetric operation, an extension of the Lie bracket of vector fields which is not a Lie bracket itself, that satisfies the properties of a Courant algebroid when $\rho = (\mathrm{id}, 0)$. The inner product, which is the fiber-wise metric on $E$, is

$$\langle V+\lambda, V'+\lambda'\rangle = \tfrac{1}{2}(\lambda'(V)+\lambda(V')) = \tfrac{1}{2}\begin{pmatrix} V & \lambda \end{pmatrix}\begin{pmatrix} 0 & \mathbf{1}^d \\ \mathbf{1}^d & 0 \end{pmatrix}\begin{pmatrix} V' \\ \lambda' \end{pmatrix} \ . \tag{5}$$

The bilinear form explicitly exhibits an indefinite $(d,d)$ signature. The $O(d,d)$ transformations are respectively the diffeomorphisms, $B$-transforms and $\beta$-transforms,

$$\begin{pmatrix} N & 0 \\ 0 & N^{-T} \end{pmatrix} \ , \ e^B = \begin{pmatrix} 1 & 0 \\ -B & 1 \end{pmatrix} \ , \ e^\beta = \begin{pmatrix} 1 & -\beta \\ 0 & 1 \end{pmatrix} \ , \tag{6}$$

where $N \in GL(d)$, $B$ is a 2-form and $\beta$ is a 2-vector. The inner product is indeed invariant under the $B$-transform,

$$\langle e^B(V+\lambda), e^B(V'+\lambda')\rangle = \langle V+\lambda, V'+\lambda'\rangle \ . \tag{7}$$

More details can be found in Ref. 3.

## 3. Double field theory

In this section we give a short introduction to double field theory. It is a theory that doubles the space of coordinates: $(x^i, \tilde{x}_i)$ where $i$ is $d$-dimensional, and it contains both coordinates conjugate to the momentum modes and the dual coordinates conjugate to the winding modes of closed strings. Interested readers may refer to Ref. 13 and references therein.

The double field theory action is formulated in doubled geometry (Ref. 14),

$$S_{DFT}(\mathcal{H}_{MN}, \Phi) = \int d^dx \ d^d\tilde{x} \ e^{-2\Phi}\mathcal{R} \ , \tag{8}$$

where its Ricci scalar is given by

$$\begin{aligned}\mathcal{R} = {} & \frac{1}{8}\mathcal{H}^{MN}\partial_M\mathcal{H}^{KL}(\partial_N\mathcal{H}_{KL} - 4\partial_K\mathcal{H}_{NL}) + 4(\partial_N\Phi\,\partial_M\mathcal{H}^{MN} - \mathcal{H}^{MN}\partial_M\Phi\,\partial_N\Phi) \\ & +4\mathcal{H}^{MN}\partial_M\partial_N\Phi - \partial_M\partial_N\mathcal{H}^{MN} \ ,\end{aligned} \tag{9}$$

expressed in terms of the generalized metric $\mathcal{H}_{MN}$,

$$\mathcal{H}_{MN} = \begin{pmatrix} g^{ij} & -g^{ik}B_{kj} \\ B_{ik}g^{kj} & g_{ij} - B_{ik}g^{kl}B_{lj} \end{pmatrix} \tag{10}$$

and a scalar field $\Phi$. The generalized metric combines the 2-form $B$ and the Riemannian metric $g$. We can raise or lower its indices as $\mathcal{H}^{MN} = \eta^{MP}\eta^{NQ}\mathcal{H}_{PQ}$, using the $O(d,d)$ metric $\eta = \eta^{-1} = \begin{pmatrix} 0 & \mathbf{1}^d \\ \mathbf{1}^d & 0 \end{pmatrix}$. The scalar field $\Phi$ in the action is

related to the dilaton $\phi$ by $e^{-2\Phi} = \sqrt{|g|}e^{-2\phi}$. Note that the capital indices are $2d$-dimensional, $M, N, K, L = 1, \ldots, 2d$, while $i, j, k, l = 1, \ldots, d$.

The DFT action $S_{DFT}$ reduces to the Neveu-Schwarz sector of supergravity action in $d$ dimensions,

$$S_{NS} = \int d^d x \sqrt{g} e^{-2\phi} \left( R + 4\partial_i \phi \, \partial^i \phi - \frac{1}{12} H_{ijk} H^{ijk} \right) , \tag{11}$$

where $H_{ijk}$ is the field strength of the 2-form $B$, after imposing the strong constraint, that is $\widetilde{\partial}^i = \frac{\partial}{\partial \tilde{x}_i} = 0$ (supergravity frame). The strong constraint is inherent in DFT. It is related to the closure of the gauge transformations. DFT is therefore an $O(d,d)$-covariant formulation of the low-energy sector of string theory on a compact space. See Ref. 6 for further details.

## 4. An algebroid for double field theory

Now we present our proposal of an algebroid structure which is underlying DFT. The strategy we follow is to double the canonical Courant algebroid, decompose the bundle and subsequently make a suitable projection.

Consider a $2d$-dimensional target space $T^*M$ with local coordinates

$$\mathbb{X} = (\mathbb{X}^I) = (\mathbb{X}^i, \mathbb{X}_i) =: (X^i, \widetilde{X}_i) \ , \tag{12}$$

where $I = 1, \ldots, 2d$ and $i = 1, \ldots, d$. The generalized tangent bundle is promoted from $TM \oplus T^*M$ with $O(d,d)$ symmetry to

$$\mathbb{E} = \mathbb{T}(T^*M) := T(T^*M) \oplus T^*(T^*M) \tag{13}$$

with $O(2d, 2d)$ symmetry. The sections of the bundle are $\mathbb{A}^{\hat{I}}$, $\hat{I} = 1, \ldots, 4d$, where $(\mathbb{A}^{\hat{I}}) = (\mathbb{A}^I, \widetilde{\mathbb{A}}_I) = (\mathbb{A}^i, \mathbb{A}_i, \widetilde{\mathbb{A}}_i, \widetilde{\mathbb{A}}^i)$. Here the generalized vector over the doubled target space is similarly a sum of vector and 1-form, $\mathbb{A} = \mathbb{A}_V + \mathbb{A}_F := \mathbb{A}^I \, \partial_I + \widetilde{\mathbb{A}}_I \, \mathrm{d}\mathbb{X}^I$, where $(\partial_I) = (\partial/\partial X^i, \partial/\partial \widetilde{X}_i) =: (\partial_i, \tilde{\partial}^i)$ and $(\mathrm{d}\mathbb{X}^I) := (\mathrm{d}X^i, \mathrm{d}\widetilde{X}_i)$. As for the anchor $\rho^I{}_{\hat{J}}$ of the bundle $\mathbb{E}$, its components are $(\rho^I{}_J, \widetilde{\rho}^{IJ})$. With that, we can define a 'large' Courant algebroid: $(\mathbb{E}, [\,\cdot\,,\,\cdot\,]_{\mathbb{E}}, \langle\,\cdot\,,\,\cdot\,\rangle, \rho)$.

Before we proceed, note that the sections of the bundle in the large Courant algebroid carry a $4d$-dimensional index. In order to relate to the DFT data which are $2d$-dimensional, we need to resolve this excess of $2d$. First we introduce a decomposition in the sections of the bundle and their corresponding basis,

$$\mathbb{A}^I_\pm = \tfrac{1}{2} \left( \mathbb{A}^I \pm \eta^{IJ} \, \widetilde{\mathbb{A}}_J \right) \ , \quad e^\pm_I = \partial_I \pm \eta_{IJ} \, \mathrm{d}\mathbb{X}^J \ . \tag{14}$$

For the anchor components $\rho^I{}_{\hat{J}}$, we define $(\rho_\pm)^I{}_J = \rho^I{}_J \pm \eta_{JK} \, \widetilde{\rho}^{IK}$. Consequently, the large generalized tangent bundle is decomposed as $\mathbb{E} = L_+ \oplus L_-$, where $L_\pm$ is the bundle with the space of sections spanned by $e^\pm_I$ locally.

The DFT data are obtained from the large Courant algebroid upon a suitable projection to $L_+$. This projection,

$$\mathsf{p}_+ : \mathbb{E} \longrightarrow L_+ \ , \quad (\mathbb{A}_V, \mathbb{A}_F) \longmapsto \mathbb{A}_+ := A \ , \tag{15}$$

reduces a generalized vector of the large Courant algebroid $\mathbb{E}$ to a DFT vector, which may be written as $A = A_i \left(\mathrm{d}X^i + \tilde{\partial}^i\right) + A^i \left(\mathrm{d}\widetilde{X}_i + \partial_i\right)$.

For elements of $L_+$ to be treated as elements of $\mathbb{E}$, we define an inclusion map $\iota : L_+ \hookrightarrow \mathbb{E}$ and the composition map $\mathsf{a} := \iota \circ \mathsf{p}_+ : \mathbb{E} \longrightarrow \mathbb{E}$. By applying the map $\mathsf{a}$ and a projection to the standard Courant bracket of the large Courant algebroid, we obtain precisely the C-bracket of DFT vectors, which is the operation related to generalized diffeomorphisms of DFT,

$$\mathsf{p}_+\big([\mathsf{a}(\mathbb{A}), \mathsf{a}(\mathbb{B})]_{\mathbb{E}}\big) = (A^K\, \partial_K B^J - \tfrac{1}{2}\, A^K\, \partial^J B_K - (A \leftrightarrow B)) e_J^+ := [\![A, B]\!]_{L_+}. \quad (16)$$

Similarly, projecting the generalized Lie derivative[a] of the large Courant algebroid yields the generalized Lie derivative in DFT,

$$\mathsf{p}_+\big(\mathbb{L}_{\mathsf{a}(\mathbb{A})}\mathsf{a}(\mathbb{B})\big) = (A^I\, \partial_I B^J - B^I\, \partial_I A^J + B_I\, \partial^J A^I) e_J^+ := \mathsf{L}_A B\ . \quad (17)$$

Note that $[\mathsf{L}_C, \mathsf{L}_A] = \mathsf{L}_{[\![C,A]\!]_{L_+}}$ only if we impose the condition $\eta^{IJ}\, \partial_I f\, \partial_J g = 0$, for all fields $f, g$ of DFT. This condition is the strong constraint or section condition.

The next step in our strategy is to examine which of the properties of a Courant algebroid survive the projection and which get obstructed. The result allows us to give the following definition.

**Definition.** Let $L_+ \to T^*M$ be a vector bundle of rank $2d$ over $T^*M$. Let $[\![\cdot\,,\cdot]\!]_{L_+} : \Gamma(L_+) \otimes \Gamma(L_+) \to \Gamma(L_+)$ be a skew-symmetric bracket (C-bracket). Let $\langle\cdot\,,\cdot\rangle_{L_+} : \Gamma(L_+) \otimes \Gamma(L_+) \to C^\infty(T^*M)$ be a non-degenerate symmetric form. Lastly, a smooth bundle map $\rho_+ : L_+ \to T(T^*M)$. We define a DFT algebroid: $(L_+, [\![\cdot\,,\cdot]\!]_{L_+}, \langle\cdot\,,\cdot\rangle_{L_+}, \rho_+)$, such that it satisfies three properties, one related to the strong constraint, one being the compatibility condition between the C-bracket and the bilinear form, and a Leibniz rule for the C-bracket respectively,

$$\langle \mathcal{D}_+ f, \mathcal{D}_+ g\rangle_{L_+} = \frac{1}{4}\, \langle \mathrm{d}f, \mathrm{d}g\rangle_{L_+}\ , \quad (18)$$

$$\begin{aligned}\rho_+(C)\langle A, B\rangle_{L_+} &= \langle [\![C, A]\!]_{L_+} + \mathcal{D}_+\langle C, A\rangle_{L_+}, B\rangle_{L_+} \\ &\quad + \langle A, [\![C, B]\!]_{L_+} + \mathcal{D}_+\langle C, B\rangle_{L_+}\rangle_{L_+}\ , \end{aligned} \quad (19)$$

$$[\![A, f\, B]\!]_{L_+} = f\, [\![A, B]\!]_{L_+} + \big(\rho_+(A) f\big)\, B - \langle A, B\rangle_{L_+}\, \mathcal{D}_+ f\ , \quad (20)$$

for sections of the bundle $A, B, C \in \Gamma(L_+)$ and functions $f, g \in C^\infty(T^*M)$. The derivative $\mathcal{D}_+ : C^\infty(T^*M) \to \Gamma(L_+)$ is defined through $\langle \mathcal{D}_+ f, A\rangle_{L_+} = \frac{1}{2}\, \rho_+(A) f$.

More generally, a DFT algebroid is a special case of a structure called pre-DFT algebroid, which is related to the Vaisman algebroid of Ref. 15. An interesting formulation of such structures in the language of graded geometry is found in Refs. 16 and 17.

[a] Antisymmetrization of the generalized Lie derivatives gives the Courant bracket: $[\mathbb{A}, \mathbb{B}]_{\mathbb{E}} = \mathbb{L}_{\mathbb{A}}\mathbb{B} - \mathbb{L}_{\mathbb{B}}\mathbb{A}$.

## 5. Conclusions

Using a method of doubling-splitting-projecting, the geometric origin of DFT can be traced to a large Courant algebroid. To summarize our finding schematically,

$$\text{Large Courant algebroid} \xrightarrow{\mathsf{p}_+} \text{DFT algebroid} \overset{\langle \mathcal{D}_+ f, \mathcal{D}_+ g \rangle_{L_+}=0}{\longrightarrow} \text{Courant algebroid}.$$

Additionally in Ref. 11, we propose a DFT membrane sigma-model which describes both geometric and non-geometric fluxes of string theory, thus completing earlier proposals in Refs. 18 and 19.

# Clarifying spatial distance measurement

Colin MacLaurin*

*School of Mathematics and Physics*
*University of Queensland, Australia*
**E-mail: colin.maclaurin@uqconnect.edu.au*

We examine length measurement in curved spacetime, based on the 1+3-splitting of a local observer frame. This situates extended objects within spacetime, in terms of a given coordinate which serves as an external reference. The radar metric is shown to coincide with the spatial projector, but these only give meaningful results on the observer's 3-space, where they reduce to the metric. Examples from Schwarzschild spacetime are given.

## 1. Introduction and motivation

Recall the textbook "radial proper distance" in Schwarzschild spacetime:

$$ds = \left(1 - \frac{2M}{r}\right)^{-1/2} dr, \tag{1}$$

which follows from setting $dt = d\theta = d\phi = 0$ in the line element in Schwarzschild coordinates. But what is the physical motivation for choosing a slice Schwarzschild $t = \text{const}$, rather than some other time coordinate? Special relativity stresses length is relative to the observer, so which observers measure Equation 1, and what do others measure? The claim the $dt = 0$ slice is "measurement by an observer at infinity" is problematic, because there are many ways to extend a local frame, or to choose a simultaneity convention between distant frames.

Consider the same procedure repeated for Gullstrand-Painlevé coordinates:

$$ds = dr. \tag{2}$$

Painlevé hence concluded relativity is self-contradictory.[1] Instead, as we shall see, these correspond to measurements by different observers. (Mathematically, note the differing expressions called "$ds$" are really restrictions to different subspaces.) We apply four complementary theoretical tools: suitably chosen coordinates, the spatial projector, the radar metric, and adapted frames.

## 2. Well-suited coordinates

An intuitive and pedagogical approach to length measurement is to provide coordinates suited to a given congruence of observers, if possible. Consider for example radial geodesic motion in Schwarzschild spacetime, with 4-velocity field $\mathbf{u}$ parametrised by the Killing energy per mass $e := -\mathbf{g}(\mathbf{u}, \partial_t)$. A generalisation of Gullstrand-Painlevé coordinates has metric:[2–6]

$$ds^2 = -\frac{1}{e^2}\left(1 - \frac{2M}{r}\right)dT^2 \mp \frac{2}{e^2}\sqrt{e^2 - 1 + \frac{2M}{r}}\,dT\,dr + \frac{1}{e^2}dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\phi^2), \tag{3}$$

where $T \equiv T_e$ is the Einstein-synchronised proper time of the observers, which all share the same $e \in \mathbb{R}\backslash\{0\}$. For details see Ref. 6. Setting $dT = d\theta = d\phi = 0$ gives:

$$dL = \frac{1}{e} dr, \tag{4}$$

where we write $dL$ in place of $ds$ for the length element, and the sign choice is mere convention. The physical justification behind $dT = 0$ is that the $T = \text{const}$ hypersurface is orthogonal to the 4-velocities, so coincides with their local 3-spaces.

Note a static observer at $r = r_0$ is identical to an observer falling from rest at $r_0$, in the sense their velocities and hence local 3-spaces coincide instantaneously. Both have $e = \sqrt{1 - 2M/r_0}$, so Equation 4 reduces to the usual quantity (Equation 1). Some textbooks set up a false dichotomy that $dr$ is not the distance but $(1 - 2M/r)^{-1/2} dr$ *is*. Instead, for radial observers with $e = \pm 1$ the $r$-coordinate is precisely proper distance.

Equation 4 is remarkably little known. Gautreau & Hoffmann derived it, using a different parameter corresponding to the $0 < e < 1$ case.[2] Taylor & Wheeler present the $e = 1$ case clearly, which is the only textbook coverage apparently.[7] Finch showed the 3-volume inside the horizon is $1/e$ times its Euclidean value $\frac{4}{3}\pi(2M)^3$, for the $e > 0$ case. (Precedents include Lemaître, who pointed out 3-space is Euclidean for $e = 1$, and mentioned measurement.[8] Painlevé made the same observations, but mistakenly saw contradiction.[1])

In general, consider a 4-velocity field $\mathbf{u}$. Define a new coordinate $T$ by:

$$dT := -N^{-1} \mathbf{u}^\flat, \tag{5}$$

where $\mathbf{u}^\flat$ is the 1-form dual to the 4-velocity, and $N$ is a lapse. $T$ exists locally iff the velocity gradient is vorticity-free, a consequence of Frobenius' theorem. Then the $T = \text{const}$ hypersurfaces are orthogonal to the congruence, since $dT(\boldsymbol{\xi}) = 0$ for any vector $\boldsymbol{\xi}$ orthogonal to $\mathbf{u}$.[a] Now express the metric in coordinates including $T$, and set $dT = 0$.

## 3. Spatial projector

Given a 4-velocity $\mathbf{u}$, the metric splits into parts parallel and orthogonal to $\mathbf{u}$ as $g_{\mu\nu} \equiv -u_\mu u_\nu + (g_{\mu\nu} + u_\mu u_\nu)$, assuming metric signature $-+++$. The latter term is the *spatial projection tensor* $\mathbf{P}$, which extracts the spatial part of tensors via contraction. In particular, $P^\mu_\nu u^\nu = 0$, and $P^\mu_\nu \xi^\nu = \xi^\nu$ for any vector $\boldsymbol{\xi}$ in the 3-space orthogonal to $\mathbf{u}$. Furthermore $P_{\mu\nu}\xi^\mu\xi^\nu = g_{\mu\nu}\xi^\mu\xi^\nu$ for such a $\boldsymbol{\xi}$, so $\mathbf{P}$ is also called the *spatial metric*.

One may wonder if $dL'^2 := P_{\mu\nu}\xi^\mu\xi^\nu$ is meaningful as a length measurement for *any* $\boldsymbol{\xi}$, not necessarily orthogonal to $\mathbf{u}$. For radial motion in Schwarzschild

[a] If in addition the congruence is geodesic, we can set $N \equiv 1$, then $dT/d\tau = -\mathbf{u}^\flat(\mathbf{u}) = 1$, so $T$ measures proper time. This trick to derive $T$ was applied to relativity by Synge, and Lagrange's 3-velocity potential in Newtonian mechanics is an antecedent.

spacetime, the projector in Schwarzschild coordinates is

$$P_{\mu\nu} = \begin{pmatrix} e^2 - 1 + \frac{2M}{r} & e\big(1 - \frac{2M}{r}\big)^{-1}\sqrt{e^2 - 1 + \frac{2M}{r}} \\ e\big(1 - \frac{2M}{r}\big)^{-1}\sqrt{e^2 - 1 + \frac{2M}{r}} & \boxed{e^2\big(1 - \frac{2M}{r}\big)^{-2}} \end{pmatrix} \tag{6}$$

in the $t$-$r$ block, plus the usual 2-sphere metric components $\mathrm{diag}(r^2, r^2 \sin^2\theta)$ in the $\theta$-$\phi$ block. One might expect the radial direction to be the coordinate basis vector $\partial_r$, at least for $r > 2M$. Contracting with $\boldsymbol{\xi} = \partial_r$ picks out the $P_{rr}$ component (boxed), for a candidate spatial measurement:

$$dL = e\Big(1 - \frac{2M}{r}\Big)^{-1} dr. \tag{7}$$

But consider the "same" contraction of tensors expressed in the generalised Gullstrand-Painlevé coordinates. The projector is:

$$P_{\mu\nu} = \begin{pmatrix} \frac{1}{e^2}(e^2 - 1 + \frac{2M}{r}) & \frac{1}{e^2}\sqrt{e^2 - 1 + \frac{2M}{r}} \\ \frac{1}{e^2}\sqrt{e^2 - 1 + \frac{2M}{r}} & \boxed{\frac{1}{e^2}} \end{pmatrix}, \tag{8}$$

in the $T$-$r$ block, so the contraction with $\partial_r$ yields $dL = \frac{1}{e} dr$ as in Equation 4. But why the discrepancy with Equation 7? While Equations 6 and 8 represent the same tensor, it turns out the coordinate vectors $\partial_r$ are distinct. By definition of coordinate basis, ${}^{(Schw)}\partial_r$ is orthogonal to $dt$, whereas ${}^{(GP)}\partial_r$ is orthogonal to $dT$. (In contrast, the vector $(dr)^\sharp$ depends only on $r$.) This potential confusion about coordinate vectors is rarely discussed explicitly.[4,6] In the present context, it shows a potential pitfall for measurement, and the superficial contradiction motivates deeper study.

In fact Equation 7 does have physical meaning: it is the measurement of a falling ruler as determined in the local static frame. By this, we mean the comparison of the ruler's length-contracted tick marks with the $r$-coordinate. The two results are related by the Lorentz factor $\gamma = |e|(1 - 2M/r)^{-1/2}$, since the frames are in standard configuration. This will be examined in future work. For now we conclude $\sqrt{\mathbf{P_u}(\boldsymbol{\xi}, \boldsymbol{\xi})}$ is *not* a measurement in $\mathbf{u}$'s frame, if $\mathbf{g}(\boldsymbol{\xi}, \mathbf{u}) \neq 0$.

## 4. Radar metric

The sonar / radar method of distance measurement involves bouncing a signal off a distant object, and timing the return journey. In relativity a null signal is used, along with the proper time $\Delta\tau$ of the emitter, hence the one-way distance is $\Delta L := \Delta\tau/2$ (assuming an isotropic speed of light $c = 1$). While radar was promoted by Poincaré, Einstein, Milne, Bondi, and others, the following formula was derived by Landau & Lifshitz:[9]

$$\gamma_{ij} := g_{ij} - \frac{g_{0i} g_{0j}}{g_{00}}, \tag{9}$$

for $i, j = 1, 2, 3$, with infinitesimal length element $dL^2 = \gamma_{ij} dx^i dx^j$. This assumes a particular coordinate system is provided, and that the radar instrument is *comoving* in those coordinates.

To apply this to radial motion in Schwarzschild, we need comoving coordinates. One choice is a case of Lemaître-Tolman-Bondi coordinates, using $\rho_e$ given in Refs. 2 and 6, together with $T_e$ from above. The radar metric is:

$$\gamma_{ij} = \begin{pmatrix} \frac{1}{e^2}\left(e^2 - 1 + \frac{2M}{r}\right) & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & r^2 \sin^2\theta \end{pmatrix}, \tag{10}$$

with radial distance $dL = \frac{1}{e}\sqrt{e^2 - 1 + 2M/r}\, d\rho$. The interval "$d\rho$" is unfamiliar, hence reinterpret the radar metric as 4-dimensional (which simply adds terms of 0), and transform into other coordinates. It turns out Equation 10 is identical to the spatial projector (Equations 6 and 8), and the coordinate vector $\partial_\rho$ is parallel to both ${}^{(GP)}\partial_r$ and the radial ruler seen later (Equation 11).[b]

In fact the spatial projector is the covariant generalisation of the radar metric. In any comoving coordinates, the observer has 4-velocity $u^\mu = ((-g_{00})^{-1/2}, 0, 0, 0)$, assuming $\partial_0$ is future-pointing. Then $P_{\mu\nu}$ reduces to $\gamma_{\mu\nu}$, taking the latter as 4-dimensional. Landau & Lifshitz interpret 3-space as spanned by the coordinate vectors $\partial_i$. However these are not necessarily orthogonal to $\partial_0$ and the 4-velocity. Equation 9 gives incorrect results for directions not orthogonal to $\mathbf{u}$, as discussed for the spatial projector. When restricted appropriately, both radar and the projector are simply $g_{\mu\nu}$.

## 5. Adapted frames

Our final technical tool is local reference frames. The observer 4-velocity splits the local tangent space into "time" $\mathbf{u}$, and 3-dimensional "space" orthogonal to $\mathbf{u}$. For our purposes a single spatial vector $\boldsymbol{\xi}$ is often sufficient. While it is well known that measurements relate to expressing tensors in an observer's frame, strangely this is not applied to spatial distance — with rare exceptions.[10] Likewise Rindler writes, "rigid scales [rulers] are of ill repute in relativity", but there is nothing wrong with " 'resilient' scales", within limits on acceleration and tidal forces.[11]

For radial motion in Schwarzschild, the obvious choice of radial vector is that orthogonal to $\mathbf{u}$, $d\theta$ and $d\phi$:

$$\xi^\mu := \Big( -\left(1 - \frac{2M}{r}\right)^{-1} \sqrt{e^2 - 1 + \frac{2M}{r}}, e, 0, 0 \Big). \tag{11}$$

Since the $r$-component is $e$ and the vector has unit length, this means a coordinate interval $\Delta r = e$ corresponds to a proper length $\Delta L = 1$. Hence $dL = \frac{1}{e} dr$ as before.[c]

[b] Taking instead Schwarzschild $t$ with $\rho$, the radar metric gives Equation 7 upon contraction with the alternative $\partial'_\rho$. As before, coordinate vector directions can be misinterpreted.

[c] Our "rulers" are vectors in a single tangent space, which approximate short rulers over spacetime.

In general, suppose a unit spatial vector $\boldsymbol{\xi}$, and a scalar $\Phi$ (for instance a coordinate) are provided. The change in $\Phi$ over the extent of the ruler is $\Delta\Phi = d\Phi(\boldsymbol{\xi})$, hence:

$$dL = \frac{1}{d\Phi(\boldsymbol{\xi})} d\Phi = \frac{1}{\xi^{\Phi}} d\Phi, \tag{12}$$

where the latter expression applies if $\Phi$ is taken as a coordinate. We require $d\Phi(\boldsymbol{\xi}) \neq 0$, meaning $\Phi$ is not constant along the ruler direction, so can demarcate length. In any spacetime, given a coordinate expression of a tetrad, one can simply read off a coordinate length interval by inverting the relevant component.

The "best" ruler direction to choose is typically not obvious. Given $\Phi$ and $\mathbf{u}$, one candidate is a certain maximal direction as follows. Recall the gradient vector $(d\Phi)^\sharp$ is the direction of steepest increase of $\Phi$ per unit length. However this is generally not *purely* spatial, according to $\mathbf{u}$. Hence, restrict $d\Phi$ to $\mathbf{u}$'s 3-space, then take the vector dual. This vector shows the fastest increase of $\Phi$ along any possible ruler of $\mathbf{u}$. The measurement turns out to be $(g^{-1}(d\Phi, d\Phi) + (d\Phi(\mathbf{u}))^2)^{-1/2} d\Phi$, or:

$$dL_{\text{max-}\Phi} = \frac{1}{\sqrt{g^{\Phi\Phi} + (u^{\Phi})^2}} d\Phi, \tag{13}$$

if $\Phi$ is a coordinate. Alternatively, given $\Phi$, we can ask which observers $\mathbf{u}$ make extremal measurements. If a $\Phi = \text{const}$ slice is spatial ($g^{\Phi\Phi} > 0$), then observers with $u^{\Phi} \equiv d\Phi/d\tau = 0$ are possible, these measure $(g^{\Phi\Phi})^{-1/2} d\Phi$ in the direction $(d\Phi)^\sharp$. No ruler orientation for observers with $u^{\Phi} \neq 0$ can achieve this.

Consider a Schwarzschild observer parametrised by both $e$ and the Killing angular momentum per mass $\ell$. Its maximum possible $r$ and $\phi$ measurements are:

$$dL_{r\text{-max}} = \left(e^2 - \left(1 - \frac{2M}{r}\right)\frac{\ell^2}{r^2}\right)^{-1/2} dr, \qquad dL_{\phi\text{-max}} = \frac{r\, d\phi}{\sqrt{1 + \ell^2/r^2}}, \tag{14}$$

where motion is in the plane $\theta = \pi/2$. Incidentally, the corresponding ruler vectors are not orthogonal to one-another. Note that while $r$ is known as the reduced circumference,[12] the Euclidean 2-sphere measurement $r\, d\phi$ only holds for zero angular momentum $\ell = 0$, under this natural ruler orientation.

Our orthonormal frame approach is trivially the zero-distance limit of Fermi coordinates, however very few exact Fermi coordinate expressions are known.[13]

## 6. Discussion

There are many potential questions and objections. It is non-trivial to start from textbook material such as $\int ds$ or first-principles radar. Despite some excellent books,[14,15] our results fill an independent niche.

Given two events, why not extremise the length of spatial geodesics between them? This is a 4-dimensional approach, whereas ours uses a 1+3-dimensional splitting, measuring within the rest space of a given observer.

Is the result coordinate-dependent? The coordinate $\Phi$ serves as an extrinsic standard, but the length element is simply the ruler $\boldsymbol{\xi}^\flat$, which is also the metric interval restricted to a 1-dimensional subspace.

In Schwarzschild, $r$ is timelike inside the horizon, so how can it describe spatial measurement? Indeed the normal vector $(dr)^\sharp$ is timelike, but the measurement direction $\boldsymbol{\xi}$ is spatial.

Why is the Universe so homogeneous and isotropic? We summarize a general study of a $\gamma$-law perfect fluid alongside an inhomogeneous, massless scalar gauge field (with homogeneous gradient) in anisotropic spaces with General Relativity. The anisotropic matter sector is implemented as a $j$-form (field-strength level), where $j \in \{1, 3\}$, and the spaces studied are Bianchi space-times of solvable type. Wald's no-hair theorem is extended to include the $j$-form case. We highlight three new self-similar space-times: the Edge, the Rope and Wonderland. The latter solution is so far found to exist in the physical state space of types I,II, IV, $\text{VI}_0$, $\text{VI}_h$, $\text{VII}_0$ and $\text{VII}_h$, and is a global attractor in I and V. The stability analysis of the other types has not yet been performed. This paper is a summary of [1], with some remarks towards new results which will be further laid out in upcoming work.

*Keywords*: $p$-form gauge fields, anisotropic space-times, Bianchi models, inflation, dynamical system, orthonormal frame.

## 1. Introduction

Why does the Universe seem so isotropic on large scales [2, 3, 4]? Standard cosmology invokes this observation as a principle, as it is hard to solve the Einstein equations without symmetry requirements [5]. In order to understand this high degree of isotropy within the paradigm of GR, it is necessary to relive the theory of such assumption, seeking to replace it instead by an *explanation*. To this end we have softened the isotropy requirement of the cosmological principle by studying the Bianchi models of solvable type (types I-$\text{VII}_h$).

A natural generalization of massless scalar fields to the anisotropic case, is the $p$-form field[a] with $p = 1$ or 3. Collectively, we shall refer to this form field as a $j$-form field, since the equations will be the same in either case (as explained in Section 3). The connection to massless scalar fields may be drawn from Eq. (4). In this study we summarize some results we have obtained in our study so far, and mention a few results to be further reported on in upcoming work(s)(Normann's Ph.D. thesis). We would like to refer the reader to [1] for further references to previous works on related topics. Also, note the recent works [6, 7] and many interesting references therein.

[a] We here and throughout reference the form field on the field strength level.

## 2. The general *p*-form action

A natural candidate for anisotropic matter sourcing is the one stemming from the general $p$-form action [8]

$$S_{\rm f} = -\frac{1}{2}\int \mathcal{P}\wedge\star\mathcal{P}\,, \tag{1}$$

where $\mathcal{P}$ is a $p$ -form constructed by the exterior derivative of a $(p-1)$-form $\mathcal{K}$.

The equations of motion and the Bianchi identity, both obtained from the action, Eq. (1), may now be given as

$$\mathbf{d}\mathcal{P}=0 \quad \rightarrow \quad \nabla_{[\alpha_0}\mathcal{P}_{\alpha_1\cdots\alpha_p]}=0 \qquad \text{Bianchi Identity.} \tag{2}$$

$$\mathbf{d}\star\mathcal{P}=0 \quad \rightarrow \quad \nabla_{\alpha_1}\mathcal{P}^{\alpha_1\cdots\alpha_p}=0 \qquad \text{Equations of motion.} \tag{3}$$

Here $\mathcal{P}_{\mu_1\cdots\mu_p}$ are the components of $\mathcal{P}$ in a general basis. As evident from the above equations[b], our study assume that there is no source to the $j$-form field.

**General properties of the *p*-form action:** Note that the theories derived from the general $p$-form action Eq. (1) respect the following properties: (i) gauge invariance $\mathcal{L}\rightarrow\mathcal{L}$ under $\mathcal{K}\rightarrow\mathcal{K}+\mathbf{d}\mathcal{U}$, where $\mathcal{U}$ is a $(p-2)$ -form; (ii) only up to second order derivatives in equations of motion; (iii) Lagrangian is up to second order in field strength $\mathcal{P}$; (iv) constructed by exterior derivative of a $p$-form and (v) minimally coupled to gravity.

## 3. The *j*-form fluid

In our study, $\mathcal{P}$ is required homogeneous: $\mathcal{P}(t,\mathbf{x})\Rightarrow\mathcal{P}(t)$. However, generally, the underlying gauge field $\mathcal{K}(t,\mathbf{x})$ is allowed to vary both with space and time. Hence we study a $j$-form fieldstrength with an underlying inhomogenous gauge field. This is different from [9], where the gauge potential is a function of time only. In order to classify the possible cases of $p$-form matter fields that can be constructed from the exterior derivative of a $(p-1)$-form, the following notation is introduced: $\{a,b\}$ where $a$ denotes the rank of the $p$-form $\mathcal{P}$ and $b$ the rank of its Hodge dual $\star\mathcal{P}$. In four dimensional space-time ($a+b=4$) there are three distinct cases to consider: (i)$\{2,2\}$, (ii) $\{3,1\}$ or $\{1,3\}$ and (iii) $\{4,0\}$. The degeneracy in (ii) is due to the symmetry of the equations Eq. (2) and Eq. (3)[c]. This symmetry can also be seen in the action Eq. (1), up to a prefactor. Since these two cases yield the same set of equations, we effectively study both cases, by studying one of them.

In the following analysis the cases $\{1,3\}$ and $\{3,1\}$ will be taken into account. In order to include both scenarios, notation shall here, and throughout the rest of the paper, be such that $\mathcal{J}$ denotes either (i) the Hodge dual of a 3-form field strength

[b]The Hodge dual $\star\mathcal{P}$ is closed.

[c]The reason why this degeneracy is not found in the case (iii) is because $\mathcal{P}\neq\mathbf{d}\mathcal{K}$ in the case $\{0,4\}$. Hence one is left only with $\{4,0\}$.

$\mathcal{C}(t) = \mathbf{d}\mathcal{B}$ (where $\mathcal{B}(t, \mathbf{x})$ is a 2-form) or (ii) the 1-form field strength $\mathcal{A}(t) = \mathbf{d}\phi$ (where $\phi(t, \mathbf{x})$ is a scalar field). That both cases give rise to the same equations is evident.

**Energy-momentum tensor:** The energy-momentum tensor of the $j$-form fluid can be shown to be

$$\mathcal{L}_{\rm jf} = -\frac{1}{2}\mathcal{J}_\mu \mathcal{J}^\mu \quad \rightarrow \quad T^{\rm jf}_{\mu\nu} = \mathcal{J}_\mu \mathcal{J}_\nu - \frac{1}{2} g_{\mu\nu} \mathcal{J}_\gamma \mathcal{J}^\gamma . \tag{4}$$

Equations Eq. (2) and Eq. (3) now take the component forms

$$\mathbf{d}\mathcal{J} = 0 \quad \rightarrow \quad \nabla_{[\mu}\mathcal{J}_{\nu]} = 0, \tag{5}$$

$$\mathbf{d}\star\mathcal{J} = 0 \quad \rightarrow \quad \nabla_\mu \mathcal{J}^\mu = 0. \tag{6}$$

These are the equations for a massless scalar field. Hence, our study can be viewed as a study of an inhomogeneous, massless scalar field with a homogeneous gradient.

**State parameter** The field strength $\mathcal{J}_\alpha$ may be decomposed according to

$$\mathcal{J}_\alpha = -w\, u_\alpha + v_\alpha \,, \tag{7}$$

where the 4-velocity $u_\alpha$ is time-like ($u_\alpha u^\alpha < 0$), whereas $v_\alpha$ is defined to be orthogonal to $u_\alpha$ and therefore space-like ($v_\alpha v^\alpha > 0$). The range of the equation of state parameter $\xi$ defined through $p_{\rm f} = (\xi - 1)\rho_{\rm f}$[d] comes as no surprise. Performing the calculations, one finds

$$\xi = \frac{w^2 - v^2/3}{w^2 + v^2} + 1 \qquad \rightarrow \qquad \frac{2}{3} \leq \xi \leq 2\,. \tag{8}$$

The range of $\xi$ follows directly from requiring that $\mathcal{J}_\alpha \in \mathbb{R}$. Note that Eq. (8) is a dynamical equation of state, since the components of $\mathcal{J}$ in general change with time. The lower bound ($\xi = 2/3$) is found for $w = 0$ and the upper bound ($\xi = 2$) is found for $v = 0$. Note also that $w = v$ gives $\xi = 4/3$, as in the case of electromagnetic radiation.

