**Publications in the Series of Proceedings**

Proceedings of the Fifteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2018)
Edited by E.S. Battistelli, R.T. Jantzen, R. Ruffini
World Scientific, 2021

Proceedings of the Fourteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2015)
Edited by M. Bianchi, R.T. Jantzen, R. Ruffini
World Scientific, 2017

Proceedings of the Thirteenth Marcel Grossmann Meeting on General Relativity
(Stockholm, Sweden, 2012)
Edited by K. Rosquist, R.T. Jantzen, R. Ruffini
World Scientific, 2015

Proceedings of the Twelfth Marcel Grossmann Meeting on General Relativity
(Paris, France, 2009)
Edited by T. Damour, R.T. Jantzen, R. Ruffini
World Scientific, 2012

Proceedings of the Eleventh Marcel Grossmann Meeting on General Relativity
(Berlin, Germany, 2006)
Edited by H. Kleinert, R.T. Jantzen, R. Ruffini
World Scientific, 2007

Proceedings of the Tenth Marcel Grossmann Meeting on General Relativity
(Rio de Janiero, Brazil, 2003)
Edited by M. Novello, S. Perez-Bergliaffa, R. Ruffini
World Scientific, 2005

Proceedings of the Ninth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2000)
Edited by V.G. Gurzadyan, R.T. Jantzen, R. Ruffini
World Scientific, 2002

Proceedings of the Eighth Marcel Grossmann Meeting on General Relativity
(Jerusalem, Israel, 1997)
Edited by T. Piran
World Scientific, 1998

Proceedings of the Seventh Marcel Grossmann Meeting on General Relativity
(Stanford, USA, 1994)
Edited by R.T. Jantzen and G.M. Keiser
World Scientific, 1996

Proceedings of the Sixth Marcel Grossmann Meeting on General Relativity
(Kyoto, Japan, 1991)
Edited by H. Sato and T. Nakamura
World Scientific, 1992

Proceedings of the Fifth Marcel Grossmann Meeting on General Relativity
(Perth, Australia, 1988)
Edited by D.G. Blair and M.J. Buckingham
World Scientific, 1989

Proceedings of the Fourth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 1985)
Edited by R. Ruffini
World Scientific, 1986

Proceedings of the Third Marcel Grossmann Meeting on General Relativity
(Shanghai, People's Republic of China, 1982)
Edited by Hu Ning
Science Press – Beijing and North-Holland Publishing Company, 1983

Proceedings of the Second Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1979)
Edited by R. Ruffini
North-Holland Publishing Company, 1982

Proceedings of the First Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1975)
Edited by R. Ruffini
North-Holland Publishing Company, 1977

## SPONSORS

International Center for Relativistic Astrophysics Network (ICRANet)
International Center for Relativistic Astrophysics (ICRA)
International Centre for Theoretical Physics (ICTP)
Istituto Nazionale di Astrofisica (INAF)
International Union of Pure and Applied Physics (IUPAP)

## FREEDOM OF MOVEMENT FOR SCIENTISTS

The Marcel Grossman Meetings were founded with the premise that scientists of all nations have a right to meet to exchange knowledge independent of national borders. As such we affirm the IUPAP declaration: "To secure IUPAP sponsorship, the organisers have provided assurance that MG15 will be conducted in accordance with IUPAP principles as stated in the IUPAP resolution passed by the General Assembly in 2008. In particular, no bona fide scientist will be excluded from participation on the grounds of national origin, nationality, or political considerations unrelated to science."

## ACKNOWLEDGEMENTS

We acknowledge the outstanding job done before, during and after the meeting by the ICRANet/ICRA administrative and secretarial staff: Cristina Adamo, Silvia Latorre, Elisabetta Natale, and Cinzia di Niccolo and the conference agency support of Sistema Congressi (Marisa Santori, Ilaria Coccato, Lorena Moretti). Finally this meeting and its proceedings could not have functioned without the dedicated IT support of the ICRA system manager Vittorio Vannini for every MG meeting this century and the ICRANet system manager Gabriele Brandolini, with some temporary assistance from Valerio Antonucci and Damiano Verzulli.

## ORGANIZING BODIES OF THE FIFTEENTH MARCEL GROSSMANN MEETING:

### INTERNATIONAL ORGANIZING COMMITTEE

David Blair, Yvonne Choquet-Bruhat, Thibault Damour, Paolo De Bernardis, Francis Everitt, Riccardo Giacconi, Theodor Haensch, Stephen Hawking, Marc Henneaux, Christine Jones Forman, Roy Kerr, Hagen Kleinert, Jutta Kunz, Claus Laemmerzahl, Malcolm Longair, Tsvi Piran, Jorge Rueda, Remo Ruffini (Chair), Misao Sasaki, Humitaka Sato, Rashid Sunayev, Gerard 't Hooft, Steven Weinberg, Shing-Tung Yau

### LOCAL ORGANIZING COMMITTEE

Amati, L., Angelantonj, C., Barbiellini, G., Bassan, M., Battistelli, E. S. (chair), Belinski, V.A., Belli, L., Benedetti, R., Bernabei, R., Bianchi, M., Bianco, C.L. (co-chair), Bini, D., Buchert, T., Burgio, F., Capozziello, S., Chakrabarti, S.K., Chardonnet, P., Dall'Agata, G., De Angelis, A., De Bernardis, P., Della Valle, M., Di Virgilio, A., Frasca S., Fraschetti, F., Fré, P., Frontera, F., Giavalisco, M., Giommi, P., Gionti, G., Ingrosso, G., Jantzen, R.T., Jetzer, P., Lee, H.-W., Lerda, A., Liberati, S., Longo, R., Luzzi, G., Mandolesi, N., Marmo, G., Menotti, P., Merafina, M., Morselli, A., Pani, P., Pelster, A., Piacentini, F., Pian, E., Procesi, C., Quevedo, H., Ricci, F., Riccioni, F., Rosati, P., Ruffo, S., Scarpetta, E.V., Tavani, M., Titarchuk, L.G., Vereshchagin, G.V., Xue, S.-S., Zen Vasconcellos, C.