## 4. Sourcing anisotropy with a $j$-form in General Relativity

We take the evolution to be governed by the Einstein Field Equations. In particular

$$R_{\mu\nu} - \frac{1}{2} R\, g_{\mu\nu} = T^{\rm pf}_{\mu\nu} + T^{\rm f}_{\mu\nu} + T^{\rm 4f}_{\mu\nu}\,, \tag{9}$$

where $R_{\mu\nu}$ is the Ricci tensor components, $R = R^\mu{}_\mu$ is the Ricci scalar and $T^{\rm pf}_{\mu\nu}$ and $T^{\rm f}_{\mu\nu}$ the perfect fluid and form fluid energy-momentum tensor components, respectively. The constants $8\pi G$ and $c$ are fixed to 1. Note that a 4-form is also added, playing the role of a cosmological constant.

It is, for simplicity, assumed that the three fluids do not interact.

[d] In a standard irreducible notation where $p$ denotes pressure and $\rho$ is the energy density.

### 4.1. *Bianchi models and choice of frame*

In dimension three there are nine different (classes of) Lie algebras – these are the nine different Bianchi types I-IX. The line element of the Bianchi models can be written as

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + \delta_{ab}\,\omega^a\omega^b \qquad \text{where} \qquad \mathbf{d}\omega^a = -\frac{1}{2}\gamma^a{}_{bc}\omega^b \wedge \omega^c - \gamma^a{}_{0c}\mathrm{d}t \wedge \omega^c. \tag{10}$$

$\{\omega^a\}$ is here a triad of 1-forms, and $\gamma^a{}_{bc}$ are the spatial structure coefficients of the Lie algebra characterizing the corresponding Bianchi type. The tetrad $\{\omega^\alpha\}$ is dual to the vector basis $\{\mathbf{e}_\alpha\}$, which must satisfy the relation $[\mathbf{e}_\mu, \mathbf{e}_\nu] = \gamma^\rho{}_{\mu\nu}\mathbf{e}_\rho$. Refer to ([10], Chapter 15) for details. The time direction is chosen orthogonal to the orbits of the isometry subgroup (i.e.: orthogonal to the three-dimensional hypersurfaces of homogeneity), and the fundamental observer's 4-velocity is aligned with this direction. It is given by $\mathbf{u} = \frac{\partial}{\partial t}$ where $t$ is the cosmological time. We also define a dimensionless time quantity $\tau$ such that $\mathrm{d}t/\mathrm{d}\tau = 1/H$, where $H$ is the Hubble parameter. The deceleration parameter $q$ is now such that $\mathrm{d}H/\mathrm{d}t = -(1+q)H^2$.

**A convenient frame** in which to conduct the analysis is the orthonormal frame. Such a frame will give first order evolution equations alongside a set of constraints which are useful to simplify the analysis. The Bianchi space-times analyzed in the present paper (I-VII$_h$) admit an Abelian $G_2$ subgroup. This allows for a $1+1+2$ split of the four dimensional space-time. As will become clear later, this translates into a $1+1+2$ decomposition of the Einstein Field Equations, as well as the Jacobi and the Bianchi identities. When the orthonormal frame approach is applied to $G_2$ cosmologies, it is common to choose a *group-invariant orbit-aligned* frame, i.e. an orthonormal frame which is invariant under the action of $G_2$ [11].

## 5. No-hair theorems for the $j$-form

No-hair theorems that in previous literature has been established for the Bianchi space-times in the presence of a cosmological constant and a perfect fluid are in this section extended to the presence of the $j$-form in the equations. In particular, it is found that the cosmic no-hair theorem [12] is valid also in this case[e]. Refer to [1] for proofs.

**Theorem 5.1 (First no-hair theorem).** *All Bianchi space-times I-VII$_h$ with a $j$-form, a non-phantom perfect fluid*[f] *and a positive cosmological constant will be asymptotically de Sitter with $\Omega_\Lambda = 1$ in the case where $\gamma > 0$ (and similarly $\Omega_\Lambda + \Omega_{\mathrm{pf}} = 1$ in the case where $\gamma = 0$).*

A similar but less general theorem holds also in the case of a perfect fluid with $0 \leq \gamma < 2/3$:

[e]Note that an anisotropic fluid may sustain an inflationary phase of expansion if it violates the strong or dominant energy condition [13]. A $j$-form respects these energy conditions.
[f]A perfect fluid is said to be phantom if $\gamma < 0$.

**Theorem 5.2 (Second no-hair theorem).** *All Bianchi space-times I-VII$_h$ with a $j$-form, a non-phantom perfect fluid $\Omega_{\rm pf}$ with equation of state parameter $0 \leq \gamma < 2/3$ will be asymptotically quasi de Sitter with $q = \frac{3}{2}\gamma - 1 < 0$.*

## 6. New stable, anisotropic, self-similar space-times

We have also performed a dynamical systems analysis of certain Bianchi types with a $\gamma$-law perfect fluid and a $j$-form fluid. Due to the no-hair theorems, we necessarily remove the cosmological constant in the further study. Among extensions of known self-similar space-times, we interestingly find three new anisotropic space-times; *Wonderland*, *The Edge* and *The Rope* in Bianchi type I. Their global stability has been determined by monotone functions. Extensions to these into other Bianchi types are found, as summarized in the following.

**Type I:** Type I splits into two further invariant subspaces; a temporal and a spatial part (as referred to the components of the $j$-form fluid). All of the three new solutions presented below are in the subspace where the $j$-form fluid is purely spatial.

*Wonderland* is an LRS solution containing both a non-rotating vector and the perfect fluid. The field strength is aligned with the LRS axis and the expansion asymmetry is of prolate type. Its range of existence is the open interval $\gamma \in (2/3, 2)$. It approaches the flat FLRW solution $\Omega_{\rm pf}$ when $\gamma \to 2/3$ and the Kasner solution ($\Sigma_+ = -1$) when $\gamma \to 2$. Interestingly, it has a deceleration parameter $q = -1+3\gamma/2$ identical to the flat FLRW solution. The line element of Wonderland is

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + t^2\mathrm{d}x^2 + t^{\frac{2-\gamma}{\gamma}}(\mathrm{d}y^2 + \mathrm{d}z^2). \tag{11}$$

Global attractor for the Bianchi type I state space for $\gamma \in (2/3, 6/5]$.

*The Rope* contains a rotating vector and the perfect fluid. Its range of existence is the open interval $\gamma \in (6/5, 4/3)$. It approaches Wonderland in the limit $\gamma \to 6/5$ and the Edge in the limit $\gamma \to 4/3$. Like Wonderland, it has a deceleration parameter $q = -1 + 3\gamma/2$ identical to the flat FLRW solution. The Rope is not an LRS solution, although it is "almost LRS" close to Wonderland. The line element of the Rope is

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + t^2\left(\mathrm{d}x + \sqrt{\frac{2(5\gamma-6)}{(2-\gamma)}}t^{1-\frac{2}{\gamma}}\mathrm{d}z\right)^2 + t^{\frac{2(4-3\gamma)}{\gamma}}\mathrm{d}y^2 + t^{\frac{4(\gamma-1)}{\gamma}}\mathrm{d}z^2. \tag{12}$$

Global attractor for the Bianchi type I state space for $\gamma \in (6/5, 4/3)$.

*The Edge* contains only a rotating vector and has deceleration parameter $q = 1$, similar to a radiation dominated universe. Since $\Omega_{\rm pf} = 0$, it exists in the entire range of models, $\gamma \in [0, 2]$. The line element of the Edge is

$$\mathrm{d}s^2 = -\mathrm{d}t^2 + t^2\left(\mathrm{d}x + \sqrt{2}t^{-1/2}\mathrm{d}z\right)^2 + \mathrm{d}y^2 + t\mathrm{d}z^2. \tag{13}$$

Global attractor for the Bianchi type I state space for $\gamma \in [4/3, 2)$.

**Type V:** In the type V subspace, we find a one-parameter extension of the Wonderland equilibrium set. Generally, in this one-parameter family, the $j-$form may have both temporal and spatial components. We also find Plane Waves. For $\gamma \in (2/3, 2)$ these two are the only attractors.

**Types II, IV, $\mathbf{VI_0}$, $\mathbf{VI_h}$, $\mathbf{VII_0}$ and $\mathbf{VII_h}$:** In an upcoming paper (part of Normann's Ph.D. thesis, due in October), we intend to study at least the types I, II, IV, $\mathrm{VII}_0$ and $\mathrm{VII}_h$ in depth. Here we only report a few preliminary results.

*Wonderland.* This solution (alongside one parameter extensions) are found in the physical state space of the types II, IV, $\mathrm{VI}_0$, $\mathrm{VI}_h$, $\mathrm{VII}_0$ and $\mathrm{VII}_h$. This is promising in the sense that this solution might not be sensitive to choices of background geometry. There remains, however, some work in order to pin down its stability.

*Edge and Rope.* These two solutions show up also in the physical state space of type II.

*Plane Waves.* In type IV we find a two parameter extension of the plane wave solution. In type $\mathrm{VII}_h$, the plane waves is a three parameter family of solutions.

# A new class of non-aligned Einstein-Maxwell solutions with a geodesic, shearfree and non-expanding multiple Debever-Penrose vector

Norbert Van den Bergh

*Department of Mathematical Analysis FEA16, Gent University, Gent, 9000, Belgium*
*E-mail: norbert.vandenbergh@ugent.be*

In a recent study of algebraically special Einstein-Maxwell fields[1] it was shown that, for non-zero cosmological constant, non-aligned solutions cannot have a geodesic and shearfree multiple Debever-Penrose vector $\boldsymbol{k}$. When $\Lambda = 0$ such solutions do exist and can be classified, after fixing the null-tetrad such that $\Psi_0 = \Psi_1 = \Phi_1 = 0$ and $\Phi_0 = 1$, according to whether the Newman-Penrose coefficient $\pi$ is 0 or not. The family $\pi = 0$ contains the Griffiths solutions[2], with as sub-families the Cahen-Spelkens, Cahen-Leroy and Szekeres metrics. It was claimed in Ref. 2 (and repeated in Ref. 1) that for $\pi = 0$ both null-rays $\boldsymbol{k}$ and $\boldsymbol{\ell}$ are necessarily non-twisting ($\bar{\rho} - \rho = \bar{\mu} - \mu = 0$): while it is certainly true that $\mu(\bar{\rho} - \rho) = 0$, the case $\mu = 0$ appears to have been overlooked. I reduce the sub-family in which $\boldsymbol{k}$ is non-expanding ($\rho + \bar{\rho} = 0$) to an integrable system of pde's and I present an explicit family of solutions.

*Keywords*: Non-aligned Einstein-Maxwell fields.

## 1. Introduction

In the quest for exact solutions of the Einstein-Maxwell equations

$$R_{ab} - \frac{1}{2}Rg_{ab} + \Lambda g_{ab} = F_{ac}F_b{}^c - \frac{1}{4}g_{ab}F_{cd}F^{cd}, \tag{1}$$

a large amount of research has been devoted to the study of so called *aligned* Einstein-Maxwell fields, in which at least one of the principal null directions (PND's) of the electromagnetic field tensor $\boldsymbol{F}$ is parallel to a PND of the Weyl tensor, a so called Debever-Penrose (DP) direction. One of the main properties in this respect is the Goldberg-Sachs theorem[3], stating that, if a space-time admits a complex null tetrad $(\boldsymbol{k}, \boldsymbol{\ell}, \boldsymbol{m}, \overline{\boldsymbol{m}})$ such that $\boldsymbol{k}$ is shear-free and geodesic and $R_{ab}k^ak^b = R_{ab}k^am^b = R_{ab}m^am^b = 0$ (as is the case when $\boldsymbol{k}$ is also a PND of $\boldsymbol{F}$), then the Weyl tensor is algebraically special, with $\boldsymbol{k}$ being a multiple Weyl-PND. One of the topics considered in Ref. 1, dealing with the reverse problem, enquired after the existence of algebraically special (non-conformally flat and non-null) Einstein-Maxwell fields with a possible non-zero cosmological constant for which the multiple Weyl-PND $\boldsymbol{k}$ is geodesic and shear-free ($\Psi_0 = \Psi_1 = \kappa = \sigma = 0$) and for which $\boldsymbol{k}$ is *not* parallel to a PND of $\boldsymbol{F}$ ($\Phi_0 \neq 0$). Choosing a null-rotation about $\boldsymbol{k}$ such that $\Phi_1 = 0$, it follows that $\Phi_2 \neq 0$: with $\Phi_2 = 0$ $\boldsymbol{\ell}$ would be geodesic and shear-free and the Goldberg-Sachs theorem would imply $\Psi_3 = \Psi_4 = 0$. The Petrov type would then be D, in which case[4,5] the only null Einstein-Maxwell solutions are given by the (doubly aligned) Robinson-Trautman metrics.

Using the GHP formalism[a] the Maxwell equations and Bianchi equations become then

$$\eth'\Phi_0 = -\pi\Phi_0, \tag{2}$$
$$\text{Þ}\Phi_0 = 0, \tag{3}$$
$$\text{Þ}'\Phi_0 = -\mu\Phi_0, \tag{4}$$
$$\eth\Phi_2 = -\nu\Phi_0 + \tau\Phi_2, \tag{5}$$
$$\text{Þ}\Phi_2 = -\lambda\Phi_0 + \rho\Phi_2, \tag{6}$$
$$\eth\Psi_2 = -\pi\Phi_0\overline{\Phi_2} + 3\tau\Psi_2, \tag{7}$$
$$\text{Þ}\Psi_2 = \mu|\Phi_0|^2 + 3\rho\Psi_2, \tag{8}$$

after which the commutators $[\eth', \eth], [\eth', \text{Þ}], [\eth, \text{Þ}'], [\eth', \text{Þ}']$ and $[\text{Þ}', \text{Þ}]$ applied to $\Phi_0$ give

$$\eth\pi = (3\rho - \overline{\rho})\mu - 2\Psi_2 + \frac{R}{12}, \tag{9}$$
$$\text{Þ}\pi = 3\rho\pi, \tag{10}$$
$$\eth\mu = \overline{\lambda}\pi + 3\mu\tau, \tag{11}$$
$$\text{Þ}'\pi - \eth'\mu = 2\nu\rho - 2\lambda\tau - \pi\overline{\mu} - \mu\overline{\tau} - 2\Psi_3, \tag{12}$$
$$\text{Þ}\mu = \pi(\overline{\pi} + 3\tau) + 2\Psi_2 - \frac{R}{12}. \tag{13}$$

Herewith one of the GHP equations becomes a simple algebraic equation for $\Psi_2$,

$$\Psi_2 = \rho\mu - \tau\pi + \frac{R}{12}, \tag{14}$$

the Þ derivative of which results in $\rho R = 0$.

As $\rho = 0$ would imply $\Phi_0 = 0$, this leads to the remarkable consequence that an algebraically special Einstein-Maxwell solution possessing a shear-free and geodesic multiple Weyl-PND which is not a PND of $\boldsymbol{F}$ necessarily has a vanishing cosmological constant. The corresponding class of solutions is non-empty, as it contains the Griffiths[2] metrics, encompassing as special cases the metrics of Refs. 7, 8, 9, 10.

In Ref. 2 it was claimed that for $\pi = 0$ both null-rays $\boldsymbol{k}$ and $\boldsymbol{\ell}$ are necessarily non-twisting ($\bar{\rho} - \rho = \bar{\mu} - \mu = 0$). As a consequence it was also claimed in Ref. 1 that the Griffiths metrics are uniquely characterised by the condition $\pi = 0$. However, when $\pi = 0$ the only conclusion to be drawn from (10, 14) is that $\mu(\bar{\rho} - \rho) = 0$. When $\rho$ is real this indeed leads to the metrics of Ref. 2, while the case $\mu = 0$ appears to have been overlooked and leads, as shown in the section below, to new classes of solutions.

[a] Throughout I use the sign conventions and notations of Ref. 6 §7.4, with the tetrad basis vectors taken as $\boldsymbol{k}, \boldsymbol{\ell}, \boldsymbol{m}, \overline{\boldsymbol{m}}$ with $-k^a\ell_a = 1 = m^a\overline{m}_a$. In order to ease comparison with the (more familiar) Newman-Penrose formalism, I will write primed variables, such as $\kappa', \sigma', \rho'$ and $\tau'$, as their NP equivalents $-\nu, -\lambda, -\mu$ and $-\pi$.

## 2. The missing class

When $\pi = 0$ and $\mu = 0$ the equations from the previous paragraph immmediately lead to $\Psi_0 = \Psi_1 = \Psi_2 = 0$ and $\Psi_3 = \rho\nu - \lambda\tau$. We try to make some progress by looking for solutions for which $\boldsymbol{k}$ is non-expanding ($\rho + \overline{\rho} = 0$). Acting on this condition with the $\eth$ and $\text{Þ}$ operators, the GHP equations lead to $\tau = 0$ and

$$\rho^2 + |\Phi_0|^2 = 0, \tag{15}$$

the $\eth$ derivative of which implies $\lambda = \Phi_2\overline{\Phi_0}\rho^{-1}$. We translate these results into Newman-Penrose (NP) language and fix a boost and spatial rotation in the $\boldsymbol{k},\boldsymbol{\ell}$ and $\boldsymbol{m},\overline{\boldsymbol{m}}$ planes such that $\Phi_0 = 1$ and $\rho = i$. It follows that the only non-0 spin coefficients are $\rho$, $\nu$ and $\lambda = -i\Phi_2$, with the only non-vanishing components of the Weyl spinor being $\Psi_3 = i\nu$ and $\Psi_4$. As $[D,\Delta] = 0$ coordinates $u, v$ and $\zeta, \overline{\zeta}$ exist such that $D = \partial_u$, $\Delta = \partial_v$ and

$$\delta = e^{-iu}(\xi\partial_\zeta + \eta\partial_{\overline{\zeta}} + P\partial_u + Q\partial_v),$$

$\xi, \eta, P, Q$ being arbitrary functions. The $e^{-iu}$ factor is included for convenience: applying the $[\delta, D]$ commutator to $u, v$ and $\zeta$ shows that $\xi, \eta, P, Q$ are functions of $v, \zeta, \overline{\zeta}$ only. Introducing new variables $n = e^{-iu}\nu$ and $\phi = e^{-2iu}\Phi_2$ it follows that also $n$ and $\phi$ depend on $v, \zeta, \overline{\zeta}$ only, with the full set of Jacobi equations and field equations reducing to the following system of pde's:

$$P_v + i\overline{P\phi} - \overline{n} = 0, \tag{16}$$
$$Q_v + i\overline{Q\phi} = 0, \tag{17}$$
$$\xi_v + i\overline{\eta}\overline{\phi} = 0, \tag{18}$$
$$\eta_v + i\overline{\xi}\overline{\phi} = 0, \tag{19}$$

$$e^{-iu}\overline{\delta}P - e^{iu}\delta\overline{P} - 2i|P|^2 = 0, \tag{20}$$
$$e^{-iu}\overline{\delta}Q - e^{iu}\delta\overline{Q} - 2i(\Re Q\overline{P} - 1) = 0, \tag{21}$$
$$e^{-iu}\overline{\delta}\xi - e^{iu}\delta\overline{\eta} - i(\xi\overline{P} + \overline{\eta}P) = 0, \tag{22}$$

$$e^{iu}\delta n = -iPn + 2|\phi|^2, \tag{23}$$
$$e^{iu}\delta\phi = -2iP\phi - n, \tag{24}$$

with the $\Psi_4$ component of the Weyl spinor given by $\Psi_4 = ie^{2iu}(\overline{n}\overline{P} + \Delta\phi) + e^{iu}\overline{\delta}n$. This system is integrable and a simple solution is obtained by assuming $\phi = H^2$ to be a positive constant: in terms of new coordinates $u, v, a, b$ the null tetrad is given by

$$\boldsymbol{\omega}^1 = \frac{e^{iu}}{2H(a+b)}[e^{i\frac{\pi}{4}-v}\mathrm{d}a - e^{-i\frac{\pi}{4}+v}\mathrm{d}b], \tag{25}$$

$$\boldsymbol{\omega}^3 = \frac{1}{H^2}\left[\mathrm{d}v - \frac{1}{2(a+b)}\mathrm{d}(a-b)\right], \tag{26}$$

$$\boldsymbol{\omega}^4 = \mathrm{d}u - \frac{1}{2(a+b)}[e^{-2v}\mathrm{d}a - e^{2v}\mathrm{d}b]. \tag{27}$$

The corresponding space-time metric is

$$\mathrm{d}s^2 = \frac{1}{H^2}\left[-2\mathrm{d}v + \frac{1}{a+b}\mathrm{d}(a-b)\right]\mathrm{d}u + \frac{1}{H^2(a+b)}(e^{-2v}\mathrm{d}a - e^{2v}\mathrm{d}b)\mathrm{d}v + \frac{\cosh 2v}{H^2(a+b)^2}\mathrm{d}a\mathrm{d}b \tag{28}$$

and the Maxwell field and energy-momentum tensor are obtained as

$$\boldsymbol{F} = iH^2(\boldsymbol{\omega}^1 - \boldsymbol{\omega}^2)\wedge\boldsymbol{\omega}^3 + i(e^{-2iu}\boldsymbol{\omega}^1 - e^{2iu}\boldsymbol{\omega}^2)\boldsymbol{\omega}^4, \tag{29}$$

$$\boldsymbol{T} = 2H^2(e^{-2iu}\boldsymbol{\omega}^{1^2} + e^{2iu}\boldsymbol{\omega}^{2^2} + H^2\boldsymbol{\omega}^{3^2}) + 2\boldsymbol{\omega}^{4^2}. \tag{30}$$

The Petrov type is III and the space-time admits three Killing vectors, $\partial_u, \partial_a - \partial_b$ and $a\partial_a + b\partial b$. At first sight it seems odd that the Weyl spinor components $\Psi_3$ and $\Psi_4$ depend on $u$, while the frame has been "invariantly" fixed. The explanation however is that the the frame was fixed by means of a null rotation putting $\Phi_0 = 1$, while the Maxwell field itself does not share the space-time symmetries: $\boldsymbol{F}$ is not Lie-propagated along the integral curves of the null Killing vector $\partial_u$ (this also shows that the family of solutions presented here is distinct from the Einstein-Maxwell solutions admitting null-Killing vectors of Ref. 11.

**Acknowledgment**

All calculations were done using the Maple symbolic algebra system, while the properties of the metric (28) were checked with the aid of Maple's Differential Geometry package.

We explore a family of solutions to Einstein-Maxwell equations with cylindrical symmetry, in which both metric and electromagnetic field are expressed in terms of elementary functions. This is achieved by choosing the integration constants in (00) and (22) components of Einstein equations equal to each other, which is equivalent to putting electric field (transversal) and magnetic field (longitudinal), under suitable rescaling of coordinates, equal to each other. We discuss the connection between our family of solutions and previously known solutions summarized in the 1983 paper by MacCallum, analyze properties of spacetime described by our solutions and show how the equal-field condition can be relaxed perturbatively.

*Keywords*: Einstein-Maxwell equations; cylindrical symmetry; perturbation theory.

## 1. Einstein-Maxwell equations

Consider cylindrical version of Weyl-Lewis-Papapetrou metric,

$$ds^2 = \frac{1}{F}(dt + Ad\phi)^2 - F[B(dr^2 + dz^2) + w^2 d\phi^2], \tag{1}$$

with the electromagnetic vector potential of the form

$$\boldsymbol{A} = A_0 \boldsymbol{d}t + A_2 \boldsymbol{d}\phi, \tag{2}$$

where the functions $F$, $A$, $B$ and $w$, as well as $A_0$ and $A_2$, depend only on the coordinate $r$ [1].

Due to high symmetry of the problem, we can perform one integration of all Maxwell equations and all Einstein equations but one, reducing them to differential equations of first order. For Maxwell equations it is seen immediately and for Einstein equations we can use identity

$$\xi^{\mu\nu}{}_{;\nu} = 2R^{\mu}_{\nu}\xi^{\nu}, \tag{3}$$

where $\xi_{\mu\nu}$ is a bivector associated with Killing vector $\xi^{\mu}$, $\xi_{\mu\nu} = \xi_{\nu,\mu} - \xi_{\mu,\nu} = -2\xi_{\mu;\nu}$, and $R_{\mu\nu}$ is Ricci tensor. Integrated equations were obtained first with the help of Hamiltonian formalism [2], and then with the help of complex potentials [3] introduced in the series of papers [4–6]. Neither procedure used the identity (3) explicitly, although in the paper [6] the authors mentioned it with a reference to Synge's book [7].

First integral of Maxwell equations is

$$\sqrt{-^2 g} A'_A = g_{AB} C^B, \tag{4}$$

and first integral of Einstein equations (five of six) is

$$\sqrt{-{}^2g}g^{ac}g'_{cb} = 2\delta^a_A\delta^B_b C^A A_B - \delta^a_b C^C A_C + K_b{}^a, \tag{5}$$

where the indices $A, B, \ldots$ assume the values 0 and 2, the indices $a, b, \ldots$ assume the values 0, 2, 3 (the coordinates are identified in a usual way as $(x^0, x^1, x^2, x^3) = (t, r, \phi, z)$), ${}^2g$ is determinant of the $(t, \phi)$ part of the metric, ${}^2g = \det(g_{AB}) = -w^2$, and $C^A$, $K_b{}^a$ are constants. After the $\binom{1}{1}$ component of Einstein equations is added to the system, we have eight equations for six functions $F$, $A$, $B$, $w$, $A_0$, $A_2$; thus, two equations are just constraints on integration constants.

The trace of the $\binom{A}{B}$ part of (5) yields $w = (1/2)K_A{}^A r$, so that by rescaling $r$ (as well as $z$, in order to preserve the quadratic form $dr^2 + dz^2$) we obtain $w = r$. If we also gauge away the constants ${K_0}^2$ and ${K_2}^0$, in the $\binom{A}{B}$ part of (5) there remains a single constant $C = (1/2)({K_0}^0 - {K_2}^2)$. The constraint on $C$ can be turned into an independent equation by inserting expressions for $A_A$ in terms of $A$, $A'$, $F$, $F'$ into it, and equations (4) can be then reinterpreted as constraints. However, one of these equations is satisfied identically, so that we are left with one constraint only.

## 2. Equal-field solution

We are interested in solutions to equations (4), (5) with $C = 0$. Their subclass was found long ago by using transformation to rotating frame in which the metric was static[8]. Later it was noted[3,9] that the subclass belongs to a broader family with constant ratio $\mathcal{R} = A'_2/A'_0$. It has $\mathcal{R} = -1/k$, where $k = C^0/C^2$, while a class of solutions proposed in[10] has another distinguished value $\mathcal{R} = -k$. We construct solutions with arbitrary $\mathcal{R}$ by solving the equations directly; however, our solutions can be obtained also from solutions with $\mathcal{R} = -1/k$ by means of the scaling discussed below.

Introduce a new function $f = (Fr/A_+)^{1/2}$, where $A_+ = A + k$. Einstein equations yield a pair of coupled equations for the functions $f$ and $A$,

$$\frac{f''}{f} - \frac{p}{2A_+r^2}\Big(1 + \frac{3}{2}\frac{rA'}{A_+}\Big) - \frac{q + 1/2}{2r^2} = 0, \quad r[A_+(f^4 - 1)]' + pf^4 = 0, \tag{6}$$

where $p = 2kC$ and $q = K_3^3 - C$. For $C = 0$ we have $p = 0$, so that the first equation (6) decouples from the second equation and can be solved analytically. The solution is

$$f = r^{1/2} \times \begin{cases} (k_1 r^a + k_2 r^{-a}), \text{ if } a > 0 \\ (k_1 \ln r + k_2), \text{ if } a = 0 \\ [k_1 \cos(\hat{a} \ln r) + k_2 \sin(\hat{a} \ln r)], \text{ if } a = i\hat{a} \end{cases}, \tag{7}$$

where $a = \sqrt{(1 + q)/2}$. The function $A_+$ is obtained immediately from the second equation (6), the function $F$ appears in the definition of $f$, for the function $\mathcal{B} = BF$ we have separate equation and the functions $A_A$ are given algebraically in terms of $A$, $A'$, $F$, $F'$. In this way we find

$$A_+ = \frac{k_A}{f^4 - 1}, \quad Fr = \frac{k_A f^2}{f^4 - 1}, \quad \mathcal{B} = k_B r^q f^2, \tag{8a}$$

$$A_0 = \frac{2}{C^2 k_A}\frac{rf'}{f}, \quad A_2 = -(k_A + k)A_0. \tag{8b}$$

Finally, upon inserting expressions for $A_0$, $F$ and $A$ into the first equation (4), we find

$$\begin{cases} 4a^2 k_1 k_2 \\ -k_1^2 \\ -\hat{a}^2(k_1^2 + k_2^2) \end{cases} = \frac{1}{2}(C^2)^2 k_A, \text{ if } \begin{cases} a > 0 \\ a = 0 \\ a = i\hat{a} \end{cases}. \tag{9}$$

The solution preserves its form under the scaling $t \to \gamma t$ and $(r, z) \to \gamma^{-1}(r, z)$, if $f$ stays unchanged, which can be always achieved by suitably scaling $(k_1, k_2)$, and if the remaining constants scale as $(k, k_A) \to \gamma(k, k_A)$ and $k_B \to \gamma^{q+2} k_B$. In case the constant $\kappa = k_A + k$ is nonzero, we can use this procedure to normalize it to $\pm 1$ by fixing the unit of length and choosing $\gamma = |\kappa|^{-1}$. As a result, we make the potentials $A_0$ and $A_2$, as well as the field strengths $F_{01}$ and $F_{21}$, equal in absolute value. In that sense we call the solution (8) "equal-field solution". Note, however, that the field strengths are the same only when computed with respect to *coordinate* basis. The physical field strengths which refer to the orthonormal basis $e_{\hat{\alpha}}{}^{\mu}$ carried by the observer at rest, $E^{\hat{1}} = F_{\hat{0}\hat{1}} = \sqrt{F/\mathcal{B}}F_{01}$ and $B^{\hat{3}} = F_{\hat{2}\hat{1}} = (1/\sqrt{F\mathcal{B}})(F_{21} - AF_{01})/r$, differ from each other.

## 3. Properties of spacetime

The $(t, \phi)$ part of the metric can be expressed in two different ways,

$$ds_2^2 = \frac{1}{F}(dt + Ad\phi)^2 - Fr^2 d\phi^2 = \frac{1}{\mathcal{F}}dt^2 - \mathcal{F}r^2(d\phi - \omega dt)^2, \tag{10}$$

where the functions $\mathcal{F}$, $\omega$ are defined in terms of the function $\mathcal{A} = A^2 - F^2 r^2$ as $\mathcal{F} = -\mathcal{A}/(Fr^2)$, $\omega = -A/\mathcal{A}$. The cylinders with $1/F = 0$ are *static limits* (surfaces separating regions in which observers can stay at rest from regions in which they must rotate) and the cylinders with $\mathcal{F} = 0$ are *chronological limits* (surfaces separating regions in which time travel is forbidden from regions in which it is allowed). Suppose $a > 0$, so that $f = (r/r_1)^{a_+} \pm (r/r_2)^{-a_-}$, where $a_\pm = a \pm 1/2$ and the sign in front of the second term is given by the sign of $k_A$. For $k_A > 0$, $a > 1/2$, as well as for $k_A < 0$, $a < 1/2$, the function $f$ has one minimum, defining a cylinder composed of photon orbits; in the latter case it has also one zero, defining a singular "cylinder" (in fact, a line parallel to the $z$ axis).

The behavior of light cones in equal-field solution is depicted in fig. 1. In the left panel, regions in the plane $(a, r_2/r_1)$ with static (S) and rotating (R) neighborhood of photon orbits are shown; in the right panel, light cones in metric with $k_A > 0$, $a > 1/2$ (upper diagram) and $k_A < 0$, $a < 1/2$ (lower diagram) are displayed at various values of $r$ in the planes tangential to respective cylinders. The sign of $k_A$ is denoted by $+$ and $-$ in the left panel and singular "cylinder", photon cylinder,

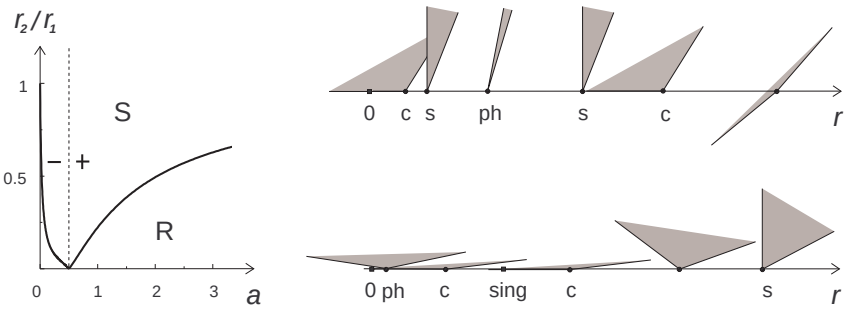

Fig. 1. Regions in parametric space with and without rotating domain in the neighborhood of photon orbits (left) and light cones in two typical spacetimes (right).

static limits and chronology limits are denoted by *sing*, *ph*, *s* and *c* in the right panel.

Circular orbits are given by the conditions $\dot{r}^2 = (\dot{r}^2)' = 0$, where $\dot{r}$ is radial component of 4-velocity. For a photon with impact parameter $b$ we have

$$\dot{r}^2 \propto (b - b_-)(b_+ - b), \quad b_\pm = -A \pm Fr, \tag{11}$$

so that on photon orbits it holds $b = b_\pm$ and $b'_\pm = 0$. From the explicit expression for the functions $b_\pm$, $b_\pm = k \pm k_A/(f^2 \pm 1)$, we find that the latter equation is equivalent to $f' = 0$. (Solution $f = 0$, which corresponds to the singular line parallel to the $z$ axis, does not count.) In the case $a > 0$ this implies that photon orbit exists only for $a > 1/2$ if $k_A > 0$ and $a < 1/2$ if $k_A < 0$, and that its radius is $r_{ph} = (\alpha r_1^{a_+} r_2^{a_-})^{1/(2a)}$, where $\alpha = |a_-|/a_+$. Condition of stability reads $(\dot{r}^2)'' < 0$, which yields, after including the prefactor into equation (11), $\pm b''_\pm < 0$, or equivalently, $k_A f f'' = k_A a_+ a_- f^2 r^{-2} > 0$. This is clearly satisfied for all orbits.

For massive particles, similar analysis leads to following conditions under which the orbits exist and are stable:

$$\text{existence: } k_A(\alpha - x)(x - \hat{\alpha}) > 0, \text{ stability: } (\alpha - x)X > 0, \tag{12}$$

where $x = \mathrm{sgn} k_A r^{2a}/(r_1^{a_+} r_2^{a_-})$, $\hat{\alpha} = (a-1)/(a+1)$ and $X = a_+(1+a)x^3 + a_+(1-3a)x^2 + a_-(1+3a)x + a_-(1-a)$. Location and character of orbits depending on the parameter $a$ is depicted in fig. 2. Blank regions contain stable ($S$) and unstable ($N$) orbits, in shaded regions there are no orbits at all. The line denoted by 'ph' represents photon orbits, the light line represents potential marginally stable orbits (circles on which $X = 0$), and the rugged line is the singularity at $f = 0$.

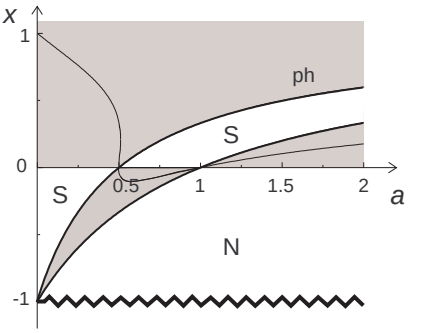

Fig. 2. Existence and stability of particle orbits.

## 4. Perturbing the metric

Equations for the functions $f$ and $\mu = A_+^{-1}$, rewritten into the variable $\tau = \ln r$, read

$$\ddot{f} - \dot{f} - Qf = \frac{p}{2}\Big(\mu - \frac{3}{2}\dot{\mu}\Big)f, \quad \Big(\frac{f^4-1}{\mu}\Big)^{\cdot} = -pf^4, \tag{13}$$

where $Q = (1/2)(q + 1/2)$ and the dot denotes differentiation with respect to $\tau$. Suppose the parameter $p$ is small. In the zeroth order in $p$ we have the previous expressions $f_0 = k_1 e^{a_+\tau} + k_2 e^{-a_-\tau}$ and $\mu_0 = k_A^{-1}(f_0^4 - 1)$, and if we write down the equations for the first corrections to $f$ and $A$,

$$\ddot{f}_1 - \dot{f}_1 - Qf_1 = \frac{p}{2k_A}(f_0 - 6\dot{f}_0)f_0^4, \quad \Big[(f_0^4-1)A_1 + \frac{4f_0^3}{\mu_0}f_1\Big]^{\cdot} = -pf_0^4 \tag{14}$$

(we have skipped the term proportional to $f_0$ from the first equation, since it can be always removed by redefining $Q$), we find

$$f_1 = \frac{p}{2k_A}f_0\Phi_0, \quad A_1 = -p\frac{f_0^4+1}{(f_0^4-1)^2}\Phi_0, \tag{15}$$

where $\Phi_0 = \int f_0^4 d\tau$. To complete the calculation of the perturbed metric, we can determine $F_1$ from the definition of $f$ and $B_1$ from the equation for $\mathcal{B}$. Finally, we can impose the first equation (4) as a constraint on the perturbed solution. With the notations $k_1 = k_{10}(1 + p\lambda_1)$, $k_2 = k_{20}(1 + p\lambda_2)$, $k_A = k_{A0}(1 + p\lambda_A)$ and $C^2 = C_0^2(1 + p\lambda_C)$, the resulting equation reads

$$\lambda_C = -\frac{1}{2}\Big(\lambda_1 + \lambda_2 - \lambda_A - \frac{1}{2a^2 k_{A0}}\Big). \tag{16}$$

# Kerr-Newman spinning particle meets "New Physics" beyond the Standard Model: Unification of gravitation with particle physics

Burinskii, Alexander*

*Nuclear Safety Institute, Russian Academy of Sciences,*
*B.Tulskaya 52, Moscow, 115191, Russia*
**E-mail: burinskii@mail.ru.*
*www.university_name.edu*

Standard model has to be generalized to a "New Physics" beyond the Standard Model. Main problem is the lack of consistency SM with gravity. We analyse Kerr-Newman spinning particle which is consistent with gravity by nature and, contrary to opinion that gravity conflicts with quantum theory, we obtain that spinning Kerr's gravity collaborates with quantum theory in the process of formation of spinning particle. The most dramatic is the shift of the fundamental scale from Planck to Compton distances.

*Keywords*: Kerr-Newman solution, spin, Compton scale, electron, supersymmetry, Higgs, Landau-Ginzburg, phase transition, bag model, strings.

## 1. Introduction

The Standard model (SM) gives at present the best understanding of the particle physics and explained successfully the most off experimental results. Meanwhile, it is not ultimate and has several unsolved problems that are supposed to be resolved in the "New Physics" beyond the SM. In particular,

(i) origin of the mechanism symmetry breaking is not defined up to corresponding nonperturbative solutions,

(ii) the extra dimensions and superpartners were not confirmed in the recent experiments: *"... the LHC experiments have found not even a hint of supersymmetry, despite many searches making different assumptions about the supersymmetric spectrum..."*, [1],

and finally, the main problem,

(iii) Quantum theory and Gravity cannot be combined in a unified theory.

Reason of this trouble is that GRAVITY REJECTS POINTLIKE particles following from stochastic interpretation of quantum theory, because the right side of Einstein equations, $G_{\mu\nu} = 8\pi T_{\mu\nu}$ requires an *extended nonperturbative* solution in configuration space.

One sees that roots of this conflict lie in stochastic interpretation of quantum theory, which had intensive objections from Einstein, de Broglie, Schrodinger and other famous founders of the modern theoretical physics. As is known, the stochastic Copenhagen interpretation won and becomes dominate, but as result of this victory, we have got incompatibility of the gravity with particle physics. People can accept this interpretation, but gravity definitely opposed to this!

Perfect old model of the consistent with gravity particle was the Kaluza-Klein (KK) theory with FIFTH CIRCLING DIMENSION. The corresponding 5d tensor

splits in 4d + 1,

$$^5G_{MN} = 0 \;\Rightarrow\; ^4G_{\mu\nu} = 8\pi T_{\mu\nu}, \tag{1}$$

and potential $A^\mu$, having extra fifth component – scalar field $\Phi$.

Main problem of this theory was invisibility of this extra dimension, and to avoid this problem, authors assumed that compactification occurs at the Planck scale, about $M_p \approx 10^{22} m_e$.

The Planck scale and the additional fifth dimension of the KK model were precursors of the modern superstring theory. The Planck scale was brilliantly matched with well-known "Weakness of gravity" – the opinion based on the known Schwarzschild solution which distorts space near gravitational radius

$$r \sim r_g = 2Gm, \tag{2}$$

which is small with respect to other interactions even at the Planck scale.

Superstring theory inherited Planck scale and higher dimensions together with other remarkable features of the KK model. Theoreticians of the string theory argued: *"... at such energies (Planck scale), strings can be accurately approximated by point particles. This explains why quantum field theory has been so successful in describing our world."* [2].

However, just the Planck scale was the main defect, because it is extremely far from the real scale of the particle physics. Considering electron as one of the principal particles of quantum theory, we should accept that unification must be defined by the Compton scale – electroweak scale of the Standard Model.

**"New physics" beyond the SM was created in 1963 by Kerr solution[3,4].** The spinning Kerr gravity changed the existing conception of gravitational interaction, resolving the principal problem – removal of the giant gap between the Planck scale and the Compton scale required for consistency gravity with physics of the Standard model[5,6].

**Kerr solution exhibited new effect of distortion**, showing that space distorts ***topologically*** at the distance

$$r \sim r_c = \frac{J}{m}, \tag{3}$$

which is proportional to angular momentum $J$ and inverse proportional to mass m. For spinning particles, which have the huge spin/mass ratio (about 20-22 orders in dimensionless units $G = c = \hbar = 1$) topological influence of gravity becomes very strong. The Kerr singular ring forms the branch line of the space, and space differs drastically from the expected flat background in the area of order radius of the Kerr ring. The black hole horizons disappear, opening the hole of another type – two-sheeted space forming the Einstein-Rosen bridge – the door to another sheet of the Kerr geometry. For parameters of an electron, size of this hole is

$$a = \hbar/2mc, \tag{4}$$

which corresponds to the reduced Compton wave length. It gives miraculous magnification of the effective gravitational interaction, scale of which is increased on 22 orders concerning the accepted Planck scale. Conflict between Gravity and Quantum theory increases dramatically, because the both theories become on the equal footing. The **nonperturbative bag-like solution** based on the supersymmetric Higgs model of symmetry breaking specifies the above problem (ii). Supersymmetric bag removes conflict without modification of the Einstein-Maxwell field equations. Bag model regularizes the original Kerr solution near the Kerr singular ring, closing the door to the second sheet. Bag is formed as a *supersymmetric Domain Wall solution (boundary of the bag) which separates external gravitational field from the supersymmetric and flat internal vacuum state* – the flat area which is necessary for work of quantum theory, see Fig. 1. As is known, *the bags are soft and flexible*, and shape of the bag, as well as its size are defined in the process of interaction between gravitational, electromagnetic and quantum fields (see Fig. 2). Problem (ii) is solved by use of the supersymmetric Landau-Ginzburg field model of phase transition instead of the "superpartner" models.

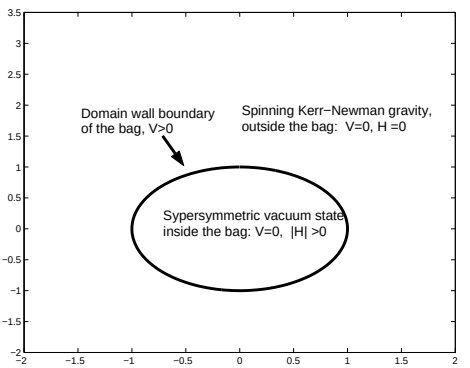

Fig. 1. Separation of the flat Quantum interior from zone of the spinning Gravity.

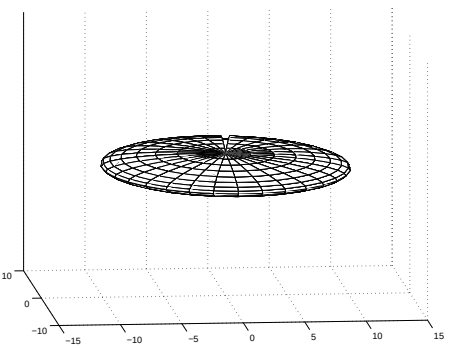

Fig. 2. Bag takes form of a thin disk.

## 2. The Kerr-Newman Spinning Particle

In 1968 Carter noticed [7], that Kerr-Newman (KN) solution has gyromagnetic ratio $g = 2$, as that of the Dirac electron [4]. The KN solution was considered as a classical model of electron [8–10]. Since for electron $a >> m$, the horizons disappear and topology becomes broken by naked singular ring. Metric of the KN solution in the Kerr-Schild form is [4]

$$g_{\mu\nu} = \eta_{\mu\nu} + 2Hk_\mu k_\nu, \tag{5}$$

where $\eta_{\mu\nu}$ is metric of auxiliary Minkowski space $M^4$, (signature $(-++{+})$), and scalar function

$$H = \frac{mr - e^2/2}{r^2 + a^2\cos^2\theta}, \tag{6}$$

is given in Kerr's oblate spheroidal coordinates $r$ and $\theta$. The null vector field $k_\mu(x)$, $(k_\mu k^\mu = 0)$ determines Kerr congruence which has the form of a vortex, dragged by the naked Kerr singular ring $r = 0, \cos\theta = 0$, see Fig. 1, Fig. 2, which is branch line of Kerr space into two sheets. The congruence $k^-_\mu$, goes to disk $r = 0$ as 'ingoing', and intersecting disk, it is extended analytically, turning into 'out-going' congruence $k^+_\mu$, which forms a second sheet of the metric on the same background. The space becomes two-sheeted, with two different metrics on the same background, $g^\pm_{\mu\nu} = \eta_{\mu\nu} + 2Hk^\pm_\mu k^\pm_\nu$. The Kerr singular ring $r = 0,\ \cos\theta = 0$, of the Compton radius $a = \hbar/2m$, breaks space topologically, forming the famous Einstein-Rosen bridge[11]. Studying of the KN solution was mainly in two directions:

A) Israel[8] suggested to truncate negative sheet of Kerr space along disk $r = 0$ and put at this disk a distribution of matter in accord with right hand side of the Einstein equations. He obtained a strange matter distribution and argued that this disk-like source of Compton radius can be considered as a classical model of electron. Hamity showed that source of Kerr solution can be considered as a relativistically rotating disk. Later on López generalized this model to model of a rotating bubble[10].

B) Another stringy version of the Kerr source was developed in our works with Prof. D. Ivanenko[9,12]. The Kerr singular ring was compared there with Nielsen-Olesen (NO) string model as a vortex in superconductor[13]. It was shown that Kerr's singular ring can be considered as a lightlike string which can bear the electromagnetic and spinor traveling waves. Much later, such pp-wave strings were considered as solitonic string solutions to low energy string theory[14,15].

Bag model merges directions A) and B). In the both these directions of investigation source of the Kerr geometry created a gravitational vortex of the Compton size, and there appeared the question: Why this vortex and singular ring were not observed experimentally, and electron looks like a point? Answer follows from mechanism of Lorentz contraction[16]. *For external observer Kerr's vortex shrinks to point by Lorentz contraction.*

The suggested in[5,17] supersymmetric bag model solves problem of unification with gravity by separation of their zones of influence. Quantum theory requires flat space, at least in the Compton zone, while spinning Kerr's gravity spoils space topologically. Supersymmetric bag model realizes expulsion of gravity and electromagnetic field from interior of the bag, forming tree zones: flat quantum interior **(I)**, external zone with exact KN solution **(E)**, and a thin zone of transition **(R)**, see Fig. 2. Surface $(R)$ is defined by the continuous transition of KN solution to Minkowski interior of the bag, (C. López[10]). According (5) and (6), zone **(R)** corresponds to $H_{KN}(r) = 0$, which gives $r = R = e^2/2m$, and shows that domain wall

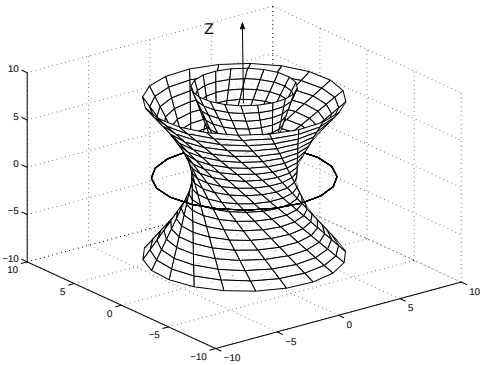

Fig. 3. The lightlike Kerr Null congruence $k^\mu$ determines space-dragging caused by mass and spin.

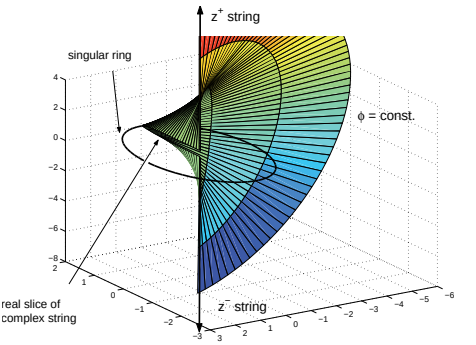

Fig. 4. Rotational dragging of vector-potential $A^\mu$ along border of bag creates a quantum Wilson loop.

boundary has an ellipsoidal form, the disk with radius $r_c = \sqrt{R^2 + a^2}$ and thickness $R$, see Fig. 2.

## 3. Landau-Ginzburg Field Model of Phase Transition

To satisfy **(I),(E),(R)**, it is natural to use Higgs mechanism of symmetry breaking which is used in many nonperturbative electroweak models and in the MIT and SLAC bag models[18,19]. The corresponding Lagrangian is also known as LG field model for superconducting phase transitions and used in famous Nielsen-Olesen (NO) model of vortex string in superconductor[13], $\mathcal{L}_{NO} = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} - \frac{1}{2}(\mathcal{D}_\mu\Phi)(\mathcal{D}^\mu\Phi)^* - V(|\Phi|)$, where $\mathcal{D}_\mu = \nabla_\mu + ieA_\mu$ are $U(1)$ covariant derivatives and $F_{\mu\nu} = A_{\mu,\nu} - A_{\nu,\mu}$. Conditions **(I),(E),(R)** require to use generalized LG model with three Higgs-like fields,[20] $(H, Z, \Sigma) \equiv (\Phi_1, \Phi_2, \Phi_3)$. Lagrangian differs from $\mathcal{L}_{NO}$ only by summation over fields $\Phi_i, i = 1, 2, 3$, while potential $V$ is to be built in analogue with supersymmetric machinery from superpotential $W(\Phi_i)$, as follows $V(r) = \sum_i F_i F_i^*, \quad F_i = \partial W/\partial\Phi_i \equiv \partial_i W$, where $W(\Phi_i, \bar{\Phi}_i) = Z(\Sigma\bar{\Sigma} - \eta^2) + (Z + \mu)H\bar{H}$, The conditions $F_i = \partial_i W = 0$ determine two vacuum states with $V = 0$ : internal-**(I)**, $r < R - \delta$, condensation of Higgs field, $|H| = \eta$, and external- **(E)**, where $r > R + \delta$ and $H = 0$, separated by domain wall with $V > 0$, – zone **(R)**, in correspondence with **(I),(E),(R)**.

Higgs field $H$ is concentrated in zone **(I)**, creating superconducting vacuum state inside bag, leading to equations

$$\partial_\nu\partial^\nu A_\mu = J_\mu = e|H|^2(\chi_{,\mu} + eA_\mu), \tag{7}$$

where $\chi$ is oscillating phase of Higgs field $H = |H|e^{i\chi(t,\phi)}$. Vector potential of KN solution is dragged in $t, \phi$ direction by the Kerr congruence near the ring, (see Fig. 2) and concentrated in equatorial plane near the Kerr singular ring, forming a Wilson loop on the boundary of superconducting disk. At $r = R = e^2/2m$ it takes

maximal value $A^*_\mu dx^\mu = -Re\ \frac{2m}{e}(dt - ad\phi)$. Inside the disk it is compensated by phase of Higgs field, $\chi_{,\mu} + eA_\mu = 0$ so that $J_\mu = 0$ inside the disk. Thus, current $J_\mu$ is expelled to surface layer. Formation of the Wilson line on the rim of the disk leads to *quantization of angular momentum*[5,17], $J = n/2,\ n = 1, 2, 3, ...$

## 4. The Supersymmetric Bag Model

By nature bag models are assumed to be soft and flexible[21–23]. Under excitations bags are deformed and take the shape of a stringy flux-tube joining the quark-antiquark pair[18,21], or toroidal string[19,22,23]. In the KN gravitational field, bag takes ellipsoidal shape, see Fig. 2, and acquires circular string at the sharp boundary, closely to Kerr singular ring[17]. This string bears lightlike traveling wave and creates circulating singular pole, reproducing zitterbewegung of the naked electron[17]. Considering fields $\Phi_i$ and $\bar{\Phi}_i$ as independent chiral field, we double the charged chiral fields $\Sigma$ and $\Phi$, and obtain five chiral fields with identification $\Phi_i = (\Phi_+, \Phi_-, \Sigma_+, \Sigma_-, Z)$. It gives supersymmetric LG model with superpotential $W(\Phi_i, \tilde{\Phi}_i) = Z(\Sigma_+\Sigma_- - \eta^2) + (Z + \mu)\Phi_+\Phi_-$, which satisfies conditions **(I)**,**(E)**,**(R)**. Kinetic part of this model coincides with that of the Wess-Zumino SuperQED model, while potential part corresponds to the most general renormalizable supersymmetric generalization of the Wess-Zumino model. In the component form $\Phi_\pm(y) = H_\pm(y^\mu) + \sqrt{2}\theta\psi_\pm(y^\mu) + \theta\theta F_\pm(y^\mu)$, we obtain doublet of the Higgs fields $H_\pm$, corresponding to supersymmetric Higgs model in which two Weyl spinors $\psi^\pm$ are combined into one massive Dirac spinor of the electron – superpartner of the Higgs doublet[24].

## 5. Conclusion

Analysis of the compatible with gravity Kerr-Newman model of the spinning particle (electron) shows that spinning gravity cardinally increases scale of gravitational interaction, extending its influence up to Compton scale, where it starts interplay with quantum theory, forming nonperturbative model of the dressed electron based on the supersymmetric field model of symmetry breaking. Contrary to the assumed confrontation, *gravity collaborates with quantum theory*, fixing the size and shape of the dressed electron corresponding to the fine structure constant. Also, Kerr-Newman gravity fixes the Wilson loop of the vector potential, leading to quantization of angular momentum and defining the related stringy structure.[25]

# Study of anisotropic compact stars

Sharif M.* and Sadiq S.

*Department of Mathematics, University of the Punjab, Lahore, 54590, Pakistan*
**E-mail: msharif.math@pu.edu.pk*
*www.pu.edu.pk*

We study the stability of anisotropic fluid configuration using a relation between density and pressure. For this purpose, we formulate the corresponding field equations, generalized Tolman-Oppenheimer-Volkoff equation and mass equation which are necessary to discuss the structure of compact stars and solve them through numerical technique. The stability of the compact object is analyzed through cracking and formulate the force distribution function after perturbing the matter quantities. Further, we plot the resulting force function and examine the occurrence of cracking/overturning.

*Keywords*: Electromagnetic field; Equation of state; Cracking.

## 1. Introduction

A stellar object is worthless if it is not stable towards perturbations in its physical variables. Herrera[1] introduced the notion of cracking as well as overturning to describe the behavior of fluid after its deviation from equilibrium state. The cracking appears when the radial force is positive in the inner regions but negative at outer ones while overturning occurs for the reverse situation. Di Prisco *et al.*[2] found that departure from equilibrium state leads to the cracking in sphere for local anisotropic perturbation. Gonzalez *et al.*[3] observed cracking in isotropic and anisotropic spheres with barotropic equation of state (EoS) using local density perturbations. Herrera *et al.*[4] observed the cracking and overturning for anisotropic polytropes by perturbing energy density as well as local anisotropy of the system.

The inclusion of charge in stellar configurations yields interesting results. Takisa and Maharaj[5] formulated exact solutions of the field equations with polytropic EoS to model charged anisotropic compact object. We have studied charged conformally flat polytropic sphere and checked its viability[6]. Azam *et al.*[7] observed cracking in charged sphere and found that stability regions increase by the increase of charge.

This paper investigates the cracking of charged spherical anisotropic polytropes. The next section is devoted to construct the generalized Tolman Oppenheimer Volkoff (TOV) equation as well as mass equation for charged anisotropic fluid distribution using two cases of polytropic EoS. In the section **3**, we formulate force function by perturbing density and anisotropy and plot the results numerically. Finally, we conclude our results in the last section.

## 2. Charged Anisotropic Matter Distribution

We consider static spherically symmetric spacetime as follows

$$ds^2 = -e^{\nu(r)}dt^2 + e^{\lambda(r)}dr^2 + r^2\left(d\theta^2 + \sin^2\theta d\phi^2\right). \tag{1}$$

The energy-momentum tensor for charged anisotropic fluid is given by

$$T_{\mu\nu}=(\rho+P_{\perp})V_{\mu}V_{\nu}+P_{\perp}g_{\mu\nu}+(P_r-P_{\perp})S_{\mu}S_{\nu}+\frac{1}{4\pi}\left(F_{\mu}{}^{\alpha}F_{\nu\alpha}-\frac{1}{4}F^{\alpha\beta}F_{\alpha\beta}g_{\mu\nu}\right), \tag{2}$$

where $P_r,\ P_{\perp},\ V^{\mu}=e^{-\nu/2}\delta^{\mu}_{0},\ S^{\mu}=e^{-\lambda/2}\delta^{\mu}_{1},\ F_{\mu\nu}=\phi_{\nu,\mu}-\phi_{\mu,\nu}$ and $\phi_{\mu}$ are the radial pressure, tangential pressure, four-velocity, four-vector, the Maxwell field tensor and four potential, respectively. The Maxwell field equation $F^{\mu\nu}_{\ ;\nu}=\mu_0 J^{\mu}$ ($\mu_0$ is the magnetic permeability and $J^{\mu}$ is the four current) for our spacetime yields $q(r)=4\pi\int_0^r\zeta e^{\frac{\lambda}{2}}r^2dr$ indicating total charge inside the sphere. The corresponding Einstein-Maxwell field equations turn out to be

$$8\pi\rho+\frac{q^2}{r^4}=\frac{e^{-\lambda}\lambda'}{r}-\frac{e^{-\lambda}-1}{r^2},\quad 8\pi P_r-\frac{q^2}{r^4}=\frac{e^{-\lambda}\nu'}{r}+\frac{e^{-\lambda}-1}{r^2},$$
$$8\pi P_{\perp}+\frac{q^2}{r^4}=e^{-\lambda}\left(\frac{\nu''}{2}+\frac{\nu'^2}{4}-\frac{\nu'\lambda'}{4}+\frac{\nu'}{2r}-\frac{\lambda'}{2r}\right).$$

The corresponding Misner-Sharp mass leads to[9]

$$m(r)=\frac{r}{2}\left(1-e^{-\lambda}\right)+\frac{q^2}{2r}\ \Rightarrow\ m'=4\pi r^2\rho+\frac{qq'}{r}. \tag{3}$$

The conservation law, $T^{\mu}_{\nu;\mu}=0$, yields the generalized TOV equation as

$$P_r{}'+\frac{4\pi r^4P_r-q^2+rm}{r^3-2r^2m+rq^2}(\rho+P_r)-\frac{2\Delta}{r}-\frac{qq'}{4\pi r^4}=0, \tag{4}$$

where $\Delta=P_{\perp}-P_r$.

The polytropic EoS is a power-law relationship between energy density and pressure. It has two possible cases given as[8]

$$P_r=k\rho_0^{\gamma}=k\rho_0^{1+\frac{1}{n}},\quad \rho-\rho_0=nP_r, \tag{5}$$
$$P_r=k\rho^{\gamma}=k\rho^{1+\frac{1}{n}},\quad \rho\left(1-k\rho_0^{\frac{1}{n}}\right)^n=\rho_0, \tag{6}$$

where $\gamma,\ k,\ n$ and $\rho_0$ denote polytropic exponent, polytropic constant, polytropic index and baryonic density, respectively. For case **1**, we construct generalized TOV equation by taking

$$P_{rc}=\alpha\rho_c,\quad \xi=rA,\quad A^2=\frac{4\pi\rho_c}{\alpha(n+1)},\quad \Phi_0^n=\frac{\rho_0}{\rho_{0c}},\quad m(r)=\frac{4\pi\rho_c\eta(\xi)}{A^3}, \tag{7}$$

where subscript $c$ indicates the value at the center, $\alpha,\ \xi,\ \Phi_0,\ \eta$ are dimensionless variables and $A$ is constant. Using the variables along with Eq. (5) in (4) and (3), we obtain

$$\left\{\frac{1-\frac{2\eta\alpha(n+1)}{\xi}+\frac{4\pi\rho_cq^2}{\xi^2\alpha(n+1)}}{\alpha(n+1)\Phi_0+1-n\alpha}\right\}\left(\xi^2\frac{d\Phi_0}{d\xi}-2\Phi_0^{-n}\frac{\alpha^4(n+1)^2\xi^3\Delta+2\pi\alpha^2\rho_c^2q\frac{dq}{d\xi}}{\alpha^5\rho_c(n+1)^3\xi^2}\right)$$
$$+\alpha\xi^3\Phi_0^{n+1}+\eta-\frac{4\pi\rho_cq^2}{\xi\alpha^2(n+1)^2}=0, \tag{8}$$
$$\xi^2\Phi_0^n(1+n\alpha\Phi_0-n\alpha)+\frac{4\pi\rho_cq}{\xi\alpha^2(n+1)^2}\frac{dq}{d\xi}=\frac{d\eta}{d\xi}. \tag{9}$$

For case **2**, we construct the structure equations by taking $\Phi^n = \rho/\rho_c$. Consequently, the TOV equation as well as mass equation turns out to be

$$\left\{\frac{1-\frac{2\eta\alpha(n+1)}{\xi}+\frac{4\pi\rho_c q^2}{\xi^2\alpha(n+1)}}{1+\alpha\Phi}\right\}\left(\xi^2\frac{d\Phi}{d\xi}-2\Phi^{-n}\frac{\alpha^4(n+1)^2\xi^3\Delta+2\pi\alpha^2\rho_c^2 q\frac{dq}{d\xi}}{\alpha^5\rho_c(n+1)^3\xi^2}\right)$$

$$+\alpha\xi^3\Phi^{n+1}+\eta-\frac{4\pi\rho_c q^2}{\xi\alpha^2(n+1)^2}=0, \tag{10}$$

$$\xi^2\Phi^n+\frac{4\pi\rho_c q}{\xi\alpha^2(n+1)^2}\frac{dq}{d\xi}=\frac{d\eta}{d\xi}. \tag{11}$$

We see that Eqs. (8)-(11) form two systems of differential equations in three unknowns for case **1** and **2**, respectively. In order to reduce one unknown, we take $\Delta=\frac{B(4\pi r^4P_r-q^2+rm)}{r^2-2rm+q^2}(\rho+P_r)$ ($B$ is a constant).

## 3. Cracking of Anisotropic Polytrope

In order to observe cracking, the force function is given as

$$\mathcal{R}=\frac{dP_r}{dr}+\beta\left[\frac{4\pi r^4P_r-q^2+rm}{r^3-2r^2m+rq^2}\right](\rho+P_r)-\frac{qq'}{4\pi r^4}, \tag{12}$$

here $\beta=1-2B$ and $\mathcal{R}$ represents the force distribution function. We perturb matter variables for both cases through a set of parameters $(k,\beta)$ and $(n,\beta)$. We perturb the density and anisotropy via $k\rightarrow\tilde{k}=k+\delta k,\quad \beta\rightarrow\tilde{\beta}=\beta+\delta\beta$, yielding $\tilde{P}_r=\tilde{k}\rho_0^{1+\frac{1}{n}}=\omega P_r,\ \tilde{\rho}=\rho_0+n\omega P_r$ with $\omega=\frac{\tilde{k}}{k}$. Introducing the dimensionless variable $\hat{\tilde{\mathcal{R}}}=\frac{A}{4\pi\rho_c^2}\tilde{\mathcal{R}}$ and using the perturbed parameters alongwith Eq. (7) in (12), we have

$$\hat{\tilde{\mathcal{R}}}=\frac{\tilde{\beta}\Phi_0^n(1-n\alpha+\alpha\omega(n+1)\Phi_0)}{\xi^2}\left\{\frac{\tilde{\eta}+\alpha\omega\xi^3\Phi_0^{n+1}-\frac{4\pi\rho_c q^2}{\xi\alpha^2(n+1)^2}}{1-\frac{2\tilde{\eta}\alpha(n+1)}{\xi}+\frac{4\pi\rho_c q^2}{\xi^2\alpha(n+1)}}\right\}+\omega\Phi_0^n\frac{d\Phi_0}{d\xi}-\frac{qq'}{4\pi r^4}. \tag{13}$$

In equilibrium state, $\hat{\tilde{\mathcal{R}}}(\xi,1+\delta\omega,\beta+\delta\beta,\eta+\delta\eta)=0$. After expansion, we obtain

$$\delta\hat{\mathcal{R}}=\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\omega}|_{\omega=1,\tilde{\beta}=\beta,\tilde{\eta}=\eta}\delta\omega+\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\tilde{\beta}}|_{\omega=1,\tilde{\beta}=\beta,\tilde{\eta}=\eta}\delta\beta+\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\tilde{\eta}}|_{\omega=1,\tilde{\beta}=\beta,\tilde{\eta}=\eta}\delta\eta. \tag{14}$$

Making use of perturbed parameters in Eq. (9), we obtain

$$\tilde{\eta}=\int_0^{\xi}\left[\frac{(1-n\alpha+n\alpha\omega\Phi_0)}{\hat{\xi}^{-2}\Phi_0^{-n}}+\frac{4\pi\rho_c q\frac{dq}{d\hat{\xi}}}{\alpha^2\hat{\xi}(n+1)^2}\right]d\hat{\xi}\ \Rightarrow\ \delta\eta=\frac{f_1(\xi)\delta\omega}{(n\alpha)^{-1}}=\frac{\int_0^{\xi}\hat{\xi}^2\Phi_0^{n+1}d\hat{\xi}\delta\omega}{(n\alpha)^{-1}}.$$

Evaluating $\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\omega}, \frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\beta}, \frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\tilde{\eta}}$ from Eq. (13) and using the variable $x = \frac{\xi}{\bar{A}}$ in (14), we have

$$\delta\hat{\mathcal{R}}_1 = \Phi_0^n \left[ \frac{\frac{d\Phi_0}{dx}}{\bar{A}} + \frac{\alpha\beta}{\bar{A}^2x^2G_1} \left\{ \frac{2(n+1)\Phi_0 + 1 - n}{(\alpha\bar{A}^3x^3\Phi_0^{n+1})^{-1}} + (n+1)\Phi_0 \left\{ \eta - \frac{4\pi\rho_c q^2}{\bar{A}x\alpha^2(n+1)^2} \right\} \right.\right.$$
$$\left.\left. + \frac{G_2}{G_1} \left( 1 + \frac{2\alpha^2(n+1)}{(x^2\bar{A}^2\Phi_0^{n+1})^{-1}} - \frac{4\pi\rho_c q^2 x^{-2}}{\bar{A}^2\alpha(n+1)} \right) n f_1(x) \right\} \right] \delta\omega + \frac{\Phi_0^n G_2 G_3}{x^2\bar{A}^2 G_1}\delta\beta, \tag{15}$$

where

$$G_1 = 1 - \frac{2\alpha(n+1)\eta}{\bar{A}x} + \frac{4\pi\rho_c q^2}{\bar{A}^2x^2\alpha(n+1)},\ G_2 = 1 - n\alpha + \alpha\Phi_0(n+1),$$
$$G_3 = \eta + \alpha x^3\bar{A}^3\Phi_0^{n+1} - \frac{4\pi\rho_c q^2}{x\bar{A}\alpha^2(n+1)^2}.$$

In cracking, $\delta\hat{\tilde{\mathcal{R}}} > 0$ inside the sphere while $\delta\hat{\tilde{\mathcal{R}}} < 0$ for outer regions, so $\delta\hat{\tilde{\mathcal{R}}} = 0$ for some value of $\xi$ implying $\delta\omega = -\frac{\delta\beta}{\Gamma}$ with $\Gamma = \frac{\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\omega} + \frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\tilde{\eta}} f_1(\xi)}{\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\beta}}|_{\omega=1,\tilde{\beta}=\beta,\tilde{\eta}=\eta}$.

Now, we perturb fluid variables via $n \to \tilde{n} = n + \delta n,\ \beta \to \tilde{\beta} = \beta + \delta\beta$. In this scheme, Taylor's expansion yields

$$\delta\hat{\mathcal{R}}_2 = \Phi_0^n \left[ \frac{\ln\Phi_0}{\bar{A}} \frac{d\Phi_0}{dx} + \frac{\beta}{\bar{A}^2x^2G_1} \left\{ \ln\Phi_0 G_2 G_3 + \alpha(\Phi_0 - 1)G_3 + G_2 \left( \alpha A^3x^3 \right.\right.\right.$$
$$\left.\left.\left. \times\ \Phi_0^{n+1}\ln\Phi_0 + \frac{8\pi\rho_c q^2}{\bar{A}x\alpha^2(n+1)^3} \right) + \frac{G_2G_3}{G_1} \left( \frac{2\eta\alpha}{\bar{A}x} + \frac{4\pi\rho_c q^2}{\bar{A}^2x^2\alpha(n+1)^2} \right) \right.\right.$$
$$\left.\left. + \frac{G_2}{G_1} \left( G_1 + \frac{2\alpha(n+1)}{\bar{A}x} G_3 \right) f_2(x) \right\} \right] \delta n + \frac{\Phi_0^n}{\bar{A}^2x^2} \frac{G_2G_3}{G_1}\delta\beta, \tag{16}$$

where

$$f_2(x) = \int_0^x \frac{\alpha(\Phi_0^{1-n} - 1) + (1 - n\alpha)\ln\Phi_0}{(\bar{A}^3\hat{x}^2\Phi_0^n)^{-1}} d\hat{x},\ \delta n = \frac{-\delta\beta}{\Gamma = \frac{\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\tilde{n}} + \frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\tilde{\eta}} f_2(\xi)}{\frac{\partial\hat{\tilde{\mathcal{R}}}}{\partial\tilde{\beta}}}|_{\tilde{n}=n,\tilde{\beta}=\beta,\tilde{\eta}=\eta}}. \tag{17}$$

For case **2**, the perturbed parameters $(k, \beta)$ lead to $\tilde{\rho} = \rho + \delta\rho = \rho + \frac{\partial\tilde{\rho}}{\partial\omega}|_{\omega=1} = \rho + nP_r(1-\omega)$ yielding

$$\delta\hat{\mathcal{R}}_3 = \Phi^n \left[ \frac{d\Phi}{\bar{A}dx} + \frac{\alpha\beta}{\bar{A}^2x^2G_1} \left\{ \Phi(1-n) \left( \eta - \frac{4\pi\rho_c q^2}{x\bar{A}\alpha^2(n+1)^2} \right) + x^3\bar{A}^3\alpha(1-n)\Phi^{n+2} \right.\right.$$
$$\left.\left. - n(1+\alpha\Phi)\left(1 + 2\alpha^2\bar{A}^2x^2(n+1)\Phi^{n+1}\right)\frac{f_3(x)}{G_1} \right\} \right] \delta\omega + \frac{(1+\alpha\Phi)\,G_3\delta\beta}{x^2\bar{A}^2\Phi^{-n}G_1}, \tag{18}$$

where $f_3(x)=\int_0^x \bar{A}^3\hat{x}^2\Phi^{n+1}d\hat{x}$. Similarly, perturbation of $n$ and $\beta$ leads to

$$\delta\hat{\mathcal{R}}_4=\Phi^n\left[\frac{\ln\Phi\frac{d\Phi}{dx}}{\bar{A}}+\frac{\beta G_5}{\bar{A}^2x^2G_1}\left\{\ln\Phi(G_4+\alpha A^3x^3\Phi^{n+1})+\frac{8\pi\rho_cq^2}{\bar{A}x\alpha^2(n+1)^3}+\frac{2G_4}{\bar{A}xG_1}\right.\right.$$
$$\left.\left.\times\left(\eta\alpha+\frac{2\pi\rho_cq^2\alpha^{-1}}{\bar{A}x(n+1)^2}\right)+\left(1+\frac{2\alpha(n+1)G_4}{\bar{A}xG_1}\right)f_4(x)\right\}\right]\delta n+\frac{\Phi^nG_4G_5}{\bar{A}^2x^2G_1}\delta\beta, \tag{19}$$

where

$$G_4=\eta+\alpha x^3\bar{A}^3\Phi^{n+1}-\frac{4\pi\rho_cq^2}{x\bar{A}\alpha^2(n+1)^2},\ G_5=1+\alpha\Phi,\ f_4(x)=\int_0^x\bar{A}^3\hat{x}^2\Phi^n\ln\Phi d\hat{x}.$$

We examine the stability of polytropic models by evaluating $\Phi_0$ ,$\Phi$ and $\eta$ with boundary conditions $\eta(0)=0,\ \Phi_0(0)=1,\ \Phi_0(\xi_\Sigma)=0,\ \Phi(0)=1,\ \Phi(\xi_\Sigma)=0$, and use these results to plot force distribution functions. The graphical behavior of force distribution functions are shown in Fig. 1. The left graph of upper panel shows that $\delta\hat{\mathcal{R}}_1$ is positive in the inner regions and becomes negative for the outer ones for all considered values of $q$ thus ensuring the occurrence of cracking in the corresponding model. The right graph of upper panel shows that there is neither cracking nor overturning in $\delta\hat{\mathcal{R}}_2$ for all values of $q$. The left graph of lower panel indicates that $\delta\hat{\mathcal{R}}_3$ exhibits stable behavior for $q=0.2M_0$ while the strongest overturning appears for other two values of $q$. The plot of $\delta\hat{\mathcal{R}}_4$ for different values of charge shows stable configuration (right plot of lower panel).

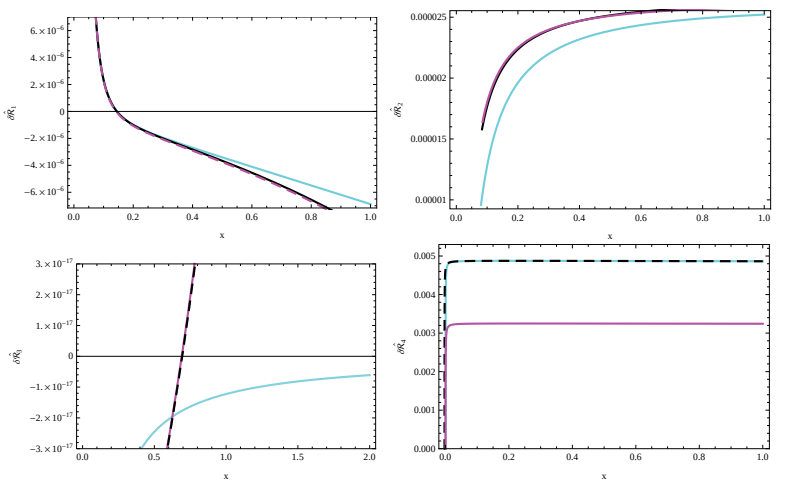

Fig. 1. Plots for force functions versus $x$ with $q=0.2M_0$ (cyan), $q=0.4M_0$ (black), $q=0.64M_0$ (magenta) and $n=1,\alpha=0.85,\beta=1.5,\Gamma=1.6$ for left plot (upper panel), $n=1.5,\alpha=0.90,\beta=0.5,\Gamma=1.4,q=0.2M_0$ for right plot (upper panel), $n=0.5,\alpha=0.98,\beta=1.5,\Gamma=0.6$ for left plot (lower panel) and $n=1.5,\alpha=0.7,\beta=1.5,\Gamma=-0.5$ for right plot (lower panel).

## 4. Concluding Remarks

This paper investigates the occurrence of cracking as well as overturning in charged anisotropic polytropic models. We have constructed the field equations for charged spherical anisotropic fluid obeying polytropic EoS. The TOV as well as mass equations in terms of dimensionless variables are formulated for two cases of polytropic EoS. We have perturbed energy density and pressure anisotropy of a system in two ways. Firstly, we have introduced perturbations through parameters $(k, \beta)$ and constructed the force distribution function $(\delta\hat{\mathcal{R}}_1)$ in terms of perturbed parameters describing total radial forces present in a system. The graphical analysis of $\delta\hat{\mathcal{R}}_1$ indicates the appearance of cracking for all choices of parameters thus leading to unstable configurations for this case. Secondly, we have used $(n, \beta)$ as perturbation parameters and constructed $\delta\hat{\mathcal{R}}_2$. It is found that the resulting models are stable towards perturbations. For case **2**, we have followed the similar procedure and constructed $\delta\hat{\mathcal{R}}_3$ as well as $\delta\hat{\mathcal{R}}_4$. It is found that polytropic models are unstable for perturbation in $(k, \beta)$, while the perturbation of $(n, \beta)$ leads to stable matter configuration representing relativistic polytrope. We have observed that charged matter distribution leads to stable configurations for $(n, \beta)$ perturbation while polytropic models remain unstable by perturbing $(k, \beta)$. The uncharged matter distribution exhibits cracking as well as overturning[4]. However, the inclusion of charge in anisotropic fluid distribution has a dominant effect on polytropes which leads to stable models.

We investigate the conformal invariant Lagrangian of the self-gravitating U(1) scalar-gauge field on the time-dependent Bondi-Marder axially symmetric spacetime. By considering the conformal symmetry as exact at the level of the Lagrangian and broken in the vacuum, a consistent model is found with an exact solution of the vacuum Bondi-Marder spacetime, written as $g_{\mu\nu} = \omega^2 \bar{g}_{\mu\nu}$, where $\omega$ is the conformal factor and $\bar{g}_{\mu\nu}$ the 'un-physical' spacetime. Curvature could then be generated from Ricci-flat $\bar{g}_{\mu\nu}$ by suitable dilaton fields and additional gauge freedom. If we try to match this vacuum solution onto the interior vortex solution of the coupled Einstein-scalar-gauge field, we need, besides the matching conditions, constraint equations in order to obtain a topological regular description of the small-scale behaviour of the model. Probably, one needs the five-dimensional warped counterpart model, where the warp factor determines the large-scale behavior of the model. This warp factor is determined by the Einstein field equations for the five-dimensional warped space, where only gravity can propagate into the bulk. The warped five-dimensional model can be reformulated by considering the warp factor as a dilaton field conformally coupled to gravity and embedded in a smooth $M_4 \otimes R$ manifold. It is conjectured that the four-dimensional conformal factor is related to the dilaton field of the five-dimensional counterpart model. The dilaton field (alias warp factor), has a dual meaning. At very early times, when $\omega \to 0$, it describes the small-distance limit, while at later times it is a warp (or scale) factor that determines the dynamical evolution of the universe. However, as expected, the conformal invariance is broken (trace-anomaly) by the appearance of a mass term and a quadratic term in the energy-momentum tensor of the scalar-gauge field, arising from the extrinsic curvature terms of the projected Einstein tensor. These terms can be interpreted as a constraint in order to maintain conformal invariance and the tracelessness of the energy-momentum tensor could then be maintained by a contribution from the bulk. By considering the dilaton field and Higgs field on equal footing on small scales, there will be no singular behavior, when $\omega \to 0$ and one can deduce constraints to maintain regularity of the action. We also present a numerical solution of the model and calculate the (time-dependent) trace-anomaly. The solution depends on the mass ratio of the scalar and gauge fields, the parameters of the model and the vortex charge $n$.

*Keywords*: Warped Spacetimes; Conformal Invariance; Gauged Scalar Field; Gravitational Waves; Axial Symmetry.

## 1. Introduction

There is a urgent necessity for a description of gravity on small scales. Modifications of standard general relativity (GR) seems to be necessary in order to overcome the serious problems which one encounters when one decreases the scale closer to the Planck scale, where quantum effects come into play. This quantum approach has not yet been reconciled with the curved spacetime of GR. An elegant way to modify GR was given by Randall and Sundrum (RS), i.e., the warped five-dimensional spacetime[1–3]. The model can be regarded as the low-energy limit of

general higher-dimensional theories which more fully address the particle interactions. Gravity can propagate freely into the 5D bulk, whereas the standard model fields are constrained to the 4D hypersurface. The hierarchy problem in these models would be solved and the cosmological constant and dark matter can be emergent[4,5]. The characteristic warp factor in the RS-model can also be considered as a dilaton field in conformal invariant (CI) models[6–8].

CI in GR can be a promising formalism for disclosing the small-distance structure of GR. It can be considered as an exact local CI, spontaneously broken as in the case of the BEH mechanism. It is a controversial alternative method to describe canonical quantum gravity, because one is saddled with serious anomalies[9–11]. The key problem is perhaps the handling of asymptotic flatness of isolated systems in GR, specially when they radiate and the generation of the metric $g_{\mu\nu}$ from at least Ricci-flat spacetimes. Close to the Planck scale one should like to have Minkowski spacetime and somehow curvature must emerge. Curved spacetime will inevitable enter the field equations on small scales. The first task is then to construct a Lagrangian, where spacetime and the fields defined on it, are topological regular. This can be done by considering the scale factor (or warp factor in higher-dimensional models) as a dilaton field besides the conformally coupled scalar field. The same procedure can be applied to the 4D spacetime and one can try to generate from (Ricci)-flat spacetimes physical acceptable spacetimes in the non-vacuum case. It is known since the 70s[12], that quantum field theory combined with Einstein's gravity runs into serious problems. The Einstein-Hilbert(EH) action is non-renormalizable and it gives rise to intractable divergences at loop levels. On very small scales, due to quantum corrections to GR, one must modify Einstein's gravity by adding higher order terms in the Lagrangian like $R^2, R_{\mu\nu}R^{\mu\nu}$ or $R_{\mu\nu\sigma\tau}R^{\mu\nu\sigma\tau}$ (or combinations of them). However, serious difficulties arise in these higher-derivative models, for example, the occurrence of massive ghosts which cause unitary problems. A next step is then to disentangle the functional integral over the dilaton field from the ones over the metric fields and matter fields. Moreover, it is desirable that all beta-functions of the matter lagrangian, in combination with the dilaton field, disappear in order to fix all the coupling constants of the model. Further, conformal invariance of the action with matter fields implies that the trace of the energy-momentum tensor is zero. A theory based on a classical "bare" action which is conformally invariant, will lose it in quantum theory as a result of renormalization and the energy-momentum tensor acquires a non-vanishing trace (trace anomaly). We consider here the breaking of conformal invariance in conventional Einstein theory and will not enter into details of these quantum-gravity problems. It is conjectures that conformal symmetry is exact at the level of the Lagrangian and only broken in the vacuum, just as the BEH mechanism in standard model of particle physics. This approach can even be an alternative to supersymmetry and the dark energy problem. Because our axially symmetric model can easily transformed to spherical symmetry, it is clear that our conformal invariant study of the self-gravitating coupled scalar-gauge field on an

axially symmetric spacetime make sense in studying the small scale properties. We describe here an example of CI on an axially symmetric Bondi-Marder spacetime with a U(1) gauged scalar field in the interior.

## 2. The field equations of the model

We consider here the time-dependent axially symmetric spacetime suitable for the description of matter-filled regions of space[13–17]

$$ds^2 = e^{-2\psi}\Big[e^{2\gamma}(d\rho^2 - dt^2) + \rho^2 d\varphi^2\Big] + e^{2\psi+2\mu}dz^2, \tag{1}$$

where $\psi, \gamma$ and $\mu$ are functions of $t$ and $\rho$. The spacetime Eq. (1) is not suitable, because we would have $T_{tt}+T_{\rho\rho}$=0. This is not the case for cosmic strings. Further, we don't make yet a gauge choice, such as the usual one $e^{\mu} = \rho$. For the matter distribution we choose the scalar-gauge field

$$\Phi = \eta X e^{in\varphi}, \qquad A_\mu = [0, 0, 0, \frac{P-n}{e}], \tag{2}$$

with potential $V = \frac{1}{8}\lambda(\Phi\Phi^* - \eta^2)^2$. X and P are functions of $t$ and $\rho$. The vacuum expectation value of the Higgs field is $\eta$, n is the winding number, $\lambda$ the Higgs coupling constant and e the electric charge of a Cooper pair. For a detailed treatment of this $\Phi^4$ gauge model, which is heuristically equivalent with the Ginsburg-Landau theory of superconductivity, we refer to the text book of Vilenkin et al.[18]. The starting point is the action

$$\mathcal{S} = \int d^4x\sqrt{-g}\Big[\frac{1}{2\kappa^2}\Big(R - 2\Lambda) - \frac{1}{2}D_\alpha\Phi(D^\alpha\Phi)^* - \frac{1}{4}F_{\alpha\beta}F^{\alpha\beta} - \frac{1}{8}\lambda(\Phi^2 - \eta^2)^2\Big], \tag{3}$$

with $F_{ab} = \partial_a A_b - \partial_b A_a$ the electro-magnetic field tensor. The gauge-covariant derivative is $D_a = \partial_a + ieA_a$. The field equations become (for the moment with $\Lambda = 0$)

$$G_{\mu\nu} = \kappa^2 T_{\mu\nu}, \tag{4}$$

$$D_\mu D^\mu\Phi - 2\frac{\partial V}{\partial\Phi^*} = 0, \tag{5}$$

and

$$\nabla^\nu F_{\mu\nu} - \frac{1}{2}ie\Big[\Phi(D_\mu\Phi)^* - \Phi^*(D_\mu\Phi)\Big] = 0, \tag{6}$$

with $T_{\mu\nu}$ the energy momentum tensor. Written out in components, the equations become

$$\partial_{tt}\psi = \partial_{\rho\rho}\psi + \frac{1}{\rho}\partial_\rho\psi + \partial_\rho\psi\partial_\rho\mu - \partial_t\psi\partial_t\mu - \frac{1}{\rho}\partial_\rho\mu + \kappa^2\Big[e^{2\psi}\frac{\partial_t P^2 - \partial_\rho P^2}{2\rho^2 e^2} - \frac{1}{8}\lambda\eta^4 e^{2\gamma-2\psi}(X^2-1)^2 - \eta^2 e^{2\gamma}\frac{X^2P^2}{\rho^2}\Big], \tag{7}$$

$$\partial_{tt}\mu = \partial_{\rho\rho}\mu + \frac{2}{\rho}\partial_\rho\mu + \partial_\rho\mu^2 - \partial_t\mu^2 + \kappa^2\Big[\frac{1}{4}\lambda\eta^4 e^{2\gamma-2\psi}(X^2-1)^2 + \eta^2 e^{2\gamma}\frac{X^2P^2}{\rho^2}\Big], \tag{8}$$

$$\begin{aligned}\partial_{tt}\gamma = {} & \partial_{\rho\rho}\gamma + \partial_\rho\psi^2 - \partial_t\psi^2 + 2(\partial_\rho\psi\partial_\rho\mu - \partial_t\psi\partial_t\mu) - \frac{2}{\rho}\partial_\rho\mu \\ & + \frac{\kappa^2}{2}\Big[e^{2\psi}\frac{\partial_t P^2 - \partial_\rho P^2}{2\rho^2 e^2} + \eta^2(\partial_\rho X^2 - \partial_t X^2) \\ & - \frac{1}{4}\lambda\eta^4 e^{2\gamma-2\psi}(X^2-1)^2 - 3\eta^2 e^{2\gamma}\frac{X^2P^2}{\rho^2}\Big],\end{aligned} \tag{9}$$

$$\partial_{tt}X = \partial_{\rho\rho}X + \frac{\partial_\rho X}{\rho} + \partial_\rho X\partial_\rho\mu - \partial_t X\partial_t\mu - \frac{e^{2\gamma}XP^2}{\rho^2} - \lambda\eta^2 e^{2\gamma-2\psi}X(X^2-1), \tag{10}$$

$$\partial_{tt}P = \partial_{\rho\rho}P - \frac{\partial_\rho P}{\rho} + \partial_\rho P(2\partial_\rho\psi + \partial_\rho\mu) - \partial_t P(2\partial_t\psi + \partial_t\mu) + e^2\eta^2 e^{2\gamma-2\psi}X^2P. \tag{11}$$

These equation can be solved numerically[6,7] and the well-know solutions of the scalar field and gauge field are expected[19]. There is still a constraint equation from the $(t,r)$-component. In order to match this solution with the exterior vacuum solution, we need the exact solution of the exterior. Marder[14] already pointed out, from a physical point of view, that the concept of a smooth pulse wave of finite duration (apart from a residual "tail") is more acceptable than a wave motion that has to take an infinite time to its present state.

### 2.1. *The exact vacuum solution*

In the vacuum situation one can solve the equations for the metric components. We find

$$\mu = \ln\Big[\frac{\beta_1\sinh(\sqrt{c_1}\rho) + \beta_2\cosh(\sqrt{c_1}\rho)}{\sqrt{c_1}\rho}\Big] + \ln\Big[\frac{\beta_3 e^{2\sqrt{c_1}t} + \beta_4}{2\sqrt{c_1}}\Big] - \sqrt{c_1}t, \tag{12}$$

$$\psi = \mathcal{G}_1(\rho - t) + e^{-\sqrt{c_1}t}\mathcal{G}_2(\rho + t) + \ln(\rho), \tag{13}$$

$$\begin{aligned}\gamma = {} & \mathcal{G}_3(\rho - t) + \mathcal{G}_4(\rho + t) + \ln(\rho) - \frac{1}{4}e^{-2\sqrt{c_1}t}\sin^2(\rho + t) \\ & + 2e^{-\sqrt{c_1}t}\Big[\sin(\rho + t) + \frac{1}{c_1 + 4}(\cos(2t) - \cos(2\rho) + \sqrt{c_1}\sin(2\rho))\Big],\end{aligned} \tag{14}$$

with $\mathcal{G}_i$ arbitrary functions in the arguments and $\beta_i, c_1$ some constants. We took, for the time being, $\beta_1 = \beta_2 = \beta_3 = 1, \beta_4 = 0$ and $\mathcal{G}_1 = \sin(\rho - t)$ and $\mathcal{G}_2 = \cos(\rho + t)$.

## 3. The conformal invariant model

Conformal invariance(CI) is an approved property in string theory by the AdS/CFT correspondence, where a conformal field theory sits on the boundary of the AdS. In CI GR with (quantum) matter fields, the dilaton field plays a fundamental role. In the low-energy limit the dilaton field can act as a dynamical warp factor in 5D

warped spacetimes, while in the small-distance limit the dilaton fields can be used to generate from (Ricci-) flat spacetimes non-flat spacetimes. The Einstein-Hilbert (EH) action can be reformulated by focusing on local conformal symmetry as an exact but spontaneously broken symmetry. Performing a conformal transformation on a spacetime manifold, means that we change our standard measuring rods and clocks. This change is not the same in different points in spacetime. In other words, we multiply the spacetime metric by a kind of scalar field (or dilaton field).

### 3.1. *The interior*

Let us rewrite the metric of Eq. (1) as

$$ds^2 = \omega^2\Big[-dt^2 + d\rho^2 + e^{2\tau}dz^2 + \rho^2 e^{-2\gamma}d\varphi^2\Big], \tag{15}$$

where we wrote $e^{4\psi+2\mu-2\gamma} \equiv e^{2\tau}$ and $\omega^2 \equiv e^{2\gamma-2\psi}$. So we define a metric $\bar{g}_{\mu\nu}$ by $g_{\mu\nu} = \omega^2\bar{g}_{\mu\nu}$. Further, we define $\Phi = \frac{1}{\omega}\bar{\Phi}$. The action

$$\mathcal{S} = \int d^4x\sqrt{-\bar{g}}\Big\{-\frac{1}{12}\Big(\bar{\Phi}\bar{\Phi}^* + \bar{\omega}^2\Big)\bar{R} - \frac{1}{4}F_{\alpha\beta}F^{\alpha\beta}$$
$$-\frac{1}{2}\Big(D_\alpha\bar{\Phi}(D^\alpha\Phi)^* + \partial_\alpha\bar{\omega}\partial^\alpha\bar{\omega}\Big) - V(\bar{\Phi},\bar{\omega}) - \frac{1}{36}\kappa^2\Lambda\bar{\omega}^4\Big\}, \tag{16}$$

is then local conformal invariant under the transformation $g_{\mu\nu} \to \Omega^2 g_{\mu\nu}, \Phi \to \frac{1}{\Omega}\Phi$ and $\omega \to \frac{1}{\Omega}\omega$. We redefined $\bar{\omega}^2 \equiv -\frac{6\omega^2}{\kappa^2}$. Varying the Lagrangian, we obtain the field equations for the metric components, the scalar field, the gauge field and the "dilaton" field[7,8].

$$\bar{G}_{\mu\nu} = \frac{1}{(\bar{\omega}^2 + \bar{\Phi}\bar{\Phi}^*)}\Big(T^{(\bar{\omega})}_{\mu\nu} + T^{(\bar{\Phi},c)}_{\mu\nu} + \bar{T}^{(A)}_{\mu\nu} + \frac{1}{6}\bar{g}_{\mu\nu}\Lambda_{eff}\kappa_4^2\bar{\omega}^4 + \bar{g}_{\mu\nu}V(\bar{\Phi},\bar{\omega})\Big), \tag{17}$$

$$\bar{\nabla}^\alpha\partial_\alpha\bar{\omega} - \frac{1}{6}\bar{R}\bar{\omega} - \frac{\partial V}{\partial\bar{\omega}} - \frac{1}{9}\Lambda\kappa^2\bar{\omega}^3 = 0, \tag{18}$$

$$D^\alpha D_\alpha\bar{\Phi} - \frac{1}{6}\bar{R}\bar{\Phi} - \frac{\partial V}{\partial\bar{\Phi}^*} = 0, \qquad \bar{\nabla}^\nu F_{\mu\nu} = \frac{i}{2}\epsilon\Big(\bar{\Phi}(D_\mu\bar{\Phi})^* - \bar{\Phi}^* D_\mu\bar{\Phi}\Big), \tag{19}$$

with

$$\bar{T}^{(A)}_{\mu\nu} = F_{\mu\alpha}F^\alpha_\nu - \frac{1}{4}\bar{g}_{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}, \tag{20}$$

$$\bar{T}^{(\bar{\Phi},c)}_{\mu\nu} = \Big(\bar{\nabla}_\mu\partial_\nu\bar{\Phi}\bar{\Phi}^* - \bar{g}_{\mu\nu}\bar{\nabla}_\alpha\partial^\alpha\bar{\Phi}\bar{\Phi}^*\Big)$$
$$-3\Big[D_\mu\bar{\Phi}(D_\nu\bar{\Phi})^* + (D_\mu\bar{\Phi})^* D_\nu\bar{\Phi} - \bar{g}_{\mu\nu}D_\alpha\bar{\Phi}(D^\alpha\bar{\Phi})^*\Big] \tag{21}$$

and

$$T^{(\bar{\omega})}_{\mu\nu} = \Big(\bar{\nabla}_\mu\partial_\nu\bar{\omega}^2 - \bar{g}_{\mu\nu}\bar{\nabla}_\alpha\partial^\alpha\bar{\omega}^2\Big) - 6\Big(\partial_\mu\bar{\omega}\partial_\nu\bar{\omega} - \frac{1}{2}\bar{g}_{\mu\nu}\partial_\alpha\bar{\omega}\partial^\alpha\bar{\omega})\Big). \tag{22}$$

Newton's constant reappears in the quadratic interaction term for the scalar field. The trace of Eq. (17) is$\sim \kappa^2\eta^2\lambda\bar{\omega}^2X^2$. It is not possible to isolate the equation for $\bar{\omega}$, as expected.

### 3.2. *The vacuum exterior*

Without matter fields one can solve the field equations exact. Varying the Einstein-Hilbert action

$$\mathcal{L}^{EH\omega} = \frac{\sqrt{-\bar{g}}}{2\kappa^2}\Big(\omega^2\bar{R} + 6\bar{g}^{\mu\nu}\partial_\mu\omega\partial_\nu\omega\Big), \tag{23}$$

with respect to $\bar{g}_{\mu\nu}$ and $\omega$, one obtains

$$\omega^2\bar{G}_{\mu\nu} = \bar{\nabla}_\mu\bar{\nabla}_\nu\omega^2 - \bar{g}_{\mu\nu}\bar{\nabla}_\alpha\bar{\nabla}^\alpha\omega^2 - 6\partial_\mu\omega\partial_\nu\omega + 3\bar{g}_{\mu\nu}\partial_\alpha\omega\partial^\alpha\omega \equiv T^{(\omega)}_{\mu\nu}, \tag{24}$$

$$\bar{\nabla}^\mu\partial_\mu\omega - \frac{1}{6}\omega\bar{R} = 0. \tag{25}$$

One can easily verify that $\mathbf{TR}[\bar{G}_{\mu\nu} - \frac{1}{\omega^2}T^{(\omega)}_{\mu\nu}] = 0$. So the trace of any matter field contribution must be zero. From the Einstein equations, Eq. (24) and the $\omega$ equation, Eq. (25), we can separate the equation for $\omega$

$$\partial_{tt}\omega = \partial_{\rho\rho}\omega + \frac{1}{\omega}(\partial_t\omega^2 - \partial_r\omega^2) + \upsilon\omega. \tag{26}$$

The solution is (we use the subscript E for exterior)

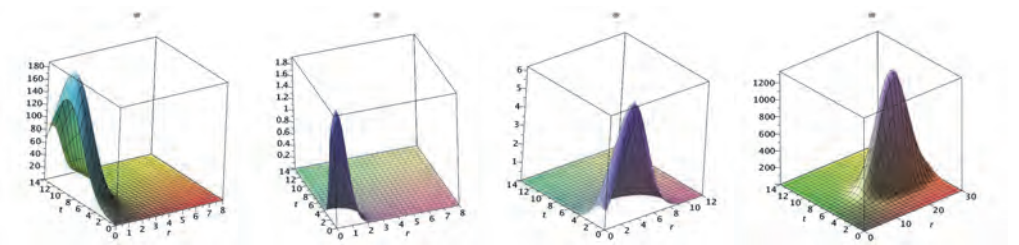

Fig. 1. Some example plots of $\omega_E$ of Eq. (27) for different values of the constants $c_i$ and $\upsilon$.

$$\omega_E = \mathcal{A}e^{\frac{1}{2}\zeta_1(\rho^2+t^2)-\frac{1}{2}\upsilon\rho^2+\zeta_2 t+r}, \tag{27}$$

with $\zeta_i$ and $\mathcal{A}$ integration constants. The constant $\upsilon$ enters the equation by the separation of variables in the Einstein equations. In Fig. 1 we plotted some typical solutions. Finally one finds the exterior metric

$$\begin{aligned} ds^2 = \mathcal{A}^2\Big\{ & e^{\zeta_1(\rho^2+t^2)-\upsilon\rho^2+2\zeta_2 t+2\rho}(-dt^2+d\rho^2) \\ & + \Big[\frac{(e^{\sqrt{\vartheta_1}t}+\delta_1 e^{-\sqrt{\vartheta_1}t})^2(e^{\sqrt{\vartheta_2}\rho}+\delta_2 e^{-\sqrt{\vartheta_2}\rho})^2}{\vartheta_1\vartheta_2}\Big]dz^2 \\ & + \Big[\frac{(e^{\sqrt{\vartheta_1^*}t}+\delta_3 e^{-\sqrt{\vartheta_1^*}t})^2(e^{\sqrt{\vartheta_2^*}\rho}+\delta_4 e^{-\sqrt{\vartheta_2^*}\rho})^2}{\vartheta_1^*\vartheta_2^*}\Big]d\varphi^2\Big\}, \end{aligned} \tag{28}$$

where $\vartheta_1 \equiv (\zeta_2^2 + c_1 + \zeta_1), \vartheta_2 \equiv (\zeta_2^2 + \upsilon + c_1 + \zeta_1), \vartheta_1^* \equiv (\zeta_2^2 - c_2 + \zeta_1), \vartheta_2^* \equiv (\zeta_2^2 + \upsilon - c_2 + \zeta_2)$. $c_i$ are integration constants. One can generate exact ($\Omega$-)conformal

equivalent spacetimes from $\bar{g}_{\mu\nu}$. One can easily verify that the Bianchi identities are fulfilled. Constraint equations can found for $\partial_t\omega$. Ricci-flat solutions will restrict the values for the several parameters. At the boundary, we have now exact values of the metric components, which can be used for the interior solution. The two line elements will be isometric at the boundary surface for the well-known junction conditions[20].

## 4. Connection with the 5D warped spacetime

In the 5D warped counterpart model[6] on the spacetime

$$ds^2 = \mathcal{W}(t,r,y)^2\Big[e^{2\gamma(t,r)-2\psi(t,r)}(-dt^2+dr^2)+e^{2\psi(t,r)}dz^2+\frac{r^2}{e^{2\psi(t,r)}}d\varphi^2\Big]+dy^2, \tag{29}$$

we found a typical solution for the warp factor

$$\mathcal{W}^2 = \frac{e^{-\frac{1}{6}\Lambda_5(y-y_0)^2}}{\tau r}\Big(d_1e^{(\sqrt{2\tau})t}-d_2e^{-(\sqrt{2\tau})t}\Big)\Big(d_3e^{(\sqrt{2\tau})r}-d_4e^{-(\sqrt{2\tau})r}\Big). \tag{30}$$

If we define

$${}^{(5)}g_{\mu\nu} = W_1(t,r)^2W_2(y)^2\tilde{g}_{\mu\nu}+n_\mu n_\nu\Gamma(y)^2, \tag{31}$$

then $W_1$ could be identified as dilaton field or "warp factor" coming from the bulk, while $W_2$ is equals the well-know warp factor in the RS brane world model[1,2]. The metric $\tilde{g}_{\mu\nu}$ is equals our $\tilde{g}_{\mu\nu}=\omega^2\bar{g}_{\mu\nu}$ of Eq. (15). In the former study[7], a numerical solution was found in the coupled Einstein-scalar-gauge field model, and the trace anomaly could possibly be solve due to contributions from the bulk. The solution for $W_1$ follows solely from the 5D Einstein equations with empty bulk (eventually with a cosmological constant $\Lambda_5$). The question is, can we in some way relate $W_1$ to the dilaton field $\bar{\omega}$ of section 3-1? After all, information about an extra dimension is visible as a curvature in a spacetime with one fewer dimension. The $W_1$-field need to be shifted to a complex contour to ensure that $W_1$ has the same unitary and positivity properties as the scalar field. One can easily check that $W_1$ has complex solutions. Further, the effective 4D Einstein equations of the warped model contain extra terms arising from the extrinsic curvature terms in the the projected Einstein tensor and the projected Weyl tensor[3]. When approaching smaller scales in the model and $W_1\to 0$, no singular behavior occurs due to the fact that the scalar field is present in the Lagrangian, which could be handled on the same footing as the dilaton field. For later times, on cosmological scale, $W_1$ behaves as a "standard" warp factor. The $\Omega$ transformation is necessary as a conformal "gauge" in order to make a renormalizable model. As 't Hooft stated[9], "We get a renormalizable gauge if we decide to choose our conformal factor $\Omega$ in such a way that the amount of activity in a given spacetime volume is fixed or at least bounded". It is then conjectured[9] that close to the Planck scale the conformal invariance is spontaneously broken due to the contributions of additional terms like $(R_{\mu\nu}R^{\mu\nu}-\frac{1}{3}R^2)$ and $\kappa^2\eta^2\lambda\bar{\omega}^2X^2$ in the action.

## 5. Conclusions

We investigated the coupled Einstein-scalar-gauge fields using a conformally invariant Lagrangian. We compare the exterior exact vacuum solution with the spacetime of an infinite line-mass and semi-infinite line-mass. We find a simple example of conformally equivalent (Ricci-) flat spacetimes $\omega^2 \bar{g}_{\mu\nu}$. This solution must then be matched on the non-vacuum solution of the cosmic string at the core. In order to obtain tracelessness of the energy momentum tensor, additional constraints are necessary. It is conjectured that a contribution from the bulk in the 5D counterpart model is needed to make the energy momentum tensor traceless. The conformal symmetry, if exact, can be broken spontaneously. This means that we need additional field transformations on the vacuum spacetime.

We present a static axisymmetric solution of Einstein's field equations. Assuming that the deviation from spherically symmetry is small, we linearize the corresponding field equations with the perfect fluid source and up to the first order in quadrupole.

*Keywords*: Quadrupole moment; linearized field equations; q-metric; perfect fluid.

## 1. Introduction

Einstein's theory of General relativity (GR) is one of the best candidate to describe the gravitational field of astrophysical compact objects. According to the GR all the information about the gravitational field should be contained in the metric tensor which must be a solution of Einstein's equations. It is well known that the exterior field of an arbitrarily rotating mass can be described by the Kerr spacetime[1]. The kerr solution has not an internal counterpart, this is a major problem in classical general relativity[2]. In view of this situation, We consider alternative approaches that contains the quadrupole moment. The quadrupole moment is responsible for the deformation of any realistic mass distribution.

In a recent work[3], it was proposed to use the Zipoy-Voorhees transformation[4,5] to generate the quadrupolar metric ($q$-metric), which can be interpreted as the simplest generalization of the Schwarzschild metric. Consequently, this metric can be used to describe the exterior gravitational field of deformed distributions of mass. The question arises whether it is possible to find an interior metric that can be matched to the exterior one in such a way that the entire spacetime is described as a whole. One usually assumes that the matter inside the object can be described by a perfect fluid with two physical parameters, namely, energy density and pressure. In this work, we will concentrate on the problem of perfect-fluid solutions, without considering the rotation parameter.

This work is organized as follows. In Sec. 2, we consider the $q$-metric as describing the exterior gravitational field of a deformed source with mass and quadrupole moment. In Sec. 3, we present the exact equations for a perfect fluid source. In Sec. 4, we construct the approximate line element with a quadrupole moment and we present some particular vacuum solutions. Finally, Sec. 5 contains discussions of our results.

## 2. Exterior $q$-metric

If we start from the Schwarzschild solution and apply a Zipoy-Voorhees transformation[4 5] the new line element can be written as

$$ds^2 = h^{1+q}dt^2 - h^{-q}\left[\left(1+\frac{m^2\sin^2\theta}{r^2 h}\right)^{-q(2+q)}\left(\frac{dr^2}{h}+r^2 d\theta^2\right)+r^2\sin^2\theta d\varphi^2\right]. \tag{1}$$

where $h = 1 - 2m/r$.

In[3] it was shown that this is the simplest generalization of the Schwarzschild solution that contains the additional parameter $q$, which describes the deformation of the mass distribution. In the literature, this metric is known as the Zipoy-Voorhees metric, delta-metric, gamma-metric and $q$-metric[7]. A stationary generalization of the $q$-metric has been obtained in[8]. The physical interpretation of the parameters $m$ and $q$ can be clarified by calculating the invariant Geroch multipoles[9].

A study of the curvature of the $q$-metric shows that the outermost singularity is located at $r = 2m$, a hypersurface which in all known compact objects is situated inside the surface of the body. This implies that in order to describe the entire gravitational field, it is necessary to cover this type of singularity with an interior solution.

## 3. Interior metric

In this work, we will concentrate on the case of static perfect fluid spacetimes. Our experience with numerical perfect fluid solutions[11] indicates that for the case under consideration the line element

$$ds^2 = f dt^2 - \frac{e^{2\gamma}}{f}\left(\frac{dr^2}{h}+d\theta^2\right) - \frac{\mu^2}{f}d\varphi^2 \ , \tag{2}$$

is particularly convenient. Here $f = f(r,\theta)$, $\gamma = \gamma(r,\theta)$, $\mu = \mu(r,\theta)$, and $h = h(r)$. A redefinition of the coordinate $r$ leads to an equivalent line element which has been used to investigate anisotropic static fluids[12].

The Einstein equations for a perfect fluid with 4-velocity $U_\alpha$, density $\rho$, and pressure $p$ (we use geometric units with $G = c = 1$)

$$R_{\alpha\beta} - \frac{1}{2}R g_{\alpha\beta} = 8\pi\left[(\rho+p)U_\alpha U_\beta - p g_{\alpha\beta}\right]. \tag{3}$$

The field equations can be represented as two second-order differential equations for $\mu$ and $f$. Moreover, the function $\gamma$ is determined by a set of two partial differential equations which can be integrated by quadratures once $f$, $\mu$, $p$, and $h$ are known.

In[13] we discussed properties of the field equations and presented a new method for generating perfect fluid solutions of the Einstein equations, starting from a given seed solution.

## 4. Approximate metric with quadrupole

For understanding influences of quadrupole moment to the structure of spacetimes we consider the case of a slightly deformed mass. Our approach consists in postulating the interior line element and evaluating the energy-momentum tensor from the Einstein equations, a method which was first proposed by Synge and has been applied to find several approximate interior solutions [14,15].

To find the corresponding interior line element, we proceed as follows. Consider the case of a slightly deformed mass. This means that the parameter $q$ for the exterior $q$-metric can be considered as small and we can linearize the line element as

$$ds^2 = h\,(1+q\ln h)\,dt^2 - r^2\,(1-q\ln h)\sin^2\theta d\varphi^2 - \left[1+q\ln h - 2q\ln\left(h+\frac{m^2}{r^2}\sin^2\theta\right)\right]\left(\frac{dr^2}{h}+r^2d\theta^2\right)\ . \tag{4}$$

We will assume that the exterior gravitational field of the compact object is described to the first order in $q$ by the line element (4), which represents a particular approximate solution to Einstein's equations in vacuum.

To construct the approximate interior line element, we start from the exact line element (2) and use the approximate solution (4) as a guide. Following this procedure, an appropriate interior line element can be expressed as

$$ds^2 = e^{2\nu}(1+qa)dt^2 - \big[1+q(c+b)\big]\frac{dr^2}{1-\frac{2\tilde{m}}{r}} - \big[1+q(a+b)\big]r^2d\theta^2 - (1-qa)r^2\sin^2\theta d\varphi^2\ , \tag{5}$$

where the functions $\nu=\nu(r)$, $a=a(r)$, $c=c(r)$, $\tilde{m}=\tilde{m}(r)$, and $b=b(r,\theta)$. Although there exists quite a large number of approximate solutions such as [16 17 18] and in [14 19] it was shown that the different approaches under diverse circumstances turn out to be equivalent from a mathematical point of view.

### 4.1. *Vacuum solution*

To test the consistency of the linearized approach, we will derive explicitly the approximate vacuum $q$-metric (4). The details of this derivation will be presented elsewhere. The final expression for the metric fucntions

$$\nu = \frac{1}{2}\ln\left(1-\frac{2m}{r}\right)+\alpha_1\ , \quad a-c=\frac{\alpha_2 m^2}{(r-m)^2}\ , \tag{6}$$

where $\alpha_1$ and $\alpha_2$ are dimensionless integration constants. The remaining system of partial differential equations can be integrated in general and yields

$$a = -\frac{\alpha_2 m}{r-m}+\frac{1}{2}\,(\alpha_3-\alpha_2)\ln\left(1-\frac{2m}{r}\right)+\alpha_4\ , \tag{7}$$

$$c = -\frac{\alpha_2 mr}{(r-m)^2}+\frac{1}{2}\,(\alpha_3-\alpha_2)\ln\left(1-\frac{2m}{r}\right)+\alpha_4\ , \tag{8}$$

$$b = \frac{2\alpha_2 m}{r-m} - (\alpha_3 - \alpha_2)\left[\ln 2 + \ln\left(1 - \frac{2m}{r} + \frac{m^2 \sin^2\theta}{r^2}\right)\right] + \alpha_5 \ , \tag{9}$$

where we have replaced $\tilde{m} = m = const.$ in the remaining equations. $\alpha_3$, $\alpha_4$ and $\alpha_5$ are dimensionless integration constants.

Thus, we see that the general approximate exterior solution with quadrupole moment is represented by a 5-parameter family of solutions. The particular case

$$\alpha_1 = 0 \ , \quad \alpha_2 = 0 \ , \quad \alpha_3 = 2 \ , \quad \alpha_4 = 0 \ , \quad \alpha_5 = 2\ln 2 \ , \tag{10}$$

corresponds to the linearized $q$-metric as represented in Eq. (4). Another interesting particular case corresponds to the choice

$$\alpha_1 = 0 \ , \quad \alpha_3 = \alpha_2 \ , \quad \alpha_4 = 0 \ , \quad \alpha_5 = 0 \ , \tag{11}$$

which leads to the following line element

$$\begin{aligned} ds^2 = &\left(1 - \frac{2m}{r}\right)\left(1 - \frac{q\alpha_2 m}{r-m}\right) dt^2 - \left(1 + \frac{q\alpha_2 m}{r-m}\right) r^2 \sin^2\theta d\varphi^2 \\ &- \left[1 + \frac{q\alpha_2 m(r-2m)}{(r-m)^2}\right] \frac{dr^2}{1 - \frac{2m}{r}} - \left(1 + \frac{q\alpha_2 m}{r-m}\right) r^2 d\theta^2 \ . \end{aligned} \tag{12}$$

This is an asymptotically flat approximate solution with parameters $m$, $q$ and $\alpha_2$. The singularity structure can be found by analyzing the Kretschmann invariant $K = R_{\alpha\beta\gamma\delta}R^{\alpha\beta\gamma\delta}$ which in this case reduces to

$$K = \frac{48m^2}{r^6}\left(1 + q\alpha_2 \frac{r-4m}{r-m} + \mathcal{O}(q^2)\right) \ , \tag{13}$$

where the term proportional to $q^2$ has been neglected due to the approximate character of the solution. We see that there is a central singularity at $r = 0$ and a second one at $r = m$. We conclude that the solution (12) describes the exterior field of two naked singularities of mass $m$ and quadrupole $q$. The parameter $\alpha_2$ can be absorbed by redefining the constant $q$ and so it has no special physical meaning. In the general solution (7)–(9), the additive constants $\alpha_4$ and $\alpha_5$ can be chosen such that at infinity the solution describes the Minkowski spacetime in spherical coordinates. This means that non asymptotically flat solutions are also contained in the 5-parameter family (7)–(9). This is the most general vacuum solution which is linear in the quadrupole moment. To our knowledge, this general solution is new.

### 4.2. *Perfect fluid case*

We now apply the approximate line element (5) to the study of perfect fluid solutions. First, we note that in this case the conservation law reduces to

$$p_{,r} = -(\rho + p)\nu_{,r} \ , \qquad p_{,\theta} = 0 \ . \tag{14}$$

Calculating the second derivative $p_{,r\theta} = 0$, the above conservation laws lead to

$$\rho_{,\theta} = 0 \ , \tag{15}$$

implying that the perfect fluid variables can depend on the coordinate $r$ only. Notice that this does not imply that the source is spherically symmetric. In fact, due to the presence of the quadrupole parameter $q$ in the line element (5), the coordinate $r$ is no longer a radial coordinate and the equation $r =$constant represents, in general, a non-spherically symmetric deformed surface[20].

The corresponding linearized Einstein equations can be represented as

$$\overset{(0)}{G}{}^{\nu}_{\mu} + q\overset{(q)}{G}{}^{\nu}_{\mu} = 8\pi \left( \overset{(0)}{T}{}^{\nu}_{\mu} + q\overset{(q)}{T}{}^{\nu}_{\mu} \right), \tag{16}$$

where the (0)-terms correspond to the limiting case of spherical symmetry. As for the energy-momentum tensor, we assume that density and pressure can also be linearized as

$$p(r) = p_0(r) + q\ p_1(r), \quad \rho(r) = \rho_0(r) + q\rho_1(r), \tag{17}$$

in accordance with the conservation law conditions (14) and (15). Here, $p_0(r)$ and $\rho_0(r)$ are the pressure and density of the background spherically symmetric solution. If we now compute the linearized field equations (16) for the line element (5), we arrive at a set of nine differential equations for the functions $\nu,\ \tilde{m},\ a,\ b,\ c$, and $p_1$. After lengthy computations, it is then possible to isolate an equation that relates $p_1(r)$ and $b(r,\theta)$ from which it follows that

$$b_{,\theta} = 0\ . \tag{18}$$

This means that for the particular approximate line element (5), the field equations for a perfect fluid do not allow the metric functions to explicitly depend on the angular coordinate $\theta$. To search for concrete solutions which can be matched with an exterior metric with quadrupole, it is necessary to modify the exterior metric accordingly. We will see that this approximate exterior solution can be used together with the interior line element (5) to search for approximate solutions with a perfect fluid source. Taking into account that the conservation laws and the approximate field equations for a perfect fluid imply that the physical quantities $p$ and $\rho$ and the metric function $b$ depend only on the spatial coordinate $r$.

## 5. Conclusions

In this work, we have investigated approximate interior and exterior solutions of Einstein's equations in the case of static and axially symmetric perfect fluid spacetimes, which characterized by an arbitrary mass and a small quadrupole moment.

We analyze the corresponding linearized field equations and derive several classes of new vacuum and perfect fluid solutions.

We limit ourselves to the study of interior solutions that can be matched with the exterior $q$-metric. We only considered the simple and idealized case of a static mass distribution with a small quadrupole.

The resulting system of differential equations for the functions of the interior metric indicates that one can try to find analytical solutions, at least in the case of a slightly deformed mass distribution. To study more realistic configurations, it is necessary to take into account the rotation the exact quadrupole of the mass. We expect to investigate these problems in future works.

## FREEDOM OF MOVEMENT FOR SCIENTISTS

The Marcel Grossman Meetings were founded with the premise that scientists of all nations have a right to meet to exchange knowledge independent of national borders. As such we affirm the IUPAP declaration: "To secure IUPAP sponsorship, the organisers have provided assurance that MG15 will be conducted in accordance with IUPAP principles as stated in the IUPAP resolution passed by the General Assembly in 2008. In particular, no bona fide scientist will be excluded from participation on the grounds of national origin, nationality, or political considerations unrelated to science."

## ACKNOWLEDGEMENTS

We acknowledge the outstanding job done before, during and after the meeting by the ICRANet/ICRA administrative and secretarial staff: Cristina Adamo, Silvia Latorre, Elisabetta Natale, and Cinzia di Niccolo and the conference agency support of Sistema Congressi (Marisa Santori, Ilaria Coccato, Lorena Moretti). Finally this meeting and its proceedings could not have functioned without the dedicated IT support of the ICRA system manager Vittorio Vannini for every MG meeting this century and the ICRANet system manager Gabriele Brandolini, with some temporary assistance from Valerio Antonucci and Damiano Verzulli.

## ORGANIZING BODIES OF THE FIFTEENTH MARCEL GROSSMANN MEETING:

### INTERNATIONAL ORGANIZING COMMITTEE

David Blair, Yvonne Choquet-Bruhat, Thibault Damour, Paolo De Bernardis, Francis Everitt, Riccardo Giacconi, Theodor Haensch, Stephen Hawking, Marc Henneaux, Christine Jones Forman, Roy Kerr, Hagen Kleinert, Jutta Kunz, Claus Laemmerzahl, Malcolm Longair, Tsvi Piran, Jorge Rueda, Remo Ruffini (Chair), Misao Sasaki, Humitaka Sato, Rashid Sunayev, Gerard 't Hooft, Steven Weinberg, Shing-Tung Yau

### LOCAL ORGANIZING COMMITTEE

Amati, L., Angelantonj, C., Barbiellini, G., Bassan, M., Battistelli, E. S. (chair), Belinski, V.A., Belli, L., Benedetti, R., Bernabei, R., Bianchi, M., Bianco, C.L. ## MARCEL GROSSMANN AWARDS

## FIFTEENTH MARCEL GROSSMANN MEETING

### Institutional Award

Planck Scientific Collaboration (ESA) (ESA)

*"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding Bpolarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy."*
— presented to its Director General Johann-Dietrich Woerner

### Institutional Award

Hansen Experimental Physics Laboratory (HEPL) at Stanford University

*"for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology."*

### Individual Awards

Lyman Page
*"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and who now leads the Atacama Cosmology Telescope as its project scientist."*

Rashid Alievich Sunyaev
*"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe."*

Shing-Tung Yau
*"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics ."*

Each recipient is presented with a silver casting of the TEST sculpture by the artist A. Pierelli. The original casting was presented to His Holiness Pope John Paul II on the first occasion of the Marcel Grossmann Awards.

**FOURTEENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

European Space Agency (ESA)

**Individual Awards**

Frank Chen Ny Yang, Tsung Dao Lee, Ken'ichi Nomoto, Martin Rees, Yakov G. Sinai, Sachiko Tsuruta

**THIRTEENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

ALBANOVA UNIVERSITY CENTER, STOCKHOLM

**Individual Awards**

David Arnett, Vladimir Belinski and Isaak M. Khalatnikov, Filippo Frontera

**TWELFTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Institut des Hautes Études Scientifique (IHES)

**Individual Awards**

Jaan Einasto, Christine Jones, Michael Kramer

**ELEVENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Freie Universität Berlin

**Individual Awards**

Roy Kerr, George Coyne, Joachim Trümper

**TENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

CBPF (Brazilian Center for Research in Physics)

**Individual Awards**

Yvonne Choquet-Bruhat, James W. York, Jr., Yval Ne'eman

**NINTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Solvay Institutes

**Individual Awards**

Riccardo Giacconi, Roger Penrose, Cecile and Bryce DeWitt

**EIGHTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Hebrew University of Jerusalem

**Individual Awards**

Tullio Regge, Francis Everitt

**SEVENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Hubble Space Telescope Institute

**Individual Awards**

SUBRAHMANYAN CHANDRASEKHAR, JIM WILSON

**SIXTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Research Institute for Theoretical Physics (Hiroshima)

**Individual Awards**

Minora Oda, Stephen Hawking

**FIFTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The University of Western Australia

**Individual Awards**

Satio Hayakawa, John Archibald Wheeler

**FOURTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Vatican Observatory

**Individual Awards**

William Fairbank, Abdus Salam

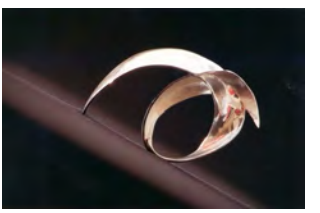

Fig. 1. TEST: sculpture by Attilio Pierelli

**PLANCK SCIENTIFIC COLLABORATION (ESA)**
presented to **Jean-Loup Puget**, the Principal Investigator of the High Frequency Instrument (HFI).

*"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding B-polarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy"*

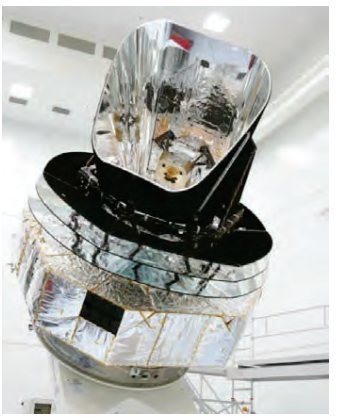

*Photo of the Planck satellite (Courtesy of ESA).*

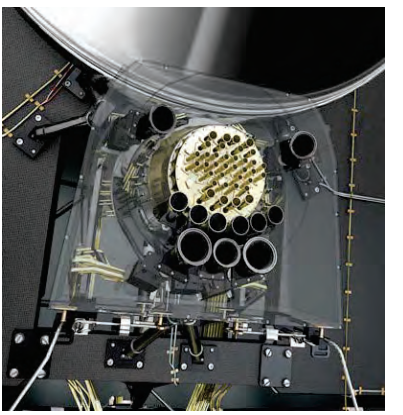


*Planck focal plane (Courtesy of ESA)*

Planck ESA's mission, was designed to image the temperature and polarization anisotropies of the CMB over the whole sky, with unrivalled angular resolution and sensitivity, pushing the technology to unprecedent limits. In the framework of the highly precision experimental cosmology the legacy Planck results on testing theories of the early universe and the origin of cosmic structure, has provided a major source of information crucial to many cosmological and astrophysical issues. Planck carried out two instruments:

- the High Frequency Instrument (HFI), Principal Investigator: Jean Loup Puget;
- the Low Frequency Instrument (LFI), Principal Investigator: Nazzareno Mandolesi.

The instruments were complementary and using different technology to cross check independently final results and systematic errors. They worked together to produce the overall mission results. The Planck space mission (ESA) has been a wonderful example of Team effort in a large international collaboration, involving scientific, technical and managerial aspects. The unprecedented accuracy of the Planck measurements have established new standards in the determination of fundamental cosmological parameters, as well as new insight in Galactic and extragalactic astrophysics. The Planck full-sky maps in temperature and polarization will remain a lasting legacy for at least dozen years to come. More than 100 papers signed by Planck collaboration have already 30 000 citations in scientific literature. The success of Planck HFI and LFI would not have been possible without the contribution of a large number of talented and dedicated scientists and engineers from many countries of Europe, USA and Canada. HFI was designed to produce high-sensitivity, multi-frequency measurements of the diffuse radiation permeating the sky in all directions in the frequency range of 84 GHz to 1 THz cooled at 100 mK. The instrument consisted of an array of 52 bolometric detectors placed in the focal plane of the telescope. LFI, a microwave instrument, was designed to produce high-sensitivity, multi-frequency measurements of the microwave sky in the frequency range of 27 to 77 GHz. The instrument consisted of an array of 22 tuned radio receivers located in the focal plane of the telescope, cooled at 20 K.

*Jean Loup Puget - PI of the HFI.*

*Nazzareno Mandolesi - PI of the LFI.*

## HANSEN EXPERIMENTAL PHYSICS LABORATORY AT STANFORD UNIVERSITY

presented to **Leo Hollberg**, HEPL Assistant Director

*"to HEPL for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology"*

### Brief History of Stanford's HEPL and Ginzton Laboratories

1947: WW Hansen (right) and team with the Mark I linear accelerator

In 1947, working in the Stanford Physics Department's Microwave Lab, Physics Professor, William W. Hansen and his research team, along with Assistant Professor of Physics and microwave expert, Edward L. Ginzton, completed development on the world's first traveling wave electron linear accelerator. Dubbed the Mark I (see photo) it generated a 1.5 million electron volt (MeV) beam. Hansen's entire report to the U.S. Office of Naval Research (ONR) that funded the project was just one sentence: "We have accelerated electrons."

This successful first step in linear electron acceleration spawned the birth of Stanford's High Energy Physics Lab (HEPL) and Ginzton labs. In 1990, HEPL was renamed the WW Hansen Experimental Physics Lab (also HEPL). HEPL and Ginzton were setup as Stanford's first independent labs. They were organized to facilitate cross-disciplinary research, enabling scientists, engineers, staff and students to work towards common research goals using cutting edge lab equipment and technologies on medium-scale projects. For the past 70 years, the HEPL and Ginzton Labs have spearheaded Stanford's leadership in cross-disciplinary physics and become nurturing homes to a variety of physics-based, research projects: including the following examples:

### Robert Hofstadter's Nobel Prize & Later Work

In 1961, Stanford Professor Robert Hofstadter was awarded the Nobel Prize for his HEPL Mark III Linear Accelerator work on nuclear form factors (nucleons). In the 1980s, Hofstadter became interested in astrophysics and helped design the EGRET telescope in the NASA Compton Gamma Ray Observatory (CGRO).

### Gravity Probe B (GP-B)

2003: Francis Everitt (left) and Brad Parkinson holding a GP-B gyro

In 1959, Physics Department Chair, Leonard Schiff, became interested in using gyroscopes in a satellite to measure the Earth's geodetic effect and the miniscule frame-dragging effect predicted by Albert Einstein's general theory of relativity. Schiff discussed this project with Stanford cryogenic physicist, William Fairbank, and gyroscope expert, Robert Cannon (Aero-Astro department).

In 1962, Fairbank invited post-doc, Francis Everitt, to join the research effort. The team sent a proposal to NASA's Office of Space Sciences requesting funding to develop gyroscopes and a satellite to carry out this unprecedented test. It took 40 years of R&D at Stanford and other places to create and ready the cryogenic satellite and all of its cutting-edge technologies for launch. In 1975, Leonard Schiff moved the GP-B program to HEPL, breathing new life into the lab. In 1981, Francis Everitt became Principal Investigator, a position he still holds. In 1984, Brad Parkinson became Project Manager and a Co-PI, along with Co-PI's John Turneaure and Daniel DeBra.

On 20 April 2004, GP-B launched from Vandenberg AFB into a polar orbit. Data collection began on 28 August 2004 and lasted 50 weeks. Data analysis took five years in order to remove confounding factors in the data. The final results, published in PRL on 31 May 2011, yielded highly accurate geodetic and frame dragging measurements, with 0.28% and 19% margins of error, respectively.

### GPS Spinoffs from GP-B

In the 1990s, Brad Parkinson's research on GPS solutions for positioning the GP-B satellite led to two revolutionary spin-off projects: 1) Wide Area Augmentation System (WAAS) provides highly precise positioning accuracy and itegrity for navigation and the automatic landing of airplanes and 2) Precision Farming adding GPS technology to tractors has enabled the automation of many aspects of farming and has spawned a $1 billion/year industry.

### Fermi Gamma Ray Space Telescope (GLAST)

Peter Michelson, Fermi LAT Principal Investigator

Stanford Physics Professor, Peter Michelson, is a former HEPL Director and the Principal Investigator for the Large Area Telescope (LAT) on board NASA's Fermi Gamma Ray Space Telescope, the successor to CGRO/EGRET. Launched on 11 June 2008, Fermi has been highly successful mapping the gamma-ray sky. Under Michelson's guidance, HEPL's collaborations with Italy are noteworthy. The development of cryogenic bar detectors of gravitational waves, in collaboration with Edoardo Amaldi and his colleagues, established new stringent upper limits to the gravitational waves incident on the Earth. Likewise, the Fermi LAT was developed by a collaboration between Italian INFN and ASI, NASA, and international partners in France, Japan, and Sweden, and used tracking detectors developed, integrated, tested, and qualified for the mission by Italy. GP-B provided the first evidence of frame-dragging on a spinning, superconducting gyroscope. The Fermi detector offers the potential of seeing, through the GeV emission in the Binary Driven Hypernova subclass of long GRBs, the emission from a newly born Black Hole, originating in the induced gravitational collapse of a supernova hypercritically accreting on a binary neutron star companion.

### Robert Byer's LIGO and ACHIP Projects

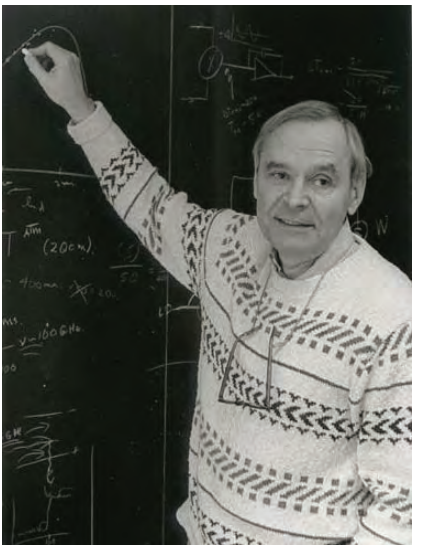
Professor Robert Byer

Robert Byer, former Stanford Dean of Research and former HEPL Director, nurtured the GP-B, GPS and Fermi programs to success during his tenure. He is currently an Applied Physics Professor specializing in lasers and optics. His LIGO Group provided seismic isolation, coatings and materials for the LIGO observatories. His ACHIP project is developing a particle accelerator on a microchip—bringing the HEPL/Ginzton Labs full circle to Hansen's 1947 research.

Professor **LYMAN PAGE**

*"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and as founding director of the Atacama Cosmology Telescope"*

*Lyman Page*



*David Wilkinson*

This award is given in recognition of Lyman Page's pivotal role in transforming cosmic microwave background observations into a high-precision experimental science over the past two decades. In particular Page provided major contributions to the success of the Wilkinson Microwave Anisotropy Probe (WMAP) space mission, which delivered outstanding measurements of the CMB anisotropy and polarization pattern. He is now continuing his effort by promoting a new generation of experiments like the Atacama Cosmology Telescope to study CMB polarization to greater precision.

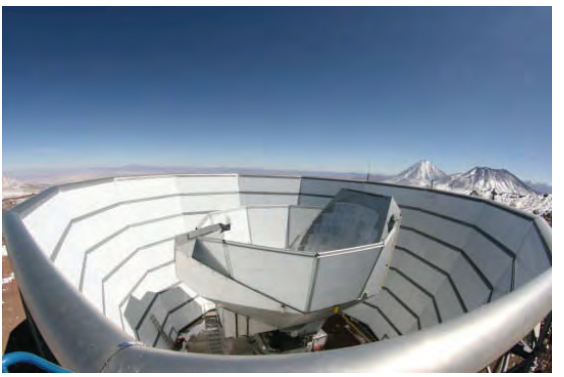


*Photo of the Atacama Cosmology Telescope*

The CMB, the faint afterglow of the Big Bang, is the most powerful probe of the early universe. From its study, we have learned the age of the universe, its major constituents, and have characterized the fundamental fluctuations in gravity that gave rise to cosmic structure. The desire to measure the CMB ever more precisely has driven the development of extraordinary detectors and techniques which will be reviewed in the Lectio Magistralis by Lyman Page. He will describe what we might hope to learn from the CMB in the next decade, including detecting gravitational waves from the birth of the universe if they exist at sufficient amplitude.

Professor **RASHID ALIEVICH SUNYAEV**
*"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe"*

*Rashid Sunyaev*

*Rashid Sunyaev and Yakov Borisovich Zeldovich*

Rashid Sunyaev gave extraordinary contributions to the understanding of physical processes in the universe which identified new and uniquely informative targets for observational cosmology. In particular, the Sunyaev-Zeldovich effect, now observed in thousands of clusters of galaxies over the entire sky, has become a cornerstone of cosmology and extragalactic astrophysics, so much so that it is now considered a research field in its own right. Furthermore, Sunyaev's studies of processes in the early universe responsible for angular anisotropy and frequency distortions of the cosmic microwave background have left a profound and lasting legacy for cosmology. In particular, Sunyaev and Zeldovich predicted the presence of acoustic peaks in the CMB angular fluctuation power spectrum and the existence of baryonic acoustic oscillations.
He is currently the project scientist leading the scientific team of the international high-energy astrophysics observatory Spektr-RG being built under the direction of the Russian Space Research Institute.

*Yakov Zeldovich and Remo Ruffini at the audience with Pope John Paul II*

Professor **SHING-TUNG YAU**
*"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics"*

*Shing-Tung Yau*

Shing-Tung Yau has made fundamental contributions to differential geometry which have influenced a wide range of scientific disciplines, including astronomy and theoretical physics. With Richard Schoen, Yau solved a longstanding question in general relativity by proving that the combined total energy of matter and gravitational field in an asymptotically flat universe is positive. In 1982 Yau was awarded the Fields Medal, the highest award in mathematics, and in 1994 he shared with Simon Donaldson the Crafoord Prize of the Royal Swedish Society in recognition of his development of nonlinear techniques in differential geometry leading to the solution of several outstanding problems.

Another outstanding achievement of Yau is his proof of the Calabi conjecture which allowed physicists to show that string theory is a viable candidate for a unified theory of nature. Furthermore in 2008 Yau (with M.T. Wang) introduced the concept of "quasi-local mass" in general relativity which can be of help to get around the old conundrum — the non-locality of the energy density in relativistic gravity.

During his scientific carrier Yau had more than 50 successful PhD students. At present he is a professor of mathematics at Harvard University where along with research he continues many pedagogical activities. For example, he has created the "Black Hole Initiative", an interdisciplinary center at Harvard University involving a collaboration between principal investigators from the fields of astronomy (Sheperd Doeleman, Avi Loeb and Ramesh Narayan), physics (Andrew Strominger), mathematics (Shing-Tung Yau) and philosophy (Peter Galison). This "Black Hole Initiative" is the first center worldwide to focus on the study of the many facets of black holes.

MG16 in 2021 will mark the $50^{th}$ anniversary of the mass-energy formula for black holes based on the Kerr metric. This timing is an omen that Yau and his school will soon further enlarge our knowledge of this formula with their powerful mathematical analysis.

# PREFACE

The Marcel Grossmann Meetings on Recent Developments in Theoretical and Experimental General Relativity, Astrophysics and Relativistic Field Theories have always had the goal of bringing together scientists from all over the world enabling them to share recent developments in general relativity and cosmology, paying attention to the interplay between physical predictions and mathematical foundations.

More than 800 scientists met at the University of Rome "la Sapienza" for the Fifteenth Marcel Grossmann Meeting (MG15) during the week of July 1–7, 2018 to discuss theoretical topics and the status of the experimental testing and observations of Einstein's theory of gravitation together with the broad spectrum of gravitational physics related phenomena. The topics discussed ranged from classical and quantum aspects of gravity, relativistic astrophysics, branes and strings, inflation theory, the thermal history of the Universe, to more concrete astrophysics experiments, observations, and modeling, reviewing the current state of the art in theory, observations, and experiments related to relativistic gravitation.

The meeting featured 39 plenary talks during the six mornings of the meeting, plus 6 public lectures given by experts in gravitation and cosmology. 73 parallel sessions, some of which were split over multiple days, kept participants busy with the crucial support of 33 students from Sapienza who managed the coordination of each parallel session and offered technical help.

Three scientists and two collaborations were presented with Marcel Grossmann awards. These were: Lyman Page, Rashid Alievich Sunyaev, Shing-Tung Yau, the Planck Scientific Collaboration (ESA) represented by Jean-Loup Puget, and the Hansen Experimental Physics Laboratory (HEPL) at Stanford University, represented by Leo Hollberg,

The detailed program of plenary and public talks is as follows:

**Shing-Tung Yau** (Harvard University): Quasi-local mass at null infinity
**Malcolm J. Perry** (University of Cambridge): Black hole entropy and soft hair
**Thomas Hertog** (KU Leuven): A smooth exit form eternal inflation
**Jean-Luc Lehners** (Max Planck Institute for Gravitational Physics): No smooth beginning for spacetime
**Ivan Agullo** (Louisiana State University): Loop quantum cosmology and the cosmic microwave background
**Elena Pian** (IASF Bologna):Kilonovae: the cosmic foundries of heavy elements
**Nial Tanvir** (University of Leicester): A new era of gravitational-wave / electromagnetic multi-messenger astronomy
**Tsvi Piran** (Hebrew University of Jerusalem): Mergers and GRBs: past present and future
**Stephan Rosswog** (Stockholm University): Neutron star mergers as heavy element production site

**David Shoemaker** (MIT LIGO Laboratory): LIGO's past and future observations of black hole and neutron star binaries
**Yu Wang** (ICRANet): On the role of binary systems in GW170817/ GRB170817A/AT2017gfo
**Hao Liu** (University of Copenhagen): An independent investigation of gravitational wave data
**Stefano Vitale** (University of Trento): Gravitation wave astronomy in ESA science programme
**Takaaki Kajita** (University of Tokyo): Status of KAGRA and its scientific goals
**Masaki Ando** (University of Tokyo): DECIGO : Gravitational-Wave observations from space
**Jun Luo** (Sun Yat-Sen University): TianQin: a space-borne gravitational wave detector
**Jo Van Den Brand** (Dutch National Institute for Subatomic Physics Nikhef, and VU University Amsterdam): Gravitational wave science and Virgo
**Ernst Maria Rasel** (Leibniz Universität Hannover): Science fiction turns into reality: Interferometry with Bose-Einstein condensates on ground and in space
**Manuel Rodrigues** (Université Paris Saclay): The first results of the MICROSCOPE test of the equivalence principle in space
**Victoria Kaspi** (McGill University): Fast radio bursts
**Bing Zhang** (University of Nevada): From gamma-ray bursts to fast radio bursts: unveiling the mystery of cosmic bursting sources
**Jean-Loup Puget** (CNRS): The Planck mission
**Jorge Armando Rueda Hernandez** (ICRANet): Binary-driven hypernovae and the understanding of gamma-ray bursts
**Remo Ruffini** (ICRANet): The essential role of the nature of the binary progenitors for understanding gamma ray bursts
**Heino Falcke** (Radboud University Nijmegen): Imaging black holes now and in the future
**Luc Blanchet** (Institut d'Astrophysique de Paris): Post-Newtonian theory and gravitational waves
**Jean-Loup Puget** (Université Paris): Frome Planck to Atacama Cosmology Telescope
**Razmik Mirzoyan** (Max Planck Institute for Physics): Gamma-ray and multimessenger highlights with MAGIC
**Elisa Resconi** (Technical University Munich): Neutrino astronomy in the multimessenger era
**Francis Halzen** (University of Wisconsin-Madison): IceCube: opening a new window on the universe from the South Pole
**James Lattimer** (Stony Brook University): The history of R-process
**Ralph Engel** (Karlsruhe Institute of Technology): What have we learned about ultra-high-energy cosmic rays from the Pierre Auger Observatory?

**Paolo De Bernardis** (Sapienza - University of Rome):
**Fabio Gargano** (INFN Bari): DAMPE and its latest results
**Markus Arndt** (University of Vienna): Experiments to probe quantum linearity at the interface to gravity & complexity
**Tobias Westphal** (University of Vienna): Micro-mechanical measurements of weak gravitational forces
**Shu Zhang** (Institute of High Energy Physics, Chinese Academy of Sciences):
**Lorenzo Amati** (INAF - OAS Bologna): Cosmology and multi-messenger astrophysics with Gamma-Ray Bursts
**Elisabetta Cavazzuti** (ASI): Gev LAT observations from GRBs and active galactic nuclei
**Remo Ruffini** (ICRANet): Concluding Remarks
**Roy Kerr** (University of Canterbury): Towards MG16

**Public Lectures**

**Jeremiah Ostriker** (Columbia University): Ultra-light scalars as cosmological dark matter
**Malcolm Longair** (University of Cambridge): Ryle and Hewish: 50 and 100 year anniversaries [Radio astrophysics and the rise of high energy astrophysics]
**Lyman Page** (Princeton University): Measuring the Cosmic Microwave Background
**Marc Henneaux** (Université Libre de Bruxelles): The cosmological singularity
**Anne Archibald** (Newcastle University): Does extreme gravity affect how objects fall?

# Concluding remarks by Prof. Remo Ruffini

For over more than four decades the Marcel Grossmann Meetings have been fostering the interaction between mathematics, relativistic field theories and observations in physics and astrophysics and has witnessed the birth and exponential growth of various new subfields within astrophysics. This has also occurred in 2018 during the MG15 (see Fig. 1), which has seen the participation of approximately one thousand participants from 71 different countries (see Fig. 2). In MG15, as is clear from the above program, we have seen considerable progress in theory on topics ranging from models of quantum gravity to the mathematical structure of Einstein's equations.

Fig. 1. MG15 official Awards Ceremony on Monday, July 2, 2018.

Fig. 2. Group photo of MG15 participants in the Aula Magna, Sapienza University of Rome.

In particular, an MG15 individual award was given to Prof. Rashid Sunyaev, as a member of the relativistic astrophysics school of Zel'dovich-Sunyaev (see Fig. 3) and to Prof. Shing-Tung Yau, as a representative of the Chinese-American school of differential geometry and general relativity (see Fig. 4).

Fig. 3. Rashid Sunyaev receiving the MG15 individual award from Roy Kerr.

Fig. 4. Shing-Tung Yau receiving the MG15 individual award from Roy Kerr.

This has been accompanied by extensive developments in the exploration of the cosmic microwave background with announcements of the final results of the Planck satellite that followed earlier predecessors, like WMAP. In this sense, particularly meaningful have been the MG15

Awards presented to Prof. Jean-Loup Puget, who has successfully accomplished the ESA Plank mission (see Fig. 5) and to Prof. Lyman Page, one of the main participants of the glorious NASA WMAP mission, successfully lead by David Wilkinson (see Fig. 6). I was very fortunate to be in Princeton as an assistant professor at the time WMAP was initially conceived.

Fig. 5. Jean-Loup Puget accepting the MG15 institutional award on behalf of the Planck Scientific Collaboration (ESA) from Roy Kerr.

Fig. 6. Lyman Page accepting the MG15 individual award from Roy Kerr.

X-ray astrophysics gradually successfully evolved from the first rockets of Riccardo Giacconi discovering Scorpius X-1 using well tested Geiger counters, moving on to larger missions using X-ray mirrors in the Einstein Observatory, in XMM and on to the NASA Chandra mission, each new mission introducing new technologies based on previous successes. The

Chandra data on GRB 170817A were amply discussed in the MG15 meeting. Analogously, starting from the earlier gamma ray detectors on the Vela satellite, gamma ray astrophysics reached maturity with the Compton Observatory with the BATSE instruments on board. These two fields joined their separate expertise together in the hybrid Beppo SAX satellite. Equally impressive was the transition from Beppo SAX to the Neil Gehrels Swift Observatory and the Fermi Gamma-Ray Space Telescope that followed EGRET and opened up the field of high energy gamma-ray astrophysics, adding further successes to this ongoing story. One of the most significant contributions to the success of the Fermi mission has been the LAT detector, jointly led by the Hansen Experimental Physics Laboratory (HEPL) at Stanford University, which received the MG15 institutional award, presented to Prof. Leo Hollberg (see Fig. 7).

Fig. 7. Leo Hollberg accepting the MG15 institutional award from Roy Kerr on behalf of the Hansen Experimental Physics Laboratory at Stanford University.

More recently we are witnessing the birth of TeV astrophysics springing from the ground-based MAGIC, HESS and Whipple telescopes, as well as neutrino astrophysics associated with underground (ICE Cube) and underwater laboratories. New tantalizing results concerning the spectrum and composition of cosmic rays have been reported by the Alpha Magnetic Spectrometer experiment on the international space station. All of these

together mark the gradual development of the largest observational effort in history, well recorded in these MG meetings (see Fig. 8). Today relativistic astrophysics is offering us the possibility of utilizing all of these multi-wavelength observations simultaneously in the study of GRBs and active galactic nuclei. Indeed the description of the distinct temporally discrete episodes for the GRB 130427A, one of the most complex astrophysical objects ever observed, requires the simultaneous knowledge of observations from all of these various wavelengths. This exponential growth in all these areas of astrophysics has been accompanied by attempts at data acquisition of gravitational wave signals arriving on the Earth. After the failure of the initial attempt by Misner and Weber in 1972, the new attempt by LIGO-VIRGO was discussed extensively in this MG15 meeting.

Fig. 8. From the left to right: Leo Hollberg, Rashid Sunyaev, Shing-Tung Yau and Remo Ruffini during the MG15 official awards ceremony.

Indeed in addition to the many topics discussed in the plenary lectures, there was a special session dedicated to kilonova and gravitational waves chaired by Enrico Costa on July 3 and a session on gravitational waves chaired by Claus Lämmerzahl on July 4. Many intense discussions took place at the meeting, both in the plenary and parallel sessions, bringing together different points of view, at times controversial, which stimulated a large number of articles published in leading scientific journals in the months following the meetings. The impossibility of finding these discussions in these proceedings is simply explained: it is due to the incomprehensible decision by Sapienza University not to renew the collaboration agreement with ICRANet. What is incomprehensible is that both the research and teaching activities of ICRA and ICRANet are

recognized internationally at a worldwide level, in more than 70 nations. Locks were put on the ICRA Offices (see Fig. 9).

Fig. 9. Remo Ruffini shows to Barry Barish the locked offices of ICRA at Sapienza University.

The preparation of the proceedings was halted. It was not possible to follow up with post-conference interactions and the impossibility of access to our offices and interact with our students. The invited lecturers, clearly indicated in the conference program and some of the world leaders in their fields who had just presented their extremely interesting lectures stimulating widespread interest, mostly chose to publish their results in international journals giving rise to some of the most highly cited articles in recent times. Only a minority were published here. This was also the case for some of the ICRA-ICRANet lectures, which appeared in:

- J.F. Rodriguez, J.A. Rueda, R. Ruffini, *On the final gravitational wave burst from binary black hole mergers*, Astron. Rep. 62, 940 (2018).
- J.A. Rueda, R. Ruffini, Y. Wang, Y. Aimuratov, U. Barres de Almeida, C.L. Bianco, Y.C. Chen, R.V. Lobato, C. Maia, D. Primorac, R. Moradia, and J.F. Rodriguez, *GRB 170817A-GW170817-AT 2017gfo and the observations of NS-NS, NS-WD and WD-WD mergers*, JCAP 10, 006 (2018); and J.A. Rueda, R. Ruffini, Y. Wang, C.L. Bianco, J.M. Blanco-Iglesias, M. Karlica, P. Lorén-Aguilar, R. Moradi and N. Sahakyan, *Electromagnetic emission of white dwarf binary mergers*, JCAP 03, 044 (2019).

- R. Ruffini, R. Moradi, J. A. Rueda, L. Becerra, C. L. Bianco, C. Cherubini, S. Filippi, Y. C. Chen, M. Karlica, N. Sahakyan, Y. Wang, and S. S. Xue, *On the GeV Emission of the Type I BdHN GRB 130427A*, The Astrophysical Journal, 886, 82 (2019).

The dialogue we had started at MG15 undoubtedly had a very stimulating effect on the community which have been followed up and expanded upon in the subsequent MG16 meeting in 2021. Paradoxically, the moments of greatest difficulty for ICRA members have coincided with the flow of new ideas which promoted the steps forward towards the final identification of some fundamental laws of black hole electrodynamics. The very night ICRA offices were locked up and its electronic communications cut, we had submitted a paper to The Astrophysical Journal for publication containing the first fundamental steps for identifying the "inner engine" of GRBs as discussed in talks in this conference. After one year and four months a judge ordered Sapienza to return the ICRA offices.

I am looking forward to a renewed successful collaboration with Sapienza University, enjoyed for more than three decades, to pursue a new common "path" for the rapidly expanding knowledge of the largest distant objects in our Universe. There is still room for improvement: now that the differences have been identified in published articles, a joint effort on an attentive scientific analysis on both sides can lead to the understanding of the nature of these differences and to jointly converge to common solutions. For this to occur, dialogue and not obstruction of office space is needed. As soon as these clarifications will be achieved, we will be able to proceed in a broad scientific effort of common topics of interest in Einstein's theory, in relativistic astrophysics, ranging from the astrophysics of black holes, neutron stars, dark matter and primordial cosmology, observing the rules of basic academic relations.

I am grateful to all members of the IOC and to Carlo Luciano Bianco, Nathalie Deruelle, Rahim Moradi, Tsvi Piran, Jorge Rueda and Narek Sahakyan for advice and discussion.

# Chiral symmetry breaking and the Unruh effect

Adrián Casado-Turrión and Antonio Dobado

*Departamento de Física Teórica and Instituto IPARCOS. Universidad Complutense, Madrid, 28040, Spain*

The possibility of chiral symmetry restoration by acceleration is considered. The Thermalization Theorem formalism and the large $N$ limit (with $N$ being the number of pions) are employed to solve the lowest-order approximation to QCD at low energies in Rindler spacetime. It is shown that chiral symmetry is restored for accelerations higher than the critical value $a_c = 4\pi f_\pi$, with $f_\pi$ being the pion decay constant. The results are completely analogous to those obtained in the inertial, finite-temperature case, evincing the ontic character of the Unruh effect.

*Keywords*: Unruh effect; chiral symmetry restoration.

## 1. Introduction

The decade of the 1970s saw the generalization of quantum field theory to curved spacetimes and arbitrary observers in Minkowski spacetime. This led to the establishment of several seminal results, such as the discovery by Hawking that black holes have an intrinsic temperature[1], and thus radiate until they evaporate.

Attempting to better understand Hawking radiation, Unruh found[2] that a similar result may be obtained even when gravity is not present: he proved that a uniformly accelerated observer in Minkowski spacetime perceives the vacuum state of a free quantum field theory as a thermal ensemble of particles at temperature $T = a/2\pi$ (in natural units), with $a$ being the observer's acceleration. Despite the fact that this phenomenon requires experimentally unattainable accelerations to be observed directly (for instance, accelerations of the order of $10^{22}$ times the Earth's mean surface gravity are required to produce an Unruh temperature similar to ambient temperature), it is nevertheless considered to be highly fundamental, since it has been derived in several ways, such as the study of the response of particle detectors along non-inertial trajectories, canonical quantization[3] and even axiomatic quantum field theory[4] (for a thorough review of the Unruh effect, see Ref. 5).

However, none of these methods allows to discern whether the temperature–acceleration analogy introduced by the Unruh effect is just a formal result or if, on the contrary, it is capable of triggering non-trivial dynamical effects, such as phase transitions. The answer to this question requires the use of a formalism which is based on a path-integral approach to field theory, which will therefore be ideally suited to address arbitrary interacting theories and the connection between quantum field theory and thermodynamics. This formalism was developed by Lee[6] in 1986, and is known as the Thermalization Theorem.

In this work, we shall make use of Lee's formalism in order to study whether accelerated observers are able to experience the spontaneous symmetry breaking or restoration of chiral symmetry, which is one of the main features of the fundamental

theory of strong interactions, QCD, at finite temperature in Minkowski spacetime. Indeed, it has already been shown that accelerating observers detect the restoration of continuous global symmetries in some systems featuring Spontaneous Symmetry Breaking (SSB), such as the Nambu-Jona-Lasinio model,[7] the $\lambda\Phi^4$ theory at the one-loop level[8] and the Linear Sigma Model (L$\sigma$M) in the large $N$ limit.[9]

## 2. Rindler spacetime and the Thermalization Theorem

Consider a uniformly accelerated observer with proper acceleration $a$ along the $X$ direction of Minkowski spacetime $\mathrm{d}s^2 = \mathrm{d}T^2 - \mathrm{d}X^2 - \mathrm{d}Y^2 - \mathrm{d}Z^2 \equiv \mathrm{d}T^2 - \mathrm{d}X^2 - \mathrm{d}X_\perp^2$, where $X^\mu = (T, X, Y, Z)$ are the usual Cartesian-like coordinates. The trajectory of such an observer is the hyperbola $T^2 - X^2 = -1/a^2$, whose asymptotes —the null lines $T = \pm X$— divide Minkowski spacetime into four quadrants: the regions $\pm X > |T|$, respectively known as the right ($R$) and left ($L$) Rindler wedges, each of which contains one of the branches of the hyperbola; and the regions $\pm T > |X|$, which are respectively the future ($F$) and past ($P$) of the origin. Notice that, while $R$ and $L$ are causally disconnected, both share a common past, and so correlations between them may exist. Hyperbolic motion is conveniently described using comoving coordinates $x^\mu = (t, x, y, z)$, which range in $(-\infty, \infty)$ and are defined by

$$T = a^{-1}\mathrm{e}^{ax}\sinh(at), \quad X = \pm a^{-1}\mathrm{e}^{ax}\cosh(at), \quad Y = y, \quad Z = z, \tag{1}$$

with the plus-sign choice covering only $R$ and the minus-sign choice covering only $L$. It is important to notice that this implies that the Euclidean Minkowski time $T_E \equiv \mathrm{i}T$ and $X$ are periodic functions of the Euclidean comoving time $t_E \equiv \mathrm{i}t$, with period $2\pi/a$. In terms of comoving coordinates, the Minkowski metric is

$$\mathrm{d}s^2 = \mathrm{e}^{2ax}(\mathrm{d}t^2 - \mathrm{d}x^2) - \mathrm{d}x_\perp^2 \tag{2}$$

in both $R$ and $L$. The worldline with $x = 0$ corresponds to the trajectory of constant proper acceleration $a$; in fact, each of the worldlines with constant $x$ is a trajectory with proper acceleration $a(x) = a\mathrm{e}^{-ax}$. Hence, it is also useful to define the so-called Rindler coordinates $\rho \equiv 1/a(x) = \mathrm{e}^{ax}/a \in [0, \infty)$ and $\eta \equiv at \in (-\infty, \infty)$.

Let us suppose now that there exists a certain quantum field theory defined over Minkowski spacetime, which describes fields of arbitrary spin and their possible interactions. Consider, without loss of generality, a Rindler observer in $R$ (the results generalize straightforwardly to $L$). Because this observer is causally disconnected from all the events in $L$, she will be insensitive to any vacuum fluctuations outside $R$. As a result, the Minkowski vacuum state of the theory, which is a pure state $|\Omega_M\rangle$ for any inertial observer, becomes a mixed state in the eyes of the accelerated observer, who needs to perform a partial trace over the degrees of freedom in $L$. Most importantly, the corresponding density matrix was shown by Lee to be

$$\rho_R = \mathrm{tr}_L|\Omega_M\rangle\langle\Omega_M| = \frac{\mathrm{e}^{-2\pi H_R/a}}{\mathrm{tr}\,\mathrm{e}^{-2\pi H_R/a}}, \tag{3}$$

where $H_R$ is the Rindler Hamiltonian (i.e. the generarator of $t$-translations). This density matrix describes a thermal ensemble at temperature $T = a/2\pi$, which is precisely the Unruh temperature originally found for free scalar field theories. However, the applicability of this result is virtually universal: it guarantees that the Minkowski vacuum state will be perceived by a Rindler observer as a thermal state, independently of the field theory considered. This is the reason why it is also known as the Thermalization Theorem.

## 3. Chiral symmetry and its restoration by acceleration

Two-flavor massless QCD in ordinary Minkowski spacetime is known to possess two distinct phases, one in which chiral $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$ symmetry is spontaneously broken into isospin symmetry $\mathrm{SU}(2)_{L+R}$, and one in which it is restored. Both phases are separated by a typical Landau-Ginzburg (i.e. second order) phase transition at a certain critical temperature $T_c$, with the order parameter being the quark condensate $\langle \bar{q}q \rangle_T$, where $q$ is the quark field and $\langle \cdot \rangle_T$ denotes the expectation value at temperature $T$ on the Minkowski QCD vacuum state. Thus, because of the temperature–acceleration analogy, it is natural to wonder whether a Rindler observer perceives a restoration of chiral symmetry if her acceleration $a$ is higher than a certain critical value $a_c$. This issue may be elucidated by functionally quantizing the low-energy effective theory for QCD[a] in the right Rindler wedge, and then computing the expectation $\langle \bar{q}q \rangle_a$ on the Minkowski QCD vacuum (which, as per the Thermalization Theorem, will be felt by the accelerated observer as a thermal ensemble at temperature $a/2\pi$). The lowest-order effective field theory for QCD is a non-linear sigma model (NL$\sigma$M) whose Euclidean partition function in $R$ is

$$Z = \int [\mathrm{d}\Phi][\mathrm{d}\lambda] \exp\left( - \int \mathrm{d}^4x \sqrt{g} \left( \frac{1}{2} \partial_\mu \Phi^{\mathrm{T}} \partial_\mu \Phi + \frac{\lambda}{2} (\Phi^{\mathrm{T}} \Phi - f_\pi^2) - M_\pi^2 f_\pi \sigma \right) \right), \quad (4)$$

where $\sqrt{g}$ is the determinant of the Euclidean Rindler metric, $M_\pi$ is the pion mass, $f_\pi$ is the pion decay constant, and $\Phi^{\mathrm{T}} = (\pi^a, \sigma)$ is a real quadruplet belonging to the fundamental representation of $\mathrm{SO}(4) \simeq \mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$, consisting of the three pion fields $\pi^a$ (with $a = 1, 2, 3$) plus an additional field $\sigma$ related to them through the non-linear constraint of the model, $\Phi^{\mathrm{T}} \Phi = \pi^a \pi^a + \sigma^2 = f_\pi^2$, which is in turn enforced through the introduction of the non-dynamical Lagrange-multiplier field $\lambda$. The fields are also required to satisfy the thermal-like Rindler boundary conditions $\pi^a(\tau = 0, \mathbf{x}) = \pi^a(\tau = 2\pi/a, \mathbf{x})$, $\sigma(\tau = 0, \mathbf{x}) = \sigma(\tau = 2\pi/a, \mathbf{x})$, $\sigma(\tau, |\mathbf{x}| = \infty) = f_\pi$ and $\lambda(\tau = 0, \mathbf{x}) = \lambda(\tau = 2\pi/a, \mathbf{x})$. In addition, by comparing (4) with the standard QCD partition function (restricted to $R$) it is clear that $\langle \bar{q}q \rangle_a \propto \langle \sigma \rangle_a$.

[a] As it is well known, QCD is asymptotically free, and thus becomes non-perturbative at low energies. In this regime, quarks and gluons cease to be the relevant degrees of freedom and an effective description in terms of the next lightest particles in the hadronic spectrum, the pions, is needed. Coincidentally, the pions are also the (pseudo-)Nambu-Goldstone bosons associated to chiral symmetry breaking.

The NL$\sigma$M model described above may be solved non-perturbatively in the large $N$ limit, where $N$ is the number of pions. This limit is properly defined if $f_\pi^2$ is of order $N$, i.e. $f_\pi^2 \equiv NF^2$, with $F^2$ being $N$-independent. Bearing this in mind, the Euclidean partition function may be rewritten in the chiral limit $M_\pi \to 0$ as

$$Z = \int [\mathrm{d}\pi][\mathrm{d}\sigma][\mathrm{d}\lambda] \exp\left(-\int \mathrm{d}^4x\,\sqrt{g}\left(-\frac{1}{2}\pi^a\Box\pi^a - \frac{1}{2}\sigma\Box\sigma + \frac{\lambda}{2}(\pi^2+\sigma^2-f_\pi^2)\right)\right). \quad (5)$$

The functional integral over the $N$ pion fields is Gaussian, and thus may be readily performed. Defining $\Gamma[\sigma,\lambda]$ as the effective action in the exponent of the remaining integral, the fields can be expanded around some point $(\bar\sigma,\bar\lambda)$ in the functional space where the first functional derivative of $\Gamma[\sigma,\lambda]$ vanishes. Using the steepest descent method, we have $Z = \mathrm{e}^{-\Gamma[\bar\sigma,\bar\lambda]} + \mathcal{O}(N^{-1/2})$ and $\bar\sigma^2(x) = \langle\sigma(x)\rangle_a^2 = \langle\sigma^2(x)\rangle_a$ in the large $N$ limit. Thus $\bar\sigma(x)$ and $\bar\lambda(x)$ are chosen to be the solutions of

$$\frac{\delta\Gamma}{\delta\sigma(x)} = -\Box\sigma + \lambda\sigma = 0, \quad (6)$$

$$\frac{\delta\Gamma}{\delta\lambda(x)} = \frac{1}{2}(\sigma^2 - f_\pi^2) + \frac{N}{2}G(x,x;\lambda) = 0, \quad (7)$$

with boundary conditions $\bar\sigma = f_\pi$ and $\bar\lambda = 0$ at $x \to \infty$, and where

$$(-\Box + \lambda)_x\, G(x,x';\lambda) = \frac{1}{\sqrt{g}}\delta^4(x-x'). \quad (8)$$

Unfortunately, an exact solution of these equations cannot be easily found. However, they may be solved approximately for $ax << 1$ (i.e. close to the origin of the accelerating frame) by exploiting the peculiar properties of Rindler spacetime. In this region, it can be shown[10] that $\lambda \simeq 0$, and that the relevant Green function is

$$G(x,x;0) = \int_0^\infty \mathrm{d}\Omega\,\frac{\Omega\pi}{2\rho^2\tanh(\Omega\pi)}. \quad (9)$$

Introducing $\omega \equiv a\Omega$ and expanding $a\rho = 1 + ax + \ldots$, equation (7) becomes

$$\sigma^2 = f_\pi^2 - \frac{N}{4\pi^2}(1-2ax)\int_0^\infty \mathrm{d}\omega\,\omega\left(1 + \frac{2}{e^{2\pi\omega/a}-1}\right) + \mathcal{O}(a^2x^2). \quad (10)$$

While the second integral on this equation may be easily calculated, the first one clearly requires regularization (for example, by introducing an $x$-dependent ultraviolet cutoff $\Lambda\mathrm{e}^{-ax}$, which leads to a renormalization of $f_\pi$). Thus, if we now define the $N$-independent critical acceleration as $a_c^2 \equiv 48\pi^2 f_\pi^2/N$ we have

$$\bar\sigma^2(x) = f_\pi^2\left(1 - \frac{a^2}{a_c^2} + 2x\frac{a^3}{a_c^2} + \ldots\right), \quad (11)$$

which is also a solution of equation (6) at this order. Assuming $\bar\sigma(0)$ to be real, the evaluation of this expression at the origin $x = 0$ of the accelerating frame yields

$$\frac{\bar\sigma(0)\big|_a}{\bar\sigma(0)\big|_0} = \frac{\langle\sigma(0)\rangle_a}{\langle\sigma(0)\rangle_0} = \frac{\langle\bar q(0)q(0)\rangle_a}{\langle\bar q(0)q(0)\rangle_0} = \begin{cases}\sqrt{1-\dfrac{a^2}{a_c^2}} & \text{if } 0 \le a < a_c,\\ 0 & \text{if } a \ge a_c.\end{cases} \quad (12)$$

Thus, we clearly see that acceleration triggers the second-order chiral phase transition at the origin of the Rindler frame. For $N = 3$ pions (i.e. the physical case for two-flavour QCD), the critical acceleration $a_c = 4\pi f_\pi$ corresponds to an Unruh-like temperature $T_c = 2f_\pi$, which is precisely the temperature at which the QCD phase transition is found to take place if the NL$\sigma$M is solved in Minkowski spacetime[11] in the same large $N$ limit that we have consider in $R$. Also, the same behavior for $\langle\bar{q}q\rangle_T/\langle\bar{q}q\rangle_0$ is found in this case, but substituting $a/a_c \mapsto T/T_c$. However, the expression for $\langle\bar{q}q\rangle_T/\langle\bar{q}q\rangle_0$ is valid in all Minkowski space, due to its homogeneity and isotropy.

We can extend our discussion to other points close to the origin by considering two different accelerated observers at Rindler coordinates $\rho = 1/a$ and $\rho' = 1/a'$. From the point of view of the first observer, the second one is located at some point with $x$ coordinate given by $\rho' = 1/a' = \mathrm{e}^{ax}/a$, i.e. her acceleration is $a' = a\mathrm{e}^{-ax}$. Thus, the position-dependent condensate is given by

$$\frac{\langle\bar{q}(x)q(x)\rangle}{\langle\bar{q}(0)q(0)\rangle} = \sqrt{1 - \frac{a^2}{a_c^2}\mathrm{e}^{-2ax}}. \tag{13}$$

Therefore, for a Rindler observer with acceleration $a \in (0, a_c)$, the condensate ranges from $\langle\bar{q}(0)q(0)\rangle$ at infinity to zero at the critical value $x_c \equiv \ln(a/a_c)/a < 0$.

This means that the chiral phase transition takes place on the $(x_c, x_\perp)$ surface. The symmetry is also restored on the region close to the horizon $x < x_c$, where $\langle\bar{q}(x)q(x)\rangle = 0$. Thus, the boundary between the broken and restored phases is completely determined by $a_c$, which only depends on QCD parameters.

Finally, it is interesting to notice that (13) implies that, for points different to the origin, what the condensate feels is equivalent to a thermal bath with a space-dependent temperature[12] $T(x) \equiv a\mathrm{e}^{-ax}/2\pi$, which diverges at the horizon and goes to zero at infinity. This temperature is consistent with the Tolman and Ehrenfest rule[13] for thermal equilibrium in static spacetimes, since $T(x)\sqrt{g_{00}} = a/2\pi$ is an $x$-independent constant, as required by the rule.

## 4. Conclusions

The powerful Thermalization Theorem formalism has allowed us to demonstrate the ability of the Unruh effect to produce non-trivial dynamical effects. In particular, we have been able to study the restoration of the highly fundamental QCD chiral symmetry by acceleration. We have shown that analogous results are found in both the thermal and Rindler cases, with a typical second-order phase transition occurring for those accelerated observers whose accelerations are higher than the critical value $a_c = 4\pi f_\pi \simeq 1.6$ GeV for $N = 3$ pions. The behavior obtained for the spacetime-dependent temperature felt by the condensate is also compatible with the standard requirements for thermodynamic equilibrium in static spacetimes, of which Rindler space is a particular example. Our results may have applications in ultra-relativistic heavy collisions, in which the Unruh effect has been proposed

as a possible thermalization mechanism,[14] and also in black holes or cosmological scenarios, since local Rindler coordinates can always be defined close to any horizon.[15]

**E-mail: valeri@fisica.uaz.edu.mx*
*fisica.uaz.edu.mx/˜valeri/*

We write solutions of relativistic quantum equations explicitly in the helicity basis for $S = 1/2$ and $S = 1$. We present the analyses of relations between Dirac-like and Majorana-like field operators. Several interesting features of bradyonic and tachyonic solutions are presented.

*Keywords*: Helicity Basis; QFT; Majorana.

## 1. Introduction

In Refs. 1, 2 we considered the procedure of construction of the field operators *ab initio* (including for neutral particles). The Bogoliubov-Shirkov method has been used. In the present article we investigate the helicity $h = 1/2$ and $h = 1$ cases in the helicity basis. We look for relations between the Dirac-like field operator and the Majorana-like field operator.

In the first part we refer to the previously found contradiction in the construction of the Majorana-like field operator for spin-1/2. In the 2nd part we analize the Majorana-like field operator in the $(1,0)\oplus(0,1)$ representation. It seems that the calculations in the helicity basis only give mathematically and physically reasonable results.

## 2. Helicity Basis in the $(1/2,0)+(0,1/2)$ Representation

The Dirac equation is:

$$[i\gamma^\mu\partial_\mu - mc/\hbar]\Psi(x) = 0\,, \quad \mu = 0,1,2,3\,. \tag{1}$$

The $\gamma^\mu$ are the Clifford algebra matrices

$$\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu}\,, \tag{2}$$

$g^{\mu\nu}$ is the metric tensor. Usually, everybody uses the definition of the field operator (in Ref. 3) in the pseudo-Euclidean metrics as given *ab initio*. After actions of the Dirac operator on $\exp(\mp ip_\mu x^\mu)$ the 4-spinors ( $u-$ and $v-$ ) satisfy the momentum-space equations: $(\hat{p} - m)u_h(p) = 0$ and $(\hat{p} + m)v_h(p) = 0$, respectively; the $h$ is the polarization index. It is easy to prove from the characteristic equations $Det(\hat{p} \mp m) = (p_0^2 - \mathbf{p}^2 - m^2)^2 = 0$ that the solutions should satisfy the energy-momentum relations $p_0 = \pm E_p = \pm\sqrt{\mathbf{p}^2 + m^2}$ for both $u-$ and $v-$ solutions.

However, the general scheme of construction of the field operator has been presented in Ref. 4. In the case of the $(1/2,0)\oplus(0,1/2)$ representation we have:

$$\begin{aligned}\Psi(x) &= \frac{1}{(2\pi)^3}\int d^4p\,\delta(p^2-m^2)e^{-ip\cdot x}\Psi(p)\\ &= \frac{1}{(2\pi)^3}\sum_h\int d^4p\,\delta(p_0^2-E_p^2)e^{-ip\cdot x}u_h(p_0,\mathbf{p})a_h(p_0,\mathbf{p})\\ &= \frac{1}{(2\pi)^3}\int\frac{d^4p}{2E_p}[\delta(p_0-E_p)+\delta(p_0+E_p)][\theta(p_0)+\theta(-p_0)]e^{-ip\cdot x}\\ &\quad\times\sum_h u_h(p)a_h(p) = \frac{1}{(2\pi)^3}\sum_h\int\frac{d^4p}{2E_p}[\delta(p_0-E_p)+\delta(p_0+E_p)]\\ &\quad\times\left[\theta(p_0)u_h(p)a_h(p)e^{-ip\cdot x}+\theta(p_0)u_h(-p)a_h(-p)e^{+ip\cdot x}\right]\\ &= \frac{1}{(2\pi)^3}\sum_h\int\frac{d^3\mathbf{p}}{2E_p}\theta(p_0)\left[u_h(p)a_h(p)|_{p_0=E_p}e^{-i(E_pt-\mathbf{p}\cdot\mathbf{x})}\right.\\ &\quad\left.+\,u_h(-p)a_h(-p)|_{p_0=E_p}e^{+i(E_pt-\mathbf{p}\cdot\mathbf{x})}\right] \qquad (3)\end{aligned}$$

During the calculations we had to represent $1=\theta(p_0)+\theta(-p_0)$ above in order to get positive- and negative-frequency parts. Moreover, we did not yet assume, which equation this field operator (namely, the $u$-spinor) satisfies, with negative- or positive-mass and/or $p^0=\pm E_p$. In general we should transform $u_h(-p)$ to the $v_h(p)$. The procedure is given below[1,2].

The explicit forms of the 4-spinors are very well known in the spinorial basis:

$$u_\sigma(\mathbf{p}) = \frac{N_\sigma^+}{2\sqrt{m(E_p+m)}}\begin{pmatrix}[E_p+m+\boldsymbol{\sigma}\cdot\mathbf{p}]\phi_\sigma(\mathbf{0})\\ [E_p+m-\boldsymbol{\sigma}\cdot\mathbf{p}]\chi_\sigma(\mathbf{0})\end{pmatrix}, \quad v_\sigma(\mathbf{p})=\gamma^5u_\sigma(\mathbf{p}), \qquad (4)$$

where $\phi_\uparrow(\mathbf{0})=\chi_\uparrow(\mathbf{0})=\begin{pmatrix}1\\0\end{pmatrix}$ and $\phi_\downarrow(\mathbf{0})=\chi_\downarrow(\mathbf{0})=\begin{pmatrix}0\\1\end{pmatrix}$. The transformation to the standard basis is produced with the $(\gamma^5+\gamma^0)/\sqrt{2}$ matrix. The normalizations, projection operators, propagators, dynamical invariants *etc* have been given in Ref. 5, for example.

We should assume the following relation in the field operator (3):

$$\sum_{h=\uparrow\downarrow}v_h(p)b_h^\dagger(p)=\sum_{h=\uparrow\downarrow}u_h(-p)a_h(-p)\,. \qquad (5)$$

We need $\Lambda_{\mu\lambda}(p)=\bar v_\mu(p)u_\lambda(-p)$. In the spinorial basis by direct calculations, we find $\Lambda_{\mu\lambda}=-im(\boldsymbol{\sigma}\cdot\mathbf{n})_{\mu\lambda}$, $\mathbf{n}=\mathbf{p}/|\mathbf{p}|$, provided that the normalization was chosen to the mass $m$. The indices $h$ and $\sigma,\mu,\lambda$ are the corresponding polarization indices. However, in the helicity basis with the helicity operator

$$\widehat{h}=\frac{1}{2}\boldsymbol{\sigma}\cdot\widehat{\mathbf{p}}=\frac{1}{2}\begin{pmatrix}\cos\theta & \sin\theta e^{-i\varphi}\\ \sin\theta e^{+i\varphi} & -\cos\theta\end{pmatrix} \qquad (6)$$

the 2-eigenspinors can be defined as follows[6,7]:

$$\phi_{\frac{1}{2}\uparrow} = \begin{pmatrix} \cos\frac{\theta}{2}e^{-i\varphi/2} \\ \sin\frac{\theta}{2}e^{+i\varphi/2} \end{pmatrix}, \quad \phi_{\frac{1}{2}\downarrow} = \begin{pmatrix} \sin\frac{\theta}{2}e^{-i\varphi/2} \\ -\cos\frac{\theta}{2}e^{+i\varphi/2} \end{pmatrix}, \tag{7}$$

for $\pm 1/2$ eigenvalues, respectively.

We can start from the Klein-Gordon equation, generalized for describing the spin-1/2 particles (i.e., two degrees of freedom); $c = \hbar = 1$:

$$(p_0 + \boldsymbol{\sigma}\cdot\mathbf{p})(p_0 - \boldsymbol{\sigma}\cdot\mathbf{p})\phi = m^2\phi\,. \tag{8}$$

If the $\phi_{\uparrow\downarrow}$ spinors are defined by the equation (7) then we can construct the corresponding $u-$ and $v-$ 4-spinors:

$$\begin{aligned} u_\uparrow(\mathbf{p}) &= N_\uparrow^+ \begin{pmatrix} \phi_\uparrow \\ \frac{E_p - p}{m}\phi_\uparrow \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{\frac{E_p+p}{m}}\phi_\uparrow \\ \sqrt{\frac{m}{E_p+p}}\phi_\uparrow \end{pmatrix}, \\ u_\downarrow(\mathbf{p}) &= N_\downarrow^+ \begin{pmatrix} \phi_\downarrow \\ \frac{E_p + p}{m}\phi_\downarrow \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{\frac{m}{E_p+p}}\phi_\downarrow \\ \sqrt{\frac{E_p+p}{m}}\phi_\downarrow \end{pmatrix}, \end{aligned} \tag{9}$$

$$\begin{aligned} v_\uparrow(\mathbf{p}) &= N_\uparrow^- \begin{pmatrix} \phi_\uparrow \\ -\frac{E_p - p}{m}\phi_\uparrow \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{\frac{E_p+p}{m}}\phi_\uparrow \\ -\sqrt{\frac{m}{E_p+p}}\phi_\uparrow \end{pmatrix}, \\ v_\downarrow(\mathbf{p}) &= N_\downarrow^- \begin{pmatrix} \phi_\downarrow \\ -\frac{E_p + p}{m}\phi_\downarrow \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{\frac{m}{E_p+p}}\phi_\downarrow \\ -\sqrt{\frac{E_p+p}{m}}\phi_\downarrow \end{pmatrix}, \end{aligned} \tag{10}$$

where the normalization to the unit ($\pm 1$) was now used:

$$\bar{u}_h(\mathbf{p})u_{h'}(\mathbf{p}) = \delta_{hh'}\,, \bar{v}_h(\mathbf{p})v_{h'}(\mathbf{p}) = -\delta_{hh'}\,, \tag{11}$$

$$\bar{u}_h(\mathbf{p})v_{h'}(\mathbf{p}) = 0 = \bar{v}_h(\mathbf{p})u_{h'}(\mathbf{p})\,. \tag{12}$$

The commutation relations may be assumed to be the standard ones[3,4,8,9] (compare with[10])

$$\left[a_h(\mathbf{p}), a_{h'}^\dagger(\mathbf{k})\right]_+ = 2E_p\delta^{(3)}(\mathbf{p}-\mathbf{k})\delta_{hh'}\,, [a_h(\mathbf{p}), a_{h'}(\mathbf{k})]_+ = 0 = \left[a_h^\dagger(\mathbf{p}), a_{h'}^\dagger(\mathbf{k})\right]_+ \tag{13}$$

$$\left[a_h(\mathbf{p}), b_{h'}^\dagger(\mathbf{k})\right]_+ = 0 = \left[b_h(\mathbf{p}), a_{h'}^\dagger(\mathbf{k})\right]_+, \tag{14}$$

$$\left[b_h(\mathbf{p}), b_{h'}^\dagger(\mathbf{k})\right]_+ = 2E_p\delta^{(3)}(\mathbf{p}-\mathbf{k})\delta_{hh'}\,, [b_h(\mathbf{p}), b_{h'}(\mathbf{k})]_+ = 0 = \left[b_h^\dagger(\mathbf{p}), b_{h'}^\dagger(\mathbf{k})\right]_+ . \tag{15}$$

Other details of the helicity basis are given in Refs. 13, 11, 12. However, in this helicity case we construct

$$\Lambda_{\mu\lambda}(p) = \bar{v}_\mu(p)u_\lambda(-p) = i\sigma^y_{\mu\lambda}\,. \tag{16}$$

It is well known that "*particle=antiparticle*" in the Majorana theory[14]. So, in the language of the quantum field theory we should have

$$b_\mu(E_p,\mathbf{p}) = e^{i\varphi}a_\mu(E_p,\mathbf{p})\,. \tag{17}$$

Usually, different authors use $\varphi = 0, \pm\pi/2$ depending on the metrics and on the forms of the 4-spinors and commutation relations, *etc.* The application of the Majorana anzatz leads to the contradiction in the spinorial basis. Namely, it leads to existence of the preferred axis in every inertial system (only $p_y$ survives), thus breaking the rotational symmetry of the special relativity.

Next, we can use another Majorana anzatz $\Psi = \pm e^{i\alpha}\Psi^c$ with usual definitions

$$\mathcal{C} = e^{i\vartheta_c}\begin{pmatrix} 0 & i\Theta \\ -i\Theta & 0 \end{pmatrix}\mathcal{K}\,, \quad \Theta = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \tag{18}$$

Thus, on using $Cu^*_\uparrow(\mathbf{p}) = -iv_\downarrow(\mathbf{p})$, $Cu^*_\downarrow(\mathbf{p}) = +iv_\uparrow(\mathbf{p})$ we come to other relations between creation/annihilation operators

$$a^\dagger_\uparrow(\mathbf{p}) = \pm ie^{-i\alpha}b^\dagger_\downarrow(\mathbf{p})\,, \quad a^\dagger_\downarrow(\mathbf{p}) = \mp ie^{-i\alpha}b^\dagger_\uparrow(\mathbf{p})\,, \tag{19}$$

which may be used instead of (17). In the case of $\alpha = \pi/2$ we have similar relations as in (16), but for positive-energy operators. Due to the possible signs $\pm$ the number of the corresponding states is the same as in the Dirac case that permits us to have the complete system of the Fock states over the $(1/2,0)\oplus(0,1/2)$ representation space in the mathematical sense. Please note that the phase factors may have physical significance in quantum field theories as opposed to the textbook nonrelativistic quantum mechanics, as was discussed recently by several authors. However, in this case we deal with the self/anti-self charge conjugate quantum field operator instead of the self/anti-self charge conjugate quantum states. Please remember that it is the latter that answer for the neutral particles. The quantum field operator contains operators for more than one state, which may be either electrically neutral or charged.

## 3. Helicity Basis in the $(1,0)+(0,1)$ Representation

The solutions of the Weinberg-like equation

$$\left[\gamma^{\mu\nu}\partial_\mu\partial_\nu - \frac{(i\partial/\partial t)}{E}m^2\right]\Psi(x) = 0\,. \tag{20}$$

are found in Refs. 15, 16, 17, 18. Here they are:

$$u_\sigma(\mathbf{p}) = \begin{pmatrix} D^S(\Lambda_R)\xi_\sigma(\mathbf{0}) \\ D^S(\Lambda_L)\xi_\sigma(\mathbf{0}) \end{pmatrix}\,,\; v_\sigma(\mathbf{p}) = \begin{pmatrix} D^S(\Lambda_R\Theta_{[1/2]})\xi^*_\sigma(\mathbf{0}) \\ -D^S(\Lambda_L\Theta_{[1/2]})\xi^*_\sigma(\mathbf{0}) \end{pmatrix} = \Gamma^5 u_\sigma(\mathbf{p}), \tag{21}$$

$$\Gamma^5 = \begin{pmatrix} 1_{3\times3} & 0 \\ 0 & -1_{3\times3} \end{pmatrix}\,, \tag{22}$$

in the "spinorial" representation. The $D^S$ is the matrix of the $(S,0)$ representation of the spinor group $SL(2,c)$.

In the $(1,0)\oplus(0,1)$ representation the procedure of derivation of the creation operators (in the similar way as in the previous Section) leads to somewhat different situation:

$$\sum_{\sigma=0,\pm1} v_\sigma(p)b^\dagger_\sigma(p) = \sum_{\sigma=0,\pm1} u_\sigma(-p)a_\sigma(-p)\,. \tag{23}$$

We obtain

$$b^\dagger_\sigma(p) \equiv 0\,. \tag{24}$$

However, if we return to the original Weinberg equations $[\gamma^{\mu\nu}\partial_\mu\partial_\nu \pm m^2]\Psi_{1,2}(x) = 0$ with the field operators:

$$\Psi_1(x) = \frac{1}{(2\pi)^3}\sum_\mu \int \frac{d^3\mathbf{p}}{2E_p}[u_\mu(\mathbf{p})a_\mu(\mathbf{p})e^{-ip\cdot x} + u_\mu(\mathbf{p})b^\dagger_\mu(\mathbf{p})e^{+ip\cdot x}], \tag{25}$$

$$\Psi_2(x) = \frac{1}{(2\pi)^3}\sum_\mu \int \frac{d^3\mathbf{p}}{2E_p}[v_\mu(\mathbf{p})c_\mu(\mathbf{p})e^{-ip\cdot x} + v_\mu(\mathbf{p})d^\dagger_\mu(\mathbf{p})e^{+ip\cdot x}], \tag{26}$$

we obtain

$$b^\dagger_\mu(p) = [1 - 2(\mathbf{S}\cdot\mathbf{n})^2]_{\mu\lambda}a_\lambda(-p)\,, \tag{27}$$

$$d^\dagger_\mu(p) = [1 - 2(\mathbf{S}\cdot\mathbf{n})^2]_{\mu\lambda}c_\lambda(-p)\,. \tag{28}$$

The application of $\overline{u}_\mu(-p)u_\lambda(-p) = \delta_{\mu\lambda}$ and $\overline{u}_\mu(-p)u_\lambda(p) = [1 - 2(\mathbf{S}\cdot\mathbf{n})^2]_{\mu\lambda}$ prove that the equations are self-consistent (similarly to the consideration of the $(1/2,0)\oplus(0,1/2)$ representation). This situation signifies that in order to construct the Sankaranarayanan-Good field operator (which was used by Ahluwalia, Johnson and Goldman[17]) we need additional postulates. One can try to construct the left- and the right-hand side of the field operator separately each other. In this case the commutation relations may also be more complicated.

Is it possible to apply the Majorana-like anzatz to the $(1,0)+(0,1)$ fields? It appears that in this basis we also come to the same contradictions as before. We have two equations

$$a_\mu(p) = +e^{-i\varphi}[1 - 2(\mathbf{S}\cdot\mathbf{n})^2]_{\mu\lambda}a^\dagger_\lambda(-p)\,, \tag{29}$$

and

$$a^\dagger_\mu(p) = +e^{+i\varphi}[1 - 2(\mathbf{S}^*\cdot\mathbf{n})^2]_{\mu\lambda}a_\lambda(-p)\,. \tag{30}$$

In the basis where $S_z$ is diagonal the matrix $S_y$ is imaginary[6]. So, $(\mathbf{S}^*\cdot\mathbf{n}) = S_x n_x - S_y n_y + S_z n_z$, and $(\mathbf{S}^*\cdot\mathbf{n})^2 \neq (\mathbf{S}\cdot\mathbf{n})^2$ in the case of $S=1$. So, we conclude that there is the same problem in this point, in the aplication of the Majorana-like anzatz, as in the case of spin-1/2. Similarly, one can proceed with (28). What would we have in the basis where all $\mathbf{S}^i_{jk} = -i\epsilon_{ijk}$ are pure imaginary? Finally,

I just want to mention that the attempts of constructing the self/anti-self charge conjugate states failed in Ref. 19. Instead, the $\Gamma^5 S^c_{[1]}-$ self/anti-self conjugate states have been constructed therein.

Now we turn to the helicity basis. The helicity operator in the $(1/2,1/2)$ representation is frequently presented:

$$\frac{(\mathbf{S}^I\cdot\mathbf{p})}{p}=\frac{1}{p}\begin{pmatrix}0&0&0&0\\0&0&-ip^3&ip^2\\0&ip^3&0&-ip^1\\0&-ip^2&ip^1&0\end{pmatrix}\,,\ \frac{(\mathbf{S}\cdot\mathbf{p})}{p}\epsilon^\mu_{\pm1}=\pm\epsilon^\mu_{\pm1}\,,\ \frac{(\mathbf{S}\cdot\mathbf{p})}{p}\epsilon^\mu_{0,0_t}=0\,. \tag{31}$$

However, we are aware about some problems with the chosen basis. The helicity operator is (in the case of $\mathbf{S}^3$ diagonal):

$$\frac{(\mathbf{S}^{II}\cdot\mathbf{p})}{p}=\frac{1}{p}\begin{pmatrix}0&0&0&0\\0&p_z&\frac{p_l}{\sqrt{2}}&0\\0&\frac{p_r}{\sqrt{2}}&0&\frac{p_l}{\sqrt{2}}\\0&0&\frac{p_r}{\sqrt{2}}&-p_z\end{pmatrix}\,. \tag{32}$$

The unitary transformation, Ref. 6, p. 55

$$U=\begin{pmatrix}0&0&0&0\\0&-\frac{1}{\sqrt{2}}&\frac{i}{\sqrt{2}}&0\\0&0&0&1\\0&+\frac{1}{\sqrt{2}}&\frac{i}{\sqrt{2}}&0\end{pmatrix}\,,\ U\frac{(\mathbf{S}^I\cdot\mathbf{p})}{p}U^\dagger=\frac{(\mathbf{S}^{II}\cdot\mathbf{p})}{p} \tag{33}$$

can be perfomed to transfer operators and polarization vectors from one basis to another. The first-basis eigenvectors are:

$$\epsilon^\mu_{+1}=\frac{1}{\sqrt{2}}\frac{e^{i\alpha}}{p}\begin{pmatrix}0\\\frac{-p^1p^3+ip^2p}{\sqrt{(p^1)^2+(p^2)^2}}\\\frac{-p^2p^3-ip^1p}{\sqrt{(p^1)^2+(p^2)^2}}\\\sqrt{(p^1)^2+(p^2)^2}\end{pmatrix}\,,\ \epsilon^\mu_{-1}=\frac{1}{\sqrt{2}}\frac{e^{i\beta}}{p}\begin{pmatrix}0\\\frac{p^1p^3+ip^2p}{\sqrt{(p^1)^2+(p^2)^2}}\\\frac{p^2p^3-ip^1p}{\sqrt{(p^1)^2+(p^2)^2}}\\-\sqrt{(p^1)^2+(p^2)^2}\end{pmatrix} \tag{34}$$

$$\epsilon^\mu_0=\frac{1}{m}\begin{pmatrix}p\\\frac{E}{p}p^1\\\frac{E}{p}p^2\\\frac{E}{p}p^3\end{pmatrix}\,,\quad \epsilon^\mu_{0_t}=\frac{1}{m}\begin{pmatrix}E_p\\p^1\\p^2\\p^3\end{pmatrix}\,. \tag{35}$$

The eigenvectors $\epsilon^\mu_{\pm1}$ are not the eigenvectors of the parity operator $(\gamma_{00}R)$ of this representation. However, the $\epsilon^\mu_{1,0}$, $\epsilon^\mu_{0,0_t}$ are. Surprisingly, the latter have no well-defined massless limit. In order to get the well-known massless limit one should use the basis of the light-front form reprersentation, cf. Ref. 20. We also note that the polarization vectors have relations to the solutions of the $(1,0)\oplus(0,1)$ representation through the Proca equations or the Duffin-Kemmer-Petiau equations.

The corresponding helicity operator of the $(1,0)\otimes(0,1)$ representation is

$$\hat{h}=\begin{pmatrix}(\mathbf{S}_{3\times3}\cdot\mathbf{p}) & 0\\ 0 & (\mathbf{S}_{3\times3}\cdot\mathbf{p})\end{pmatrix} \tag{36}$$

The eigen 3-vectors are[6,7]

$$\phi_{\uparrow}=N\,e^{i\vartheta_{+}}\begin{pmatrix}\frac{1}{2}(1+\cos\theta)e^{-i\varphi}\\ \sqrt{\frac{1}{2}}\sin\theta\\ \frac{1}{2}(1-\cos\theta)e^{+i\varphi}\end{pmatrix},\ \phi_{\downarrow}=N\,e^{i\vartheta_{-}}\begin{pmatrix}-\frac{1}{2}(1-\cos\theta)e^{-i\varphi}\\ \sqrt{\frac{1}{2}}\sin\theta\\ -\frac{1}{2}(1+\cos\theta)e^{+i\varphi}\end{pmatrix} \tag{37}$$

$$\phi_{\rightarrow}=N\,e^{i\vartheta_{0}}\begin{pmatrix}-\sqrt{\frac{1}{2}}\sin\theta\,e^{-i\varphi}\\ \cos\theta\\ \sqrt{\frac{1}{2}}\sin\theta\,e^{+i\varphi}\end{pmatrix}. \tag{38}$$

Finally, some notes concerning with the tachyonic solutions of the Weinberg equations in the $(1,0)\oplus(0,1)$ representation space. While some authors, e.g. Ref. 21, argued recently that the tachyonic energy-momentum relation $E=\pm\sqrt{\mathbf{p}^2c^2-m_0^2c^4}$ may lead to some interpretational problems, we still consider it in this paper. The Weinberg equations $[\gamma^{\mu\nu}\partial_\mu\partial_\nu\pm m^2]\Psi_{1,2}(x)=0$ give us both bradyonic and tachyonic solutions, $E=\pm\sqrt{\mathbf{p}^2c^2\pm m_0^2c^4}$. We present them now in the helicity basis which may help us to overcome the difficulties in constructions of the Majorana(-like) field operators, as shown above. If $\phi_R(\mathbf{0})=\phi_L(\mathbf{0})$, the 6-objects can be normalized to the unit. The solutions of $[\gamma^{\mu\nu}p_\mu p_\nu-m^2]\Psi(x)=0$ are

$$u_{\uparrow}(\mathbf{p})=\frac{1}{\sqrt{2}}\begin{pmatrix}\frac{m}{E_p-p}\chi_{\uparrow}\\ \frac{E_p-p}{m}\chi_{\uparrow}\end{pmatrix},\ u_{\downarrow}(\mathbf{p})=\frac{1}{\sqrt{2}}\begin{pmatrix}\frac{m}{E_p+p}\chi_{\downarrow}\\ \frac{E_p+p}{m}\chi_{\downarrow}\end{pmatrix},\ u_{\rightarrow}(\mathbf{p})=\frac{1}{\sqrt{2}}\begin{pmatrix}\chi_{\rightarrow}\\ \chi_{\rightarrow}\end{pmatrix}. \tag{39}$$

In the case of tachyonic solutions ($E_p<p$) we shall be no able to normalize to 1. However, it is possible to normalize to $-1$. In this case we have in the helicity basis:

$$U_{\uparrow}(\mathbf{p})=\frac{1}{\sqrt{2}}\begin{pmatrix}\frac{E_p+p}{m}\chi_{\uparrow}\\ -\frac{m}{E_p+p}\chi_{\uparrow}\end{pmatrix},\ U_{\downarrow}(\mathbf{p})=\frac{1}{\sqrt{2}}\begin{pmatrix}\frac{m}{E_p+p}\chi_{\downarrow}\\ -\frac{E_p+p}{m}\chi_{\downarrow}\end{pmatrix},\ U_{\rightarrow}(\mathbf{p})=\frac{1}{\sqrt{2}}\begin{pmatrix}\chi_{\rightarrow}\\ -\chi_{\rightarrow}\end{pmatrix}. \tag{40}$$

Nevertheless, self/anti-self charge-conjugated 6-objects have not been constructed till now.

## 4. Conclusions

We conclude that the calculations in the helicity basis may be useful to give mathematically and physically reasonable results when dealing with the Majorana(-like) particles.

## Acknowledgments

I acknowledge discussions with colleagues at recent conferences. I am grateful to the Zacatecas University for professorship.

# Sidetracked inflation

Sebastian Garcia-Saenz,† Sébastien Renaux-Petel and John Ronayne

*Sorbonne Université, UPMC Paris 6 and CNRS, UMR 7095, Institut d'Astrophysique de Paris, GReCO, Paris 75014, France*
†*E-mail: sebastian.garcia-saenz@iap.fr*

Scalar fields during inflation naturally define a curved field space through their kinetic interactions. When the curvature of this space is negative, the geodesic deviation of the inflationary trajectory may overcome the stabilizing force of the potential, and drive the system away from its original path in field space into a new attractor solution — a scenario known as *sidetracked inflation*. This note presents a brief introduction to the proposal along with a review of its main features and predictions. In particular, we highlight the strongly non-geodesic nature of the sidetracked inflationary phase and how this relates to some of the hallmarks of the model, such as the possibility of realizing inflation with steep potentials and a transient instability of perturbations that leads to unique observational signatures.

## 1. Introduction and set-up

Inflationary models with multiple scalar fields are attractive for a number of reasons. String theory for instance generically predicts a large number of fields in the form of moduli that arise upon compactifying to four spacetime dimensions. While single-field models of inflation are in strong tension with quantum gravity constraints, namely the eta problem and the swampland conjectures, multi-field theories can in principle be made consistent with such requirements. The presence of multiple scalars naturally leads one to consider non-linear sigma models of inflation characterized by a curved target space, a class of theories that can give rise to very interesting dynamical behaviors, such as strongly non-geodesic motion, non-standard inflationary attractors, and the phenomenon of geometrical destabilization.

Motivated by these considerations, we scrutinize a class of inflationary models defined by the action

$$S = \int d^4x\sqrt{-g}\left[\frac{M_P^2}{2}\,R[g] - \frac{1}{2}\,G_{IJ}(\phi)\nabla^\mu\phi^I\nabla_\mu\phi^J - V(\phi)\right]. \tag{1}$$

The gravitational part is the Einstein–Hilbert term for the metric tensor $g_{\mu\nu}$, and $\phi^I$ denotes the multiplet of scalar fields. The matrix $G_{IJ}$ has the natural interpretation of a metric in the internal *field space* in which the scalars $\phi^I$ perform as coordinates. Lastly $V(\phi)$ is the potential term and is a priori an arbitrary function of all the fields. An inflationary state is defined by a flat FLRW spacetime metric with scale factor $a(t)$ and Hubble parameter $H(t) \equiv \dot{a}/a$ (with $t$ the cosmic time), and by spatially homogeneous fields $\bar{\phi}^I(t)$. The latter define the *background trajectory* in the field space, which is in general not a geodesic due to the effects of gravity and the force from the potential.

As advertised, we are interested in the case where the field space has a non-trivial curvature. This means that there exists no choice of fields' parametrization for which $G_{IJ} = \delta_{IJ}$, and for this reason we refer to this class of models as *non-canonical*. Note that non-canonical models are necessarily multi-field as there is no intrinsic curvature in one dimension. The metric $G_{IJ}$, being a function of the fields, induces interactions among the scalars given by higher (mass) dimension operators,

$$G_{IJ}(\phi) = \delta_{IJ} + \frac{1}{M}\, a^{(1)}_{IJ,K}\phi^K + \frac{1}{M^2}\, a^{(2)}_{IJ,KL}\phi^K\phi^L + \cdots\,, \tag{2}$$

where the coefficients $a^{(n)}$ are dimensionless, and $M$ is the typical energy scale that characterizes the interactions. This implies that the curvature of the field space is of order $1/M^2$. We assume that $H \ll M \ll M_P$ so that the "new physics" associated to the scale $M$ may in principle have sizable effects on the physics of inflation.

Particularly interesting is the situation where the field space curvature is *negative*. Theories with a negatively curved target space are of prime importance in top-down constructions of inflation within supergravity, to wit the $\alpha$-attractor class of models. The geometrical destabilization of inflation alluded to before also relies on having a negative curvature, and which serves as a physical motivation for the scenario of sidetracked inflation that we introduce and review below. To this end, we consider linear perturbations about an inflationary solution of the action (1), parametrized by variables $Q^I$ corresponding to gauge invariant combinations of the scalar and metric perturbations (and they coincide with the scalar field fluctuations $\delta\phi^I \equiv \phi^I - \bar{\phi}^I$ in the spatially flat gauge). At this stage we restrict our attention to theories with two fields, as this is already enough to capture most of the interesting multi-field effects. We can then perform a projection of the linearized equation of motion along the adiabatic direction, i.e. the direction tangential to the background trajectory, and the entropic direction, which by definition is orthogonal to the adiabatic one, with the metric $G_{IJ}$ defining the inner product. The two projections of $Q^I$ are denoted by $Q_\sigma$ and $Q_s$ for the adiabatic and entropic perturbations, respectively. At linear level, the adiabatic mode is in fact related to the comoving curvature perturbation $\zeta$ via $Q_\sigma = \frac{\dot{\sigma}}{H}\,\zeta$, where $\dot{\sigma} \equiv \sqrt{G_{IJ}\dot{\bar{\phi}}^I\dot{\bar{\phi}}^J}$ is the speed of the background trajectory. The entropic mode on the other hand satisfies the equation of motion

$$\ddot{Q}_s + 3H\dot{Q}_s + \left(\frac{k^2}{a^2} + m_s^2\right) Q_s = -2\dot{\sigma}\eta_\perp\dot{\zeta}\,, \tag{3}$$

with the definitions

$$\eta_\perp \equiv -\frac{V_{,s}}{H\dot{\sigma}}\,, \qquad m_s^2 \equiv V_{;ss} - H^2\eta_\perp^2 + \epsilon M_P^2 H^2 R_{\rm fs}\,. \tag{4}$$

Here $\eta_\perp$ is known as the *bending parameter*,[a] which quantifies the deviation of the background trajectory from a geodesic path. We say that an inflationary solution

[a] To be more precise, the bending parameter is defined as the turning rate (in units of $H$) of the background trajectory. The relation $\eta_\perp = -\frac{V_{,s}}{H\dot{\sigma}}$ then follows from the background equation of motion rather than as a definition.

features *strongly non-geodesic motion* if $|\eta_\perp| \gg 1$. Lastly, $m_s^2$ corresponds to the effective *entropic mass* of the fluctuations, and crucially depends on the field space Ricci scalar $R_{\rm fs}$.

The interpretation of $m_s^2$ as an effective mass requires some care, as $Q_s$ is actually coupled to $\zeta$. In fact, on super-Hubble scales $k/a \ll H$ it can be shown that (4) reduces to $\ddot{Q}_s + 3H\dot{Q}_s + m_{s(\rm eff)}^2 Q_s = 0$, with $m_{s(\rm eff)}^2 \equiv m_s^2 + 4H^2\eta_\perp^2$. On the other hand, on sub-Hubble scales the perturbations' equations remain coupled and there is no clean notion of an effective mass for either field. Nevertheless, the quantity $m_s^2$ can still serve as a powerful probe of the dynamics of the fluctuations, in particular of their stability, and will play a crucial role in the scenario of inflation that we will describe below.

Returning to the super-Hubble evolution, we observe that the quantity $m_{s(\rm eff)}^2$ is a measure of the stability of large scale perturbations and hence of the background itself. As remarked above, in a negatively curved field space the curvature gives a contribution proportional to $-\epsilon|R_{\rm fs}|$ to the effective mass, which may eventually overcome the stabilizing effect of the potential provided that the slow-roll parameter $\epsilon$ grows fast enough. In a standard picture of inflation where the potential has a flat direction corresponding to the inflaton field, the effective mass $m_{s(\rm eff)}^2$ may thus transition from positive to negative at some critical time when the inflationary state becomes unstable. This is known as the *geometrical destabilization* of inflation[1]. The onset of the instability implies that perturbation theory breaks down and that the homogeneous inflationary vacuum can no longer be trusted. On physical grounds, however, it is plausible that the mayhem will eventually subside and that the system will settle down into a new homogeneous state,[b] i.e., into a second inflationary phase known as *sidetracked inflation*,[3] owing to the way in which the background trajectory deviates from its original path in field space (Fig. 1).

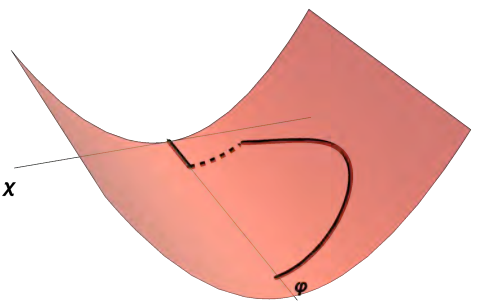

Fig. 1. Schematic plot of the field-space trajectory in sidetracked inflation.

[b] A recent analysis based on the stochastic formalism supports this assumption[2].

## 2. Sidetracked inflation

The story we have described relies on the existence of an attractor solution to the equations of motion that proceeds away from the minimum of the potential. Such an attractor may be heuristically understood as arising from the balance between the stabilizing force of the potential and the destabilizing geodesic deviation caused by the negative curvature of the field space.

For concreteness we focus on two-field models and write $\phi^1 \equiv \varphi$ and $\phi^2 \equiv \chi$. It will be useful to think of $\varphi$ as the inflaton and of $\chi$ as an additional heavy field. The potentials we consider will be of the form $V = \Lambda^4 \mathcal{V}(\varphi) + \frac{m_h^2}{2}\chi^2$, where $\mathcal{V}(\varphi)$ is the dimensionless inflaton potential (the scale $\Lambda$ being determined a posteriori by the normalization of the curvature power spectrum) and $m_h \gg H$ is the mass of $\chi$. Motivated by our goal of understanding the effects of the field space curvature in inflation, we restrict our attention to two simple field space metrics. A first one that we dub "minimal",

$$G^{(\mathrm{min})}_{IJ} d\phi^I d\phi^J = \left(1 + \frac{2\chi^2}{M^2}\right) d\varphi^2 + d\chi^2 \,, \qquad R^{(\mathrm{min})}_{\mathrm{fs}} = -\frac{4}{M^2(1 + 2\chi^2/M^2)} \,, \quad (5)$$

and a second corresponding to a hyperbolic plane metric,

$$G^{(\mathrm{hyp})}_{IJ} d\phi^I d\phi^J = \left(1 + \frac{2\chi^2}{M^2}\right) d\varphi^2 + \frac{2\sqrt{2}\,\chi}{M}\, d\varphi d\chi + d\chi^2 \,, \qquad R^{(\mathrm{hyp})}_{\mathrm{fs}} = -\frac{4}{M^2} \,. \quad (6)$$

The unusual parametrization of the hyperbolic plane given in (6) will be useful in order to compare the effects of the two geometries.

We begin by outlining the salient properties of the background dynamics. First, the sidetracked inflationary phase lasts in general much longer than it would in the absence of a geometrical destabilization. This is in fact common to other non-canonical theories and is due to the effective stretching of the inflaton potential as a result of the effect of the heavy field $\chi$ in the normalization of the inflaton's kinetic term. Second, sidetracked inflation is crucially different from standard slow-roll in that the covariant acceleration of $\chi$ is non-negligible. More explicitly, the equation of motion $D_t\dot{\chi} + 3H\dot{\chi} + V^{,\chi} = 0$ allows for two types of attractors (depending on the parameters of the model): a standard slow-roll attractor characterized by a negligible acceleration $D_t\dot{\chi}$, yielding the usual relation $\dot{\chi} \simeq -V^{,\chi}/3H$; and a "sidetracked attractor" where both $\dot{\chi}$ and $\ddot{\chi}$ are negligible, hence giving the relation $\Gamma^{\chi}_{\varphi\varphi}\dot{\varphi}^2 + V^{,\chi} \simeq 0$ which shows the balance between geometrical and potential effects that we alluded to above. Third, the expressions for the slow-roll parameters in sidetracked inflation are approximately given by

$$\epsilon \simeq \frac{1}{2\sqrt{2}} \frac{m_h}{H} \frac{M|V_{,\varphi}|}{V} \,, \qquad \eta \simeq 3\epsilon - \frac{1}{\sqrt{2}} \frac{m_h}{H} \frac{MV_{,\varphi\varphi}}{|V_{,\varphi}|} \,, \quad (7)$$

which differ from the usual single-field results. Given that $m_h/H$ is large (albeit not too much, for otherwise there will be no destabilization of the standard attractor), we conclude that the quasi-de Sitter approximation is valid provided that the

inflaton potential is flat in units of $M$, which should be contrasted to the single-field case where the potential is required to be flat in Planck units. This is a very welcome feature of the model in view of the swampland conjectures that constrain the derivatives of the potential in the context of inflation and that could rule out large classes of single-field theories.

Next we turn to the behavior of perturbations. A first remark is that the super-Hubble entropic mass $m^2_{s(\mathrm{eff})}$ is always large and positive, thanks to the contribution from the bending parameter $\eta_\perp$, which is large in our set-up. Sidetracked inflation is thus characterized by a strongly non-geodesic motion, and this is indeed at the heart of many of the peculiar properties of the proposal. The large value of $m^2_{s(\mathrm{eff})}$ also implies that entropic (or isocurvature) perturbations quickly decay after horizon crossing as well as the standard conservation law $\dot{\zeta} = 0$ for the adiabatic mode. On the other hand, the sub-Hubble evolution is quite model-dependent, although we can identify three qualitatively distinct behaviors based on the value of the effective mass $m_s^2$, as we now explain (see Ref. 3 for details).

**$|m_s^2| \ll H^2$.** For the inflaton potentials that we have scrutinized, this case arises for the choice of the minimal metric, Eq. (5). Naively, a light entropic mass would suggest strong multi-field effects around the time of horizon crossing. However, the strongly non-geodesic motion gives rise to a new scale $H^2\eta_\perp^2 \gg H^2$ in the problem, allowing for an effective single-field description featuring a non-linear dispersion relation $\omega(k) \propto k^2$ for the relevant degree of freedom. The large value of the bending typically also implies a reduced tensor-to-scalar ratio of order $r \sim \epsilon/\sqrt{\eta_\perp}$ (however with a time of evaluation that occurs later than Hubble crossing).

**$|m_s^2| \gg H^2$ and $m_s^2 > 0$.** This case occurs for the hyperbolic metric, eq. (6), whenever $V_{,\varphi} > 0$. The large entropic mass signifies that an effective theory for the adiabatic mode may be obtained upon integrating out the entropic perturbation. The resulting dispersion relation is given by $\omega^2 = c_s^2 k^2$, where $c_s$ is the effective sound speed, and we find $0 < c_s^2 \ll 1$ for the models we have looked at. This is the usual scenario of single-field inflation with a reduced speed of sound. The tensor-to-scalar ratio is correspondingly suppressed as $r \sim \epsilon c_s$, while non-Gaussianities are enhanced by a factor of $1/c_s^2$.

**$|m_s^2| \gg H^2$ and $m_s^2 < 0$.** This situation also arises when the field space is hyperbolic, but now with $V_{,\varphi} < 0$. The *negative* value of $m_s^2$ signals a tachyonic instability of the entropic mode (again with the caveat that the perturbations are coupled at linear order). Although counterintuitive, this situation allows one to integrate out the tachyonic field in a standard way, with the consequence that the resulting effective theory is characterized by an *imaginary speed of sound* — the low-energy "issue" given by the tachyonic instability has now become a high-energy phenomenon in the form of a gradient instability. This is not a priori catastrophic, as the instability is only transient, lasting a few e-folds around the time of horizon crossing. The predictions in this set-up are quite interesting, notably an exponentially reduced tensor-to-scalar ratio and non-Gaussianities of the flattened shape.[4]

## 3. Final remarks

We conclude this note with a brief discussion of some recent developments concerning the proposal of sidetracked inflation and other closely related topics. The non-standard attractor that defines the sidetracked inflationary phase has been understood to belong to a general class of attractor solutions characterized by a large degree of bending.[5–7] These analyses provide a unifying picture for several novel multi-field theories of inflation in which the curvature of the internal field space plays a crucial role. On the other hand, the possibility of having a transient tachyonic instability — which has been observed in the model of hyperinflation[8] and, as we have seen, in a class of models of sidetracked inflation — has been critically studied in Ref. 9. An important conclusion is that the exponential growth of the perturbations that results from the instability can easily lead to a breakdown of perturbation theory. Avoiding this can only be achieved by a strong restriction of the parameter space of these models, thus serving as a powerful criterion by which various recent proposals can be constrained and eventually ruled out.

# Inflation driven by scalar field and solid matter

Peter Mészáros

*Department of Theoretical Physics, Comenius University, Bratislava, Slovakia*
**E-mail: peter.meszaros@fmph.uniba.sk*

This paper is a brief summary of work already published in Ref. 1. It is inspired by solid inflation which is a cosmological model with inflation driven by fields which enter the Lagrangian in the same way as body coordinates of a solid matter enter the equation of state. We construct a simple generalization of this model by adding a scalar field with standard kinetic term to the action, and focus on calculation of quantities which can be compared with observations of CMB anisotropies.

*Keywords*: Inflation; Solid Matter; Quantum Field Theory in Curved Spacetime.

## 1. Model Under Consideration

One of less standard example of multi-field inflationary models is *solid inflation*[2,3], driven by three-component scalar field $\phi^I$ which enter the Lagrangian in the same way as body coordinates of solid matter enter the equation of state, so that the matter action has to be invariant under internal translations and rotations,

$$\phi^I \to M^I{}_J \phi^J + C^I, \quad M^I{}_J \in SO(3), \quad C^I \in \mathbb{R}^3, \quad I, J = 1, 2, 3, \tag{1}$$

where the capital indices are raised and lowered by the Euclidean metric. The simplest possible background configuration, $\phi^I = \delta^I_i x^i$, with $x^i$ denoting spatial coordinates, breaks the spatial translational and rotational symmetry, but in a flat universe it is invariant under the combined spatial-internal transformations. As shown by Endlich et al.[3], in this model there appears anisotropic dependence of the scalar bispectrum on how the squeezed limit is approached. Further development of the theory includes[4–7].

In this paper we study a combined inflationary model including scalar field $\varphi$ with standard kinetic term and three-component scalar field $\phi^I$ with symmetries defined above. Similar approach can be found in Ref. 8 where the authors study a model with special form of equation of state of the solid but non-trivial coupling of scalar fields to gravity. In our Lagrangian

$$\mathcal{L} = \frac{1}{2} g^{\mu\nu} \partial_\mu \varphi \partial_\nu \varphi + F(\varphi, X, Y, Z), \quad X = \mathrm{Tr}B, \quad Y = \frac{\mathrm{Tr}B^2}{X^2}, \quad Z = \frac{\mathrm{Tr}B^3}{X^3}, \tag{2}$$

there is no non-trivial coupling of scalar fields to gravity, but we keep the form of the equation of state as general as possible, omitting derivative couplings only. Variables $X$, $Y$ and $Z$ are three independent quantities invariant under transformations (1), for which we have adopted definitions from Ref. 3, where $B^{IJ} = -g^{\mu\nu} \partial_\mu \phi^I \partial_\nu \phi^J$ is the body metric. (We have changed its sign in order to reconcile it with the signature of the metric tensor $(+---)$, which we use throughout the paper.) Our model represents a straightforward combination of the solid inflation and the basic

single-field models. It can be considered as, for instance, a simple toy model of interactions of fields driving the solid inflation with fields of an effective field theory of the standard model.

For different functions $F$ there are different solutions of the background equations and a useful quantity measuring the deviation from the de Sitter solution is the slow-roll parameter $\epsilon = -\dot{H}/H^2$, with $H = \dot{a}/a$, which can be written as

$$\epsilon = p + q - \frac{1}{3}pq, \quad p = \frac{\dot{\varphi}^2}{2M_{\rm Pl}^2 H^2}, \quad q = X\frac{F_X}{F}, \tag{3}$$

where $p$ and $q$ are the slow-roll parameters of the single-field inflation and the solid inflation respectively. In our combined model we have an additional degree of freedom, so that the slow-roll parameter can be small also for finite values of the parameters $p$ and $q$; however, in this work we restrict ourselves to the special case in which both $p$ and $q$ are small.

## 2. Cosmological Perturbations

For the perturbation theory we adopt the technical approach from Ref. 9. In the ADM parametrisation the metric is $ds^2 = N^2dt^2 - h_{ij}(dx^i + N^i dt)(dx^j + N^j dt)$. The flat Friedmann–Robertson–Walker–Lematre metric corresponds to $N = 1$, $N^i = 0$, and $h_{ij} = a^2\delta_{ij}$, where $a(t)$ is the scale factor. For analysing perturbations we will use spatially flat slicing gauge in which the scalar and vector perturbations of the three-dimensional metric are set to zero. The metric and matter perturbations are given by

$$\begin{aligned} N &= 1 + \delta N, \quad N^i = \xi_{,i} + N_T^i, \quad h_{ij} = a^2 e^{\gamma_{ij}}, \\ \varphi &= \varphi_0 + \delta\varphi, \quad \phi^I = x^I + \pi^I, \quad \pi^I = \rho_{,I} + \pi_T^I, \end{aligned} \tag{4}$$

where $N^i$ and $\pi^I$ are decomposed into scalar and vector parts (longitudinal and transversal parts in Helmholtz decomposition), $N_T^i$ and $\pi_T^I$ satisfying $N_{T,i}^i = 0$ and $\pi_{T,I}^I = 0$, and $\gamma_{ij}$ is traceless and transversal, i.e. $\gamma_{ii} = 0$ and $\gamma_{ij,j} = 0$. By varying the action consisting of the Einstein–Hilbert part and the matter Lagrangian with respect to $N^i$ and $\delta N$ we obtain the momentum and Hamiltonian constraints. By inserting solutions of constraints into the action and expanding it up to the second order of the perturbation theory we obtain the scalar quadratic action

$$\begin{aligned} S_S^{(2)} = \int \frac{d^3k dt}{(2\pi)^3} a^3 \Big[ & M_{\rm Pl}^2 a^2 H^2 (k^2 - 3a^2H^2Q)Q\dot{\rho}^2 + 2M_{\rm Pl}^2 a^2 H^3 k^2 Q^2 \dot{\rho}\rho \\ & - M_{\rm Pl}^2 H^2 c_L^2 k^4 Q\rho^2 + \frac{1}{2}\dot{\delta\varphi}^2 + \frac{1}{2}\left(F_{\varphi\varphi} - \frac{k^2}{a^2} + 3H^2 p\right)\delta\varphi^2 \\ & - Hp\delta\varphi\dot{\delta\varphi} \pm \sqrt{2}M_{\rm Pl} a^2 H^2 \sqrt{p} Q \left(\frac{k^2}{a^2}\delta\varphi\rho - \dot{\delta\varphi}\dot{\rho}\right) - 2F_{X\varphi}\frac{k^2}{a^2}\delta\varphi\rho \Big], \end{aligned} \tag{5}$$

where only terms up to the first order of the slow-roll approximation have been kept, and $Q = \epsilon - p$ must be positive in order to have the proper sign of action. The tensor quadratic action obtained in the same way is

$$S_T^{(2)} = \frac{1}{4}M_{\rm Pl}^2 \int d^4x a^3 \left( \frac{1}{2}\dot{\gamma}_{ij}\dot{\gamma}_{ij} - \frac{1}{2}a^{-2}\gamma_{ij,k}\gamma_{ij,k} + 2\tilde{h}c_T^2\gamma_{ij}\gamma_{ij} \right), \tag{6}$$

where $\tilde{h} = \dot{H} + \dot{\varphi}_0^2/(2M_{\rm Pl}^2) = H^2(p-\epsilon)$. The longitudinal sound speed appearing in the scalar quadratic action and the transverse sound speed in the tensor action are

$$c_L^2 = 1 + \frac{2}{3}\frac{XF_{XX}}{F_X} + \frac{8}{9}\frac{F_Y + F_Z}{XF_X}, \quad c_T^2 = 1 + \frac{2}{3}\frac{F_Y + F_Z}{XF_X}. \tag{7}$$

Unfortunately, equations of motion for scalar perturbations derived by variation of the action are coupled. Due to the effect of gravity, this occurs even if $F_{X\varphi}$ is zero. They are decoupled only in the special case such that

$$F_{X\varphi} = \pm\frac{\sqrt{p}F_X}{\sqrt{2}M_{\rm Pl}}\left(c_L^2 - 1\right). \tag{8}$$

Furthermore, the scalar perturbation $\rho$ must be replaced by $\mathcal{U} = H\delta u^{(s)} = a^2H(\dot{\rho} - \xi)$, where the $\delta u^{(s)}$ is the scalar part of the solid matter velocity, $u_i^{(s)} = \delta u_{,i}^{(s)} + u_i^{(s)T}$, $u_{i,i}^{(s)T} = 0$, and the term $-\xi$ in the brackets originates from lowering the index with use of the perturbed metric.

In order to solve equations of motion for perturbations it is useful to introduce the conformal time $\tau$ defined in the standard way as $\tau = \int a^{-1}dt$, $\tau \in (-\infty, 0)$. By replacing the cosmological time by it and considering assumptions imposed above including special form of $F_{X\varphi}$ given by (8), we find

$$\mathcal{U}'' - \frac{2 + 2\epsilon_c + \eta_{Q,c} - 2\eta_{L,c}}{\tau}\mathcal{U}' + \left( k^2c_L^2(\tau) + 3\frac{(1 + c_{L,c}^2)Q_c - 2\eta_{L,c}}{\tau^2} \right)\mathcal{U} = 0, \tag{9}$$

$$\delta\varphi_k'' - 2\frac{1 + \epsilon_c}{\tau}\delta\varphi_k' + \left( k^2 - \frac{6p_c + H_c^{-2}F_{\varphi\varphi,c}}{\tau^2} \right)\delta\varphi_k = 0, \tag{10}$$

where the prime denotes the differentiation with respect to the conformal time, $\mathcal{H} = a'/a$, both $\eta_Q = \dot{Q}/(\epsilon H)$ and $\eta_L = \dot{c}_L/(c_L H)$ have been considered to be of the first order in the slow-roll parameters, and the subscript $c$ stands for quantities evaluated at the reference time $\tau_c$ when the longest mode of observational relevance today with the wavenumber $k_{\rm min} \sim H_{\rm today}$ ($a_{\rm today} \equiv 1$) exits the horizon. The creation and annihilation operators defined when the perturbations are quantized obey the canonical commutation relations, and the correctly normalized classical modes obeying equations of motion (9) and (10) are

$$\begin{aligned} \mathcal{U}_k^{(\rm cl)} &= i\frac{\sqrt{\pi}}{2\sqrt{2}}\frac{H_c c_{L,c}}{M_{\rm Pl}\sqrt{Q_c}}(-\tau)^{\frac{3}{2}+\epsilon_c^{(\mathcal{U})}} H^{(1)}_{\frac{3}{2}+p_c^{(\mathcal{U})}}(-c_L(\tau)(1+\eta_{L,c})k\tau), \\ \delta\varphi_k^{(\rm cl)} &= -\frac{\sqrt{\pi}}{2}H_c(-\tau)^{\frac{3}{2}+\epsilon_c} H^{(1)}_{\frac{3}{2}+\epsilon_c^{(\delta\varphi)}}(-k\tau), \end{aligned} \tag{11}$$

where $H^{(1)}$ denotes Hankel functions of the first kind, $\epsilon^{(\mathcal{U})} = \epsilon + \frac{1}{2}\eta_Q - \eta_L$, $p^{(\mathcal{U})} = p - c_L^2 Q + \frac{1}{2}\eta_Q + \frac{5}{2}\eta_L$, and $\epsilon^{(\delta\varphi)} = \epsilon + 2p + \frac{1}{3}\frac{F_{\varphi\varphi}}{H^2}$.

From Ref. 10 we adopt definition of the scalar quantity $\zeta$ that parametrizes the curvature perturbations. In our model in the leading order in slow-roll parameters it is

$$\zeta_k = \frac{A_k}{2} - H\frac{\delta\rho_k}{\dot{\bar{\rho}}} = \frac{\pm\sqrt{p}}{\sqrt{2}M_{\rm Pl}\epsilon}\left(\frac{\delta\dot{\varphi}}{3H} - \delta\varphi\right) + \frac{Q}{c_L^2\epsilon}\left(\frac{\dot{\mathcal{U}}}{3H} + \mathcal{U}\right). \tag{12}$$

The corresponding power spectrum $\mathcal{P}_\zeta(k)$ is defined by the two-point function in the late time limit, $\langle 0|\,\zeta_{k_1}\zeta_{k_2}\,|0\rangle = \left[\mathcal{P}_\zeta(k_1)/(2k_1^3)\right](2\pi)^5\delta^{(3)}(\mathbf{k}_1 + \mathbf{k}_2)$. It is usually approximated by power-law function, $\mathcal{P}_\zeta(k) \propto k^{n_S - 1}$, where $n_S$ is the scalar spectral index, being close to one for a nearly flat spectrum. The spectral tilt up to the leading order of the slow-roll approximation is

$$n_S - 1 = -2\frac{c_{L,e}^5\sigma p_e\epsilon_c^{(\delta\varphi)} + (\epsilon_e - p_e)\,p_c^{(\mathcal{U})}}{\epsilon_e + \left(c_{L,e}^5\sigma - 1\right)p_e}, \quad \sigma = e^{2N_{\min}\left(\epsilon_c^{(\delta\varphi)} - p_c^{(\mathcal{U})}\right)} \tag{13}$$

where the subscript $e$ stands for quantities evaluated in the time when the inflation ends, $\tau_e \approx 0^-$, $N_{\min}$ is the minimal number of e-foldings ($N_{\min} \sim 60$), and $(k_{\max}/k_{\min})^{2\left(p_c^{(\mathcal{U})} - \epsilon_c^{(\delta\varphi)}\right)}$, $k_{\max} \sim 3000 k_{\min}$ being the maximal wavenumber corresponding to the highest observed multipole moment of the cosmic microwave background, and $c_{L,c}^{-2p_c^{(\mathcal{U})}}$ were replaced by one. (For example $3000^{0.01} \doteq 1.08$ and $0.1^{0.01} \doteq 0.98$.)

The tensor perturbations can be treated in a more straightforward way than scalar perturbations, since in contrast to them the tensor perturbations with two independent polarization are decoupled. The tensor spectral tilt in our model is $n_T - 1 = 2c_{L,c}^2\epsilon_c - 2(1 + c_{L,c}^2)p_c$ and tensor-to-scalar ratio is $r = \mathcal{P}_\gamma/\mathcal{P}_\zeta = 4c_L^5\epsilon^2/\left[\epsilon + \left(c_L^5 - 1\right)p\right]$.

## 3. Primordial Non-Gaussianity

In the linear order of the perturbation theory Gaussianity is preserved. Therefore, in order to compute bispectrum which encodes the non-Gaussianity, cubic terms in the action are needed. Since in our model we have $0 \le F_Y + F_Z \le -(3/8)XF_X = (9/8)M_{\rm Pl}^2H^2\,(\epsilon - p)$, $F_Y + F_Z$ can be neglected as well as $F_{XX}$, $F_{XXX}$,...$F_{X\varphi}$, $F_{XX\varphi}$,... However, it must be small, its time derivative may not be, because this restriction is just an inequality, and therefore there are no restrictions on $F_{XY} + F_{XZ}$ and $F_{Y\varphi} + F_{Z\varphi}$. On the other hand, small functions with not small derivative usually do not occur in physical problems, so that it is reasonable to restrict ourselves to the special case in which $F_Y + F_Z = (9/8)AM_{\rm Pl}^2H^2\,(\epsilon - p)$, where $A$ is a constant, or a slowly varying function, of order unity, $A \sim 1$. By differentiating this equation we obtain the restriction $X\,(F_{XY} + F_{XZ}) \mp M_{\rm Pl}\sqrt{p/2}\,(F_{Y\varphi} + F_{Z\varphi}) \sim \epsilon^2$, which is

satisfied if we put

$$\tilde{F} = X\left(F_{XY} + F_{XZ}\right) = \pm\frac{M_{\rm Pl}}{\sqrt{2}}\sqrt{p}\left(F_{Y\varphi} + F_{Z\varphi}\right), \tag{14}$$

and allow $\tilde{F}$ to be of arbitrary order in the slow-roll parameters, so that we have to keep this parameter when deriving the cubic action.

The scalar bispectrum is given by the three-point function of the scalar $\zeta$, which can be computed with the use of the in-in formalism[11] as

$$\langle\zeta_{\mathbf{k}_1}(\tau)\zeta_{\mathbf{k}_2}(\tau)\zeta_{\mathbf{k}_3}(\tau)\rangle = -i\int\limits_{-\infty}^{\tau} a(\tau')d\tau'\,\langle 0|\left[\zeta_{\mathbf{k}_1}(\tau)\zeta_{\mathbf{k}_2}(\tau)\zeta_{\mathbf{k}_3}(\tau), H_{\rm int}(\tau')\right]|0\rangle\,, \tag{15}$$

where only the first order term with a single integration and a simple commutator is considered. Using the relations above we find that the scalar bispectrum $B_\zeta(k_1,k_2,k_3)$, defined by relation $\langle\zeta_{\mathbf{k}_1}\zeta_{\mathbf{k}_2}\zeta_{\mathbf{k}_3}\rangle = (2\pi)^3\delta^{(3)}(\mathbf{k}_1+\mathbf{k}_2+\mathbf{k}_3)B_\zeta(k_1,k_2,k_3)$, consists of two parts,

$$B_\zeta(k_1,k_2,k_3) = F_Y B_\zeta^Y(k_1,k_2,k_3) + \mathcal{N}_\zeta c_{L,c}^2\tilde{F}\tilde{B}_\zeta(k_1,k_2,k_3), \tag{16}$$

parametrized by three independent parameters of the theory, $F_Y$, $\tilde{F}$ and $\mathcal{N}_\zeta c_{L,c}$, where $\mathcal{N}_\zeta$ is a number of of the order of number of $e$-foldings. Due to the delta-function in the tree-point correlation function, three wavenumbers $k_1$, $k_2$ and $k_3$ can be identified with the sides of a triangle, and all information about bispectrum is encoded in a function of two variables which characterize the shape of the triangle. Following conventions of Ref. 12, we define $x = k_2/k_1$ and $y = k_3/k_1$ and describe the bispectrum by the function $x^2y^2B_\zeta(1,x,y)$ defined in region $1-x \le y \le x$, $1/2 \le x \le 1$, $0 \le y \le 1$. Shapes of the functions $x^2y^2B_\zeta^Y(1,x,y)$ and $x^2y^2\tilde{B}_\zeta(1,x,y)$ are depicted in Fig. 1. All functions in the figure are normalized to have value 1 in the equilateral limit, $x = y = 1$.

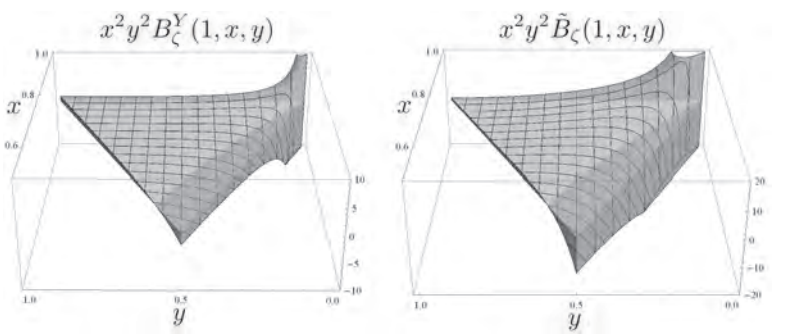

Fig. 1. Shapes of the scalar bispectrum. Flat triangles represent the zero plane.

Our model with the additional degree of freedom allows for a wider range of different shapes of the bispectrum than the solid inflation. The overall bispectrum

peaks in the squeezed limit, unless $\tilde{F}/F_Y = (5/6)\mathcal{N}_\zeta^{-1} c_{L,c}^{-2}$, when it peaks in the equilateral limit instead.

The size of the bispectrum is given by the non-linearity parameter $f_{\rm NL}$. Following the definition (4) in Ref. 13, we find

$$f_{\rm NL} = \frac{5}{72\pi^4}\frac{k^6 B_\zeta(k,k,k)}{\mathcal{P}_\zeta^2(k)} = \frac{\epsilon_c\left(\frac{19415}{13122}\frac{1}{c_{L,c}^2}\frac{F_Y}{F} - \frac{5}{18}\mathcal{N}_\zeta\frac{\tilde{F}}{F}\right)}{\left[\epsilon_c + \left(c_{L,c}^5 - 1\right)p_c\right]^2}. \tag{17}$$

We can see that if $\epsilon - p \sim \epsilon \sim p$, the non-linearity parameter is of the order $f_{\rm NL} \sim (F_Y/F)c_L^{-2}\epsilon^{-1}$, the same as for the solid inflation without the scalar field, or $f_{\rm NL} \sim \mathcal{N}_\zeta(\tilde{F}/F)\epsilon^{-1}$. Supposing that $c_L^5 \sim \epsilon$ we have $f_{\rm NL} \sim (F_Y/F)c_L^{-2}\epsilon^{-3}$ or $f_{\rm NL} \sim \mathcal{N}_\zeta(\tilde{F}/F)\epsilon^{-3}$ if $\epsilon - p$ is of the order $\epsilon^2$. The condition $\epsilon - p \lesssim \epsilon^2$ leading to an amplification of the non-linearity parameter can be rewritten as $q \ll p$, which means that the contribution of the solid matter to the overall stress-energy tensor is negligible in comparison to the contribution of the scalar field.

By applying the covariant Taylor expansion method of the heat kernel, Einstein anomaly associated with the Weyl fermion of spin-$\frac{1}{2}$ interacting with nonabelian vector and axial-vector fields in six-dimensional curved space are manifestly given. From the relation between Einstein and Lorentz anomalies, which are the gravitational anomalies, all terms of the Einstein anomaly should form total derivatives. It is shown before the trace operation of the gamma-matrices that the anomaly is expressed by the form expected.

Motivated by the quantum effects in supergravity, we study gravitational anomalies in higher dimensional curved space. In supergravity coupled with super Yang-Mills theory,[1,2] the Lagrangian contains four-fermion interactions, which are regarded as some two-fermion interactions with bosonic background fields expressed by odd-order tensors. The completely antisymmetric part of the highest order tensor should be rewritten as an axial-vector by contracting its tensor with the Levi-Civita symbol. The (polar-)vector and the axial-vector parts in the two-fermion interactions can be absorbed in the vector and the axial-vector gauge fields. The concrete form of the gravitational anomalies in the model may directly be calculated by using the heat kernel.[3]

The heat kernel $K^{\{d\}}(x,x')$ for a fermion of spin-$\frac{1}{2}$ in $d$ dimensions defined by

$$\frac{\partial}{\partial t}K^{(d)}(x,x';t) = -HK^{(d)}(x,x';t), \tag{1}$$

$$K^{(d)}(x,x';0) = \mathbf{1}|h(x)|^{-\frac{1}{2}}|h(x')|^{-\frac{1}{2}}\delta^{(d)}(x,x'), \tag{2}$$

where $\delta^{(d)}(x,x')$ is the $d$-dimensional invariant $\delta$-function, $\mathbf{1} = \{\delta^A{}_B\}$ the unit matrix for the spinor, and $h = \det h^a{}_\mu$, in which $h^a{}_\mu$ is a vielbein. Here $H$ is the second order differential operator, corresponding to the square of the Dirac operator $\not{D}$ in the case of the fermion $\psi$,

$$H = \not{D}^2 = D_\mu D^\mu + X, \quad \not{D} = \gamma^\mu\nabla_\mu + Y, \quad D_\mu = \nabla_\mu + Q_\mu, \quad Q_\mu = \frac{1}{2}\{\gamma_\mu, Y\},$$

$$X = Z - \nabla_\mu Q^\mu - Q_\mu Q^\mu, \quad \nabla_\mu\psi = \partial_\mu\psi + \frac{1}{4}\,\omega^{ab}{}_\mu\,\gamma_{ab}\,\psi, \quad \gamma_{a_1\cdots a_j} = \gamma_{[a_i}\cdots\gamma_{a_j]},$$

$$Z = \frac{1}{2}\,\gamma^{\mu\nu}\,[\nabla_\mu, \nabla_\nu] + \gamma^\mu\nabla_\mu Y + Y^2, \qquad [D_\mu, D_\nu]\psi = \Lambda_{\mu\nu}\,\psi, \tag{3}$$

where $\omega^{ab}{}_{\mu}$ is the Ricci's coefficient of rotation. When in $d = 2n$ dimensions the fermion interacts with vector and axial-vector fields which do not commute each other, the Dirac operator contains the coupling of these bosons in $Y$,

$$Y = \gamma^{\mu} V_{\mu} + \gamma_{2n+1} \gamma^{\mu} A_{\mu}, \quad V_{\mu} \equiv V_{\mu}^{a} T^{a}, \quad A_{\mu} \equiv A_{\mu}^{a} T^{a}, \quad \gamma_{2n+1} = i^{n} \gamma^{1} \gamma^{2} \cdots \gamma^{2n}. \tag{4}$$

Here the representation matrix $T^a$ of a gauge group, and $V_{\mu}^{a}$ ($A_{\mu}^{a}$) is pure imaginary (real), because of the hermiticity of the Dirac operator. The quantities $Q_{\mu}$, $X$ and $\Lambda_{\mu\nu}$ in (3) are expressed in the following tensorial form,

$$\begin{aligned}
&Q_{\mu} = V_{\mu} - \gamma_{2n+1}\, \gamma_{\mu\rho} A^{\rho}, \qquad F_{\mu\nu} = \partial_{\mu} V_{\nu} - \partial_{\nu} V_{\mu} + [V_{\mu}, V_{\nu}], \\
&X = -\frac{1}{4}\, R + 2(n-1)\, A_{\mu} A^{\mu} - \gamma_{2n+1}^{\prime} A^{\mu}{}_{;\mu} + \gamma^{\mu\nu} \left( \frac{1}{2}\, F_{\mu\nu} + \frac{2n-3}{2}\, [A_{\mu}, A_{\nu}] \right), \\
&\Lambda_{\mu\nu} = \frac{1}{4}\, \gamma^{\rho\sigma} R_{\rho\sigma\mu\nu} + F_{\mu\nu} - [A_{\mu}, A_{\nu}] - 2\, \gamma_{\mu\nu} A_{\rho} A^{\rho} + 2\, \gamma_{[\mu|}{}^{\rho} \{ A_{|\nu]}, A_{\rho} \} \\
&\qquad + 2\, \gamma_{2n+1}\, \gamma_{[\mu|\rho} A^{\rho}{}_{;|\nu]} - 2\, \gamma_{\mu\nu\rho\sigma} A^{\rho} A^{\sigma},
\end{aligned} \tag{5}$$

where $R_{\rho\sigma\mu\nu}$ denotes the curvature tensor, and the semi-colon '$;\mu$' means the Riemannian covariant differentiation $\nabla_{\mu} + V_{\mu}$ with respect to the vector gauge field. The completely antisymmetric product $\gamma_{\mu\nu\rho\sigma}$ of $\gamma$-matrices in the last term of $\Lambda_{\mu\nu}$ is rewritten by $-\epsilon_{\mu\nu\rho\sigma}\gamma_5$ and $-\frac{i}{2}\epsilon_{\mu\nu\rho\sigma\kappa\lambda}\gamma_7\gamma^{\kappa\lambda}$ in 4 and 6 dimensions, respectively.

The differential equation (1) of the heat kernel for the fermion interacting with the general boson fields is not solvable strictly. Therefore the heat kernel is usually calculated by using De Witt's ansatz[4], automatically satisfying (2),

$$K^{(2n)}(x, x'; t) \sim \frac{\Delta^{1/2}(x, x')}{(4\pi t)^{n}} \exp\left( \frac{\sigma(x, x')}{2t} \right) \sum_{q=0}^{\infty} a_q(x, x')\, t^{q}, \tag{6}$$

where $\sigma\,(x, x')$ is a half of square of the geodesic distance between $x$ and $x'$, $\Delta\,(x, x') = |h(x)|^{-1} |h(x')|^{-1} \det\{\nabla_{\mu} \nabla_{\nu'} \sigma\,(x, x')\}$, and $a_q(x, x')$ are bispinors. Note that the metric tensor in curved space is $g_{\mu\nu} = h^{a}{}_{\mu} h^{b}{}_{\nu} \eta_{ab}$ with $\eta_{ab} = -\,\delta_{ab}$ in flat tangent space, and that the coincidence limit of $a_0$ is $\lim_{x' \to x} a_0(x, x') \equiv [a_0](x) = \mathbf{1}$. The products of $\sigma_{;\mu}$ ($\equiv \nabla_{\mu}\sigma$) construct orthonormal bases $|n\rangle$ being the eigenfunctions for $\sigma^{;\nu} D_{\nu}$, and the bispinor $a_q$ can be expanded by the bases,[5]

$$\begin{aligned}
&a_q = \sum_{n=0}^{\infty} |n\rangle\langle n|a_q\rangle = \sum_{n} \frac{(-1)^{n}}{n!} \sigma^{;\mu_1'} \cdots \sigma^{;\mu_n'} \lim_{x \to x'} \left[ D_{(\mu_1} \cdots D_{\mu_n)} a_q \right], \\
&a_q\,(x, x') = \langle 0|a_q\rangle\,(x') - \langle \mu|a_q\rangle\,(x')\, \sigma^{;\mu'}\,(x, x') + \cdots .
\end{aligned} \tag{7}$$

The gravitational anomalies are obtained in the case of a massless Weyl fermion $\psi_L$ in $2n$ dimensions. The formal expressions of two gravitational anomalies, *i.e.* the general coordinate anomaly $\mathcal{A}_{\mu}^{(2n)}$ and the Lorentz anomaly $\mathcal{A}_{\mu\nu}^{(2n)}$, are given from the path integral measure.[6] They are expressed by using the heat kernel

$K^{(2n)}(x,x';t)$ after the Gaussian cut-off regularization,

$$
\begin{aligned}
&D^\mu\langle T_{\mu\nu}\rangle = \mathcal{A}_\nu^{(2n)}, \qquad \langle T_{\mu\nu}\rangle_{\rm A} \equiv \frac{1}{2}(\langle T_{\mu\nu}\rangle - \langle T_{\nu\mu}\rangle) = \mathcal{A}_{\mu\nu}^{(2n)},\\
&\mathcal{A}_\nu^{(2n)}(x) = -\frac{1}{2}\lim_{t\to 0}\lim_{x'\to x}{\rm Tr}\left\{\gamma_{2n+1}\left(D_\nu - D_{\nu'}\right)K^{(2n)}(x,x';t)\right\},\\
&\mathcal{A}_{\mu\nu}^{(2n)}(x) = -\frac{1}{4}\lim_{t\to 0}\lim_{x'\to x}{\rm Tr}\left\{\gamma_{2n+1}\gamma_{\mu\nu}K^{(2n)}(x,x';t)\right\},
\end{aligned}
\tag{8}
$$

where Tr runs over both indices of $\gamma$-matrices and representation matrices of the gauge group. Since these anomalies simultaneously appear and are related to each other, $\mathcal{A}_\nu^{(2n)} = 2D^\mu\mathcal{A}_{\mu\nu}^{(2n)}$,[7] it seems that both general covariance and local Lorentz symmetry break down.

We consider the "pure" general coordinate anomaly $G_\mu$ is given by redefining the energy-momentum tensor density so that the local Lorentz symmetry is preserved,

$$
D^\mu\langle T'_{\mu\nu}\rangle = D^\mu\langle T'_{\mu\nu}\rangle_S = G_\nu^{(2n)} = D^\mu\mathcal{A}_{\mu\nu}^{(2n)} = \frac{1}{2}\mathcal{A}_\nu^{(2n)}, \qquad \langle T'_{\mu\nu}\rangle_A = 0 \tag{9}
$$

with $\langle T'_{\mu\nu}\rangle = \langle T_{\mu\nu}\rangle - \mathcal{A}_{\mu\nu}^{(2n)}$, where $\langle T'_{\mu\nu}\rangle_S$ is the symmetric part of the expectation value of the energy-momentum tensor. The "pure" general coordinate anomaly in (9) is called as the Einstein anomaly. The "pure" Lorentz anomaly is also obtained by redefining the energy-momentum tensor density so that the general covariance is preserved,

$$
\langle T''_{\mu\nu}\rangle = \langle T_{\mu\nu}\rangle - 2\mathcal{A}_{\mu\nu}^{(2n)}, \qquad D^\mu\langle T''_{\mu\nu}\rangle = 0, \qquad \langle T''_{\mu\nu}\rangle_A = -\mathcal{A}_{\mu\nu}^{(2n)}. \tag{10}
$$

In order to perform the concrete calculation in $2n$ dimensions, the Einstein anomaly is rewritten by the expansion coefficients of $a_n$ in (7) and its derivatives,

$$
G_\nu^{(2n)}(x) = -\frac{1}{4(4\pi)^n}{\rm Tr}\left\{\gamma_{2n+1}(2\langle\nu|a_n\rangle - \langle 0|a_n\rangle_{!\nu})(x)\right\}. \tag{11}
$$

where the exclamation mark '$!\nu$' means the modified covariant differentiation $D_\nu$. The anomaly in 4-dimensional curved space had already been derived,[8,9]

$$
\begin{aligned}
G_\nu^{(4)} &= -\frac{1}{64\pi^2}{\rm Tr}\big\{\gamma_5(2\langle\nu|a_2\rangle - \langle 0|a_2\rangle_{!\nu})\big\} = \frac{1}{192\pi^2}{\rm Tr}\,\gamma_5\left(\Lambda_{\mu\nu}X\right)^{!\mu}\\
&= \frac{1}{64\pi^2}{\rm tr}\Big[\epsilon_{\mu\nu\rho\sigma}\Big(\frac{1}{6}R^{\rho\sigma}{}_{\kappa\lambda}F^{\kappa\lambda} - \frac{1}{6}RF^{\rho\sigma} + \frac{1}{3}F^{\rho\sigma;\lambda}{}_\lambda\\
&\quad + \frac{4}{3}\{A_\lambda, A^\rho\}F^{\lambda\sigma} + \frac{8}{3}A^\rho A^\sigma A_\lambda A^\lambda\Big)\\
&\quad - \frac{4}{3}(F_{\mu\nu}A^\sigma{}_{;\sigma} + 2F_{[\mu|\lambda}A^\lambda{}_{;|\nu]}) + 8A_{[\mu}A_\nu A^\sigma{}_{;\sigma]}\Big]^{;\mu},
\end{aligned}
\tag{12}
$$

where "tr" means a trace over the representation matrices of the gauge group. A derivative term in $G_\nu^{(4)}$ before the trace operation of $\gamma$-matrices becomes some terms in tensorial form after the operation, and the Lorentz anomaly $\mathcal{A}_{\mu\nu}^{(4)}$ may easily be given from the resultant form of $G_\nu^{(4)}$ by the relation (9). Such properties of $G_\nu^{(4)}$

is succeeded in the case of $G_\nu^{(6)}$. Indeed, the straightforward calculation gives the concrete form of $G_\nu^{(6)}$ as expected,

$$
\begin{aligned}
G_\nu^{(6)} &= -\frac{1}{256\pi^3}\mathrm{Tr}\big\{\gamma_7(2\langle\nu|a_3\rangle - \langle 0|a_3\rangle_{!\nu})\big\} \\
&= -\frac{1}{256\pi^3}\mathrm{Tr}\Big\{\gamma_7\Big[\frac{1}{6}\Lambda_{\mu\nu}\left(\frac{1}{6}R + X\right)^2 + \frac{1}{45}J_{[\mu}X_{!\nu]} - \frac{1}{60}J_{[\mu!\nu]}X \\
&\quad + \frac{1}{15}\Lambda_{\mu\nu}X_{!\rho}{}^{\rho} + \frac{2}{45}\Lambda_{\mu\nu!\rho}X^{!\rho} + \frac{1}{40}\Lambda_{\mu\nu!\rho}{}^{\rho}X + \frac{1}{180}[\Lambda_{\mu\rho},\Lambda_\nu{}^\rho]X \\
&\quad + \frac{1}{180}R^\rho{}_{[\mu}\Lambda_{\nu]\rho}X + \frac{17}{360}R_{\mu\nu\rho\sigma}\Lambda^{\rho\sigma}X + \frac{1}{36}\Lambda_{\mu\nu}\Lambda_{\rho\sigma}\Lambda^{\rho\sigma} \\
&\quad + \frac{1}{45}\Lambda_{[\mu}{}^\rho\Lambda_{\nu]}{}^\sigma\Lambda_{\rho\sigma} - \frac{1}{90}\Lambda_{\mu\nu!\rho}J^\rho + \frac{1}{45}\Lambda_{\rho[\mu}J_{\nu]}{}^{!\rho}\Big]^{;\mu}\Big\} \\
&= \frac{i}{32\pi^3}\,\mathrm{tr}\Big[\epsilon^{\alpha\beta\gamma\delta\kappa\lambda}\Big\{\frac{1}{96}R_{\mu\nu\alpha\beta}F_{\gamma\delta}F_{\kappa\lambda} + \frac{1}{2304}R_{\mu\nu\alpha\beta}R_{\rho\sigma\gamma\delta}R^{\rho\sigma}{}_{\kappa\lambda} \\
&\quad + \frac{1}{2880}R_{[\mu|\rho\alpha\beta}R_{|\nu]\sigma\gamma\delta}R^{\rho\sigma}{}_{\kappa\lambda}\Big\} + \frac{1}{15}A^{\rho;\sigma}{}_{\sigma[\mu}F_{\nu]\rho} - \frac{1}{15}A^\rho{}_{;\rho\sigma}{}^\sigma F_{\mu\nu} \\
&\quad - \frac{1}{45}A^\rho{}_{;\rho[\mu}F_{\nu]\sigma}{}^{;\sigma} + \frac{1}{90}A_{\rho;\sigma}{}^\sigma F_{\mu\nu}{}^{;\rho} + \frac{1}{45}A_{\rho;\sigma[\mu}F^{\rho\sigma}{}_{;\nu]} - \frac{2}{45}A_\sigma{}^{;\sigma\rho}F_{\mu\nu;\rho} \\

\end{aligned}
\tag{13}
$$

where $J^\rho\equiv\Lambda^{\sigma\rho}{}_{!\sigma}$. Some total derivative terms in $G^{(6)}_\nu$ before the trace operation yield many terms in tensorial form, by using (5), and the derivation is still in progress. The third order terms of $A$ in (13) are 157 terms, of which some terms contain the vector field strength and the curvature tensor, though these terms may be rewritten by the Bianchi and Jacobi identities and by symmetries of the curvature tensor and the vector field strength.

If all $A_\mu$ are abelian in (12), then $G^{(4)}_\nu$ corresponds to the anomaly in space with torsion, which is originally expressed by the third order antisymmetric tensor. The dual vector of the tensor in four dimensions behaves as the axial-vector.[8] Note that the dual tensor of torsion in six or higher dimensions is the third or higher order antisymmetric tensor. In supergravity, there appear the contributions of the vector, the axial-vector and the third order antisymmetric tensor fields, together, which do not commute. The anomaly with the vector and the axial-vector fields in

six-dimensional space with nonabelian torsion may have the new terms containing the third order torsion tensor.

We consider rigidly-rotating thermal states of a massless Klein-Gordon field enclosed within a cylindrical boundary, where Robin boundary conditions (RBCs) are imposed. The connection between the parameter of the RBCs and the energy density and four-velocity expressed in the Landau frame is revealed.

*Keywords*: Klein-Gordon field; Finite temperature field theory; Robin boundary conditions; Landau decomposition.

## 1. Introduction

In quantum field theory, the boundary conditions (b.c.s) are imposed at the level of the field operator $\Phi$, or equivalently, of the quantum modes. The interplay between the b.c. formulation and the ensuing operator expectation values in various states is far from obvious. In this paper, we consider the connection between the choice of b.c.s and the thermal expectation value (t.e.v.) of the stress-energy tensor (SET) operator in rigidly-rotating finite temperature states of the massless Klein-Gordon (KG) field. We show that the free parameter $\Psi$ in the Robin b.c.s (RBCs) can be related to the values of the Landau frame macroscopic four-velocity and energy density on the boundary.

The outline of this paper is as follows. In Sec. 2, the mode solutions of the KG equation inside a cylinder are reviewed. The procedure for constructing t.e.v.s in rigidly-rotating systems is summarised in Sec. 3. The analysis of the SET using the Landau frame decomposition and the connection between the Landau velocity $v$ and $\Psi$ is presented in Sec. 4. Section 5 concludes this paper.

## 2. Rigidly-rotating thermal expectation values

Let $\hat{\Phi}(x)$ be the field operator for a massless, neutral (real) scalar field which is confined within a cylinder of radius $R$, obeying the KG equation:

$$\Box\hat{\Phi}(x) = 0. \tag{1}$$

The mode solutions of Eq. (1) can be obtained as follows:[1]

$$f_j = \frac{N_j}{\sqrt{8\pi^2\omega_j}} e^{-i\omega_j t + ik_j z + im_j\varphi} J_{m_j}(q_j\rho), \tag{2}$$

where $(\rho, \varphi, z)$ are the usual cylindrical coordinates, while $\omega_j > 0$, $k_j$ and $m_j$ are the eigenvalues of the Hamiltonian $\hat{H}$, longitudinal momentum $\hat{P}_z$ and $z$ component of the angular momentum, $\hat{L}_z$. In order to fix the normalisation constant $N_j$, we

evaluate the KG inner product for $f_j$ and $f_{j'}$:

$$\begin{aligned}\langle f_j, f_{j'}\rangle &= i\int_{-\infty}^{\infty} dz \int_0^{\infty} \rho\, d\rho \int_0^{2\pi} d\varphi (f_j^* \partial_t f_{j'} - f_{j'} \partial_t f_j^*) \\ &= \frac{N_j^* N_{j'}(\omega_j + \omega_{j'})}{2\sqrt{\omega_j \omega_{j'}}} e^{i(\omega_j - \omega_{j'})t} \delta_{m_j, m_{j'}} \delta(k_j - k_{j'}) \frac{R}{q_j^2 - q_{j'}^2} \\ &\quad \times \left[ J_{m_j}(q_j R) q_{j'} J'_{m_j}(q_{j'} R) - J_{m_j}(q_{j'} R) q_j J'_{m_j}(q_j R) \right], \end{aligned} \tag{3}$$

where a standard identity involving integrals of Bessel functions was employed.[2] Orthogonality is ensured when the transverse momenta $q_j \to q_{m,\ell}$ are discretised according to the Robin boundary conditions:[3]

$$q_{m,\ell} R J'_m(q_{m,\ell} R) + \Psi J_m(q_{m,\ell} R) = 0, \tag{4}$$

where $\ell = 1, 2, \ldots$ indexes the non-negative solutions of Eq. (4) for fixed $m$ in ascending order, while $\Psi$ is considered to be a constant, real number. It is easy to see that $\Psi = 0$ corresponds to the von Neumann b.c.s $[J'_m(q_{m,\ell} R) = 0]$, while the Dirichlet b.c.s $[J_m(q_{m,\ell} R) = 0]$ can be recovered in the limit $\Psi \to \infty$. Imposing $\langle f_{km\ell}, f_{k'm'\ell'}\rangle = \delta(k - k')\delta_{m,m'}\delta_{\ell,\ell'}$ yields:[3]

$$N_{k,m,\ell} = \frac{q_{m,\ell}\sqrt{2}}{|J_m(q_{m,\ell} R)| \sqrt{q_{m,\ell}^2 R^2 + \Psi^2 - m^2}}. \tag{5}$$

The canonical expansion of the field operator with respect to the modes $f_j$ is:

$$\hat{\Phi}(x) = \sum_j \left[ f_j(x) \hat{a}_j + f_j^*(x) \hat{a}_j^\dagger \right], \tag{6}$$

where the one-particle creation ($\hat{a}_j^\dagger$) and annihilation ($\hat{a}_j$) operators obey the standard commutation relation $[\hat{a}_j, \hat{a}_{j'}^\dagger] = \delta(j, j')$.

## 3. Rigidly-rotating thermal states

We now consider rigidly-rotating thermal states, corresponding to an inverse temperature $\beta$ and an angular velocity $\Omega$. The thermal expectation value (t.e.v.) of an operator $\hat{A}$ is computed using the density operator $\hat{\rho}$ as follows:

$$\langle \hat{A} \rangle_\beta = Z^{-1} \mathrm{tr}(\hat{\rho} \hat{A}), \qquad \hat{\rho} = \exp\left[ -\beta(\hat{H} + \Omega \hat{L}_z) \right], \tag{7}$$

where $Z = \mathrm{tr}(\hat{\rho})$ is the partition function. It can be shown that:[4]

$$\langle \hat{a}_j^\dagger \hat{a}_{j'} \rangle_\beta = \frac{\delta(j, j')}{e^{\beta \widetilde{\omega}_j} - 1}, \qquad \widetilde{\omega}_j = \omega_j - \Omega m_j. \tag{8}$$

Equation (8) is not valid when the co-rotating energy $\widetilde{\omega}_j < 0$, since in this case, the vacuum limit (corresponding to $\beta \to \infty$) yields a non-vanishing value.[5] Moreover, modes with $\widetilde{\omega} < 0$ make infinite contributions to rigidly-rotating t.e.v.s.[1] It is noteworthy that finite quantum corrections can still be computed perturbatively.[6]

It is reasonable to expect that t.e.v.s should stay finite for all values of $\Omega$ provided that $\Omega R < 1$, which requires that $q_{m,\ell} R \geq m$. This property can be ensured only when $\Psi \geq 0$, thus we do not consider negative values of $\Psi$ in this paper.

Starting from the following expressions for the SET operator:[7,8]

$$\hat{T}_{\mu\nu} = \frac{2}{3}\nabla_{(\mu}\hat{\Phi}\nabla_{\nu)}\hat{\Phi} - \frac{1}{3}\hat{\Phi}\nabla_{(\mu}\nabla_{\nu)}\hat{\Phi} - \frac{1}{6}g_{\mu\nu}[(\nabla\hat{\Phi})^2 + \mu^2\hat{\Phi}^2], \tag{9}$$

the t.e.v. of the components of the SET can be obtained using the mode expansion (6) of the field operator. It is convenient to express the results with respect to the tetrad comprised of the vectors $e_{\hat{t}} = \partial_t$, $e_{\hat{\rho}} = \partial_\rho$, $e_{\hat{\varphi}} = \rho^{-1}\partial_\varphi$ and $e_{\hat{z}} = \partial_z$. Using the notation $T_{\hat{\alpha}\hat{\gamma}} \equiv \langle : \hat{T}_{\hat{\alpha}\hat{\gamma}} : \rangle_\beta$, the following results can be obtained:[9]

$$\begin{aligned}
T_{\hat{\alpha}\hat{\gamma}} &= \sum_{m=-\infty}^{\infty}\sum_{\ell=1}^{\infty}\int_{-\infty}^{\infty}\frac{N_{km\ell}^2 dk}{12\pi^2\omega_{km\ell}(e^{\beta\widetilde{\omega}_{km\ell}}-1)}F_{\hat{\alpha}\hat{\gamma}},\\
F_{\hat{t}\hat{t}} &= \left(6\omega^2 + \rho^{-2}m^2 - q^2\right)J_m^2 + q^2 {J'_m}^2,\\
F_{\hat{\varphi}\hat{t}} &= -6\omega\rho^{-1}mJ_m^2,\\
F_{\hat{\rho}\hat{\rho}} &= \left(-3\rho^{-2}m^2 + 3q^2\right)J_m^2 + 2q\rho^{-1}J_m J'_m + 3q^2 {J'_m}^2,\\
F_{\hat{\varphi}\hat{\varphi}} &= \left(5\rho^{-2}m^2 + q^2\right)J_m^2 - 2q\rho^{-1}J_m J'_m - q^2 {J'_m}^2,\\
F_{\hat{z}\hat{z}} &= \left(6k^2 - \rho^{-2}m^2 + q^2\right)J_m^2 - q^2 {J'_m}^2,
\end{aligned} \tag{10}$$

where it is understood that $\omega \equiv \omega_{m,\ell}$ and $q \equiv q_{m,\ell}$, while the Bessel functions and their derivatives take the argument $q_{m,\ell}\rho$. It can be shown that the components of the SET not displayed above vanish for all values of $\rho$, $\beta$ and $\Omega$.

## 4. Landau decomposition

The matrix structure of the SET given in Eq. (10) can be summarised as follows:

$$T_{\hat{\alpha}\hat{\gamma}} = \begin{pmatrix} T_{\hat{t}\hat{t}} & 0 & T_{\hat{t}\hat{\varphi}} & 0 \\ 0 & T_{\hat{\rho}\hat{\rho}} & 0 & 0 \\ T_{\hat{t}\hat{\varphi}} & 0 & T_{\hat{\varphi}\hat{\varphi}} & 0 \\ 0 & 0 & 0 & T_{\hat{z}\hat{z}} \end{pmatrix}. \tag{11}$$

The energy density $E$ and macroscopic four-velocity $u^{\hat{\alpha}}$ can be obtained in the Landau frame by solving the eigenvalue equation $T^{\hat{\alpha}}{}_{\hat{\gamma}}u^{\hat{\gamma}} = -Eu^{\hat{\alpha}}$.[10,11] The physically relevant solution for $E$ reads:

$$E = \frac{1}{2}\left[T_{\hat{t}\hat{t}} - T_{\hat{\varphi}\hat{\varphi}} + \sqrt{(T_{\hat{t}\hat{t}} + T_{\hat{\varphi}\hat{\varphi}})^2 - 4T_{\hat{t}\hat{\varphi}}^2}\right], \tag{12}$$

while the Landau velocity $u^{\hat{\alpha}} = \Gamma(1, 0, v, 0)^T$ can be characterised via:

$$v = -\frac{T_{\hat{t}\hat{\varphi}}}{E + T_{\hat{\varphi}\hat{\varphi}}}, \qquad \Gamma = \frac{1}{\sqrt{1-v^2}}. \tag{13}$$

Further manipulation of the above relations gives:

$$\frac{v}{1+v^2} = -\frac{T_{\hat{t}\hat{\varphi}}}{T_{\hat{t}\hat{t}} + T_{\hat{\varphi}\hat{\varphi}}}. \tag{14}$$

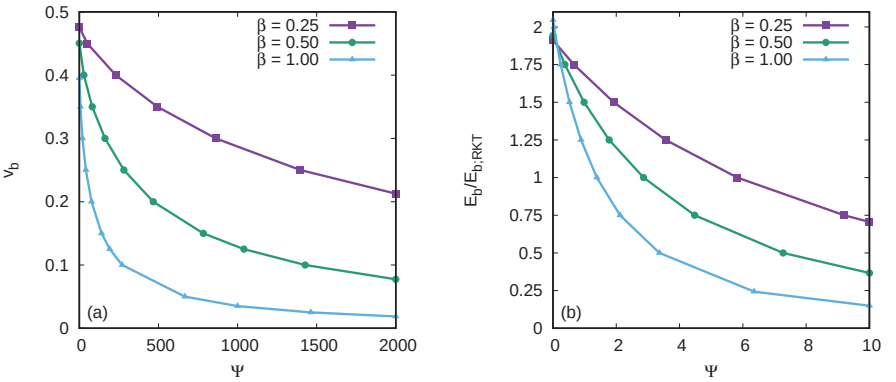

Fig. 1. The dependence of (a) $v_\mathrm{b}$ and (b) $E_\mathrm{b}/E_{\mathrm{b;RKT}}$ on $\Psi$ for various values of the inverse temperature $\beta$ when $\Omega = 0.5$ and $R = 1$.

When Dirichlet b.c.s are employed, it is easy to see that $v$ vanishes on the boundary. For finite values of $\Psi$, $v$ is in general non-vanishing on the boundary. Let $v_\mathrm{b}$ denote the value of $v$ on the boundary. We now ask what is the value of $\Psi$ which ensures $v(R) = v_\mathrm{b}$. Inverting Eq. (14) in order to obtain $\Psi$ as a function of $v_\mathrm{b}$ does not seem feasible. Instead, an iterative procedure can be established which allows the value of $\Psi$ to be computed numerically. Starting from:

$$
\begin{aligned}
T_{\hat{t}\hat{\varphi}}\rfloor_R &= -\sum_{m,\ell}\left(1+\frac{\Psi^2-m^2}{q^2R^2}\right)^{-1}\int_0^\infty dk\frac{2m}{\pi^2R^3(e^{\beta\widetilde{\omega}}-1)},\\
(T_{\hat{t}\hat{t}}+T_{\hat{\varphi}\hat{\varphi}})_R &= \sum_{m,\ell}\left(1+\frac{\Psi^2-m^2}{q^2R^2}\right)^{-1}\int_0^\infty dk\frac{2(m^2+\omega^2R^2+\frac{\Psi}{3})}{\pi^2R^4\omega(e^{\beta\widetilde{\omega}}-1)},
\end{aligned}
\tag{15}
$$

where the sums over $m$ and $\ell$ run between $-\infty$ and $\infty$ and 1 and $\infty$, respectively, it can be seen that $\Psi$ can be isolated from the last term of the second equality above:

$$
\Psi = \frac{3\displaystyle\sum_{m,\ell}\left(1+\frac{\Psi^2-m^2}{q^2R^2}\right)^{-1}\int_0^\infty \frac{dk}{\omega(e^{\beta\widetilde{\omega}}-1)}\left[m\omega R-\frac{v_\mathrm{b}(\omega^2R^2+m^2)}{1+v_\mathrm{b}^2}\right]}{\dfrac{v_\mathrm{b}}{1+v_\mathrm{b}^2}\displaystyle\sum_{m,\ell}\left(1+\frac{\Psi^2-m^2}{q^2R^2}\right)^{-1}\int_0^\infty\frac{dk}{e^{\beta\widetilde{\omega}}-1}}.
\tag{16}
$$

Equation (16) is solved iteratively. The value $\Psi^{(n)}$ corresponding to iteration $n$ is obtained by evaluating the right hand side of Eq. (16) after replacing $\Psi$ with the value $\Psi^{(n-1)}$ obtained at iteration $n-1$, while $v_\mathrm{b}$ is kept fixed at the desired value. Starting from $\Psi^{(0)} = 0$ yields the convergence value within a relatively small number of iterations and the process seems to be stable as long as $v_\mathrm{b}$ can be obtained using $\Psi \geq 0$. To illustrate the procedure, we consider a system with $R = 1$ and $\Omega = 0.5$. Figure 1(a) shows the variation of $v_\mathrm{b}$ with $\Psi$ for $\beta \in \{0.25, 0.5, 1\}$.

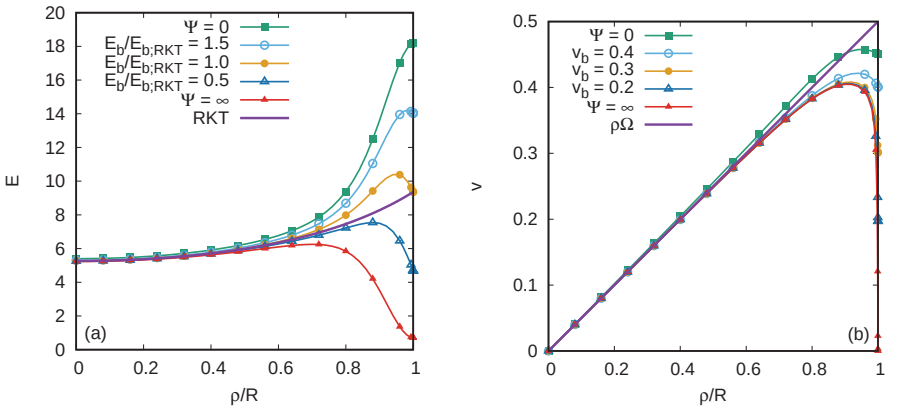

Fig. 2. Profiles of (a) $E$ and (b) $v$ for various values of $\Psi$ at $\beta = \Omega = 0.5$ and $R = 1$. The QFT results are shown using lines and points, while the solid purple line represents the RKT results.

It is natural to consider the relation between the Landau energy density $E_{\rm b}$ measured on the boundary and the energy density $E_{\rm b;RKT}$ expected for a rigidly-rotating Bose-Einstein gas, for which[12]

$$v_{\rm RKT} = \rho\Omega, \qquad E_{\rm RKT} = \frac{\pi^2 \Gamma_{\rm RKT}^4}{30\beta^4}. \tag{17}$$