### INTERNATIONAL COORDINATING COMMITTEE

ALBANIA: Hafizi, M. ARGENTINA: Arguelles, C., Ghezzi, C.R., Mirabel, F., Romero, G.E. ARMENIA: Sahakyan, N. AUSTRALIA: Blair, D., Ju, L., Lun, A., Manchester, D., Melatos, A., Quinn, P., Scott, S.M., Steele, J.D., AUSTRIA: Aichelburg, P.C., Schindler, S. BELARUS: Kilin, S., Minkevich, A.V., Siutsou, I.A. ## MARCEL GROSSMANN AWARDS

## FIFTEENTH MARCEL GROSSMANN MEETING

### Institutional Award

Planck Scientific Collaboration (ESA) (ESA)

*"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding Bpolarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy."*
— presented to its Director General Johann-Dietrich Woerner

### Institutional Award

Hansen Experimental Physics Laboratory (HEPL) at Stanford University

*"for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology."*

### Individual Awards

Lyman Page
*"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and who now leads the Atacama Cosmology Telescope as its project scientist."*

Rashid Alievich Sunyaev
*"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe."*

Shing-Tung Yau
*"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics ."*

Each recipient is presented with a silver casting of the TEST sculpture by the artist A. Pierelli. The original casting was presented to His Holiness Pope John Paul II on the first occasion of the Marcel Grossmann Awards.

**FOURTEENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

European Space Agency (ESA)

**Individual Awards**

Frank Chen Ny Yang, Tsung Dao Lee, Ken'ichi Nomoto, Martin Rees, Yakov G. Sinai, Sachiko Tsuruta

**THIRTEENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

ALBANOVA UNIVERSITY CENTER, STOCKHOLM

**Individual Awards**

David Arnett, Vladimir Belinski and Isaak M. Khalatnikov, Filippo Frontera

**TWELFTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Institut des Hautes Études Scientifique (IHES)

**Individual Awards**

Jaan Einasto, Christine Jones, Michael Kramer

**ELEVENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Freie Universität Berlin

**Individual Awards**

Roy Kerr, George Coyne, Joachim Trümper

**TENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

CBPF (Brazilian Center for Research in Physics)

**Individual Awards**

Yvonne Choquet-Bruhat, James W. York, Jr., Yval Ne'eman

**NINTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Solvay Institutes

**Individual Awards**

Riccardo Giacconi, Roger Penrose, Cecile and Bryce DeWitt

**EIGHTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Hebrew University of Jerusalem

**Individual Awards**

Tullio Regge, Francis Everitt

**SEVENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Hubble Space Telescope Institute

**Individual Awards**

SUBRAHMANYAN CHANDRASEKHAR, JIM WILSON

**SIXTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Research Institute for Theoretical Physics (Hiroshima)

**Individual Awards**

Minora Oda, Stephen Hawking

**FIFTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The University of Western Australia

**Individual Awards**

Satio Hayakawa, John Archibald Wheeler

**FOURTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Vatican Observatory

**Individual Awards**

William Fairbank, Abdus Salam

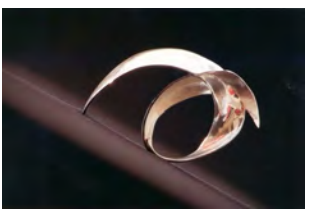

Fig. 1. TEST: sculpture by Attilio Pierelli

**PLANCK SCIENTIFIC COLLABORATION (ESA)**
presented to **Jean-Loup Puget**, the Principal Investigator of the High Frequency Instrument (HFI).

*"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding B-polarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy"*

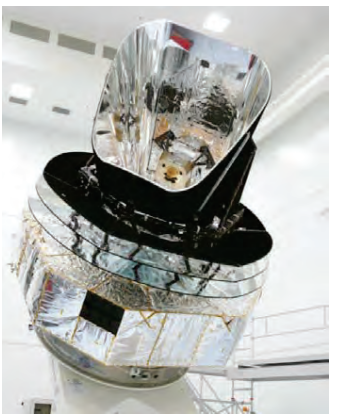

*Photo of the Planck satellite (Courtesy of ESA).*

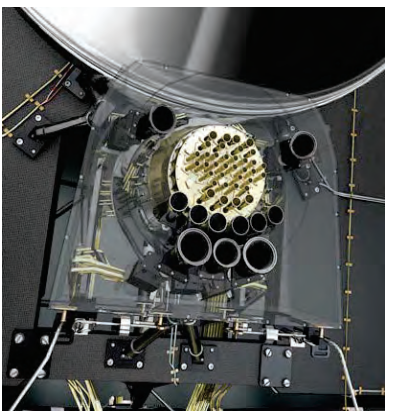


*Planck focal plane (Courtesy of ESA)*

Planck ESA's mission, was designed to image the temperature and polarization anisotropies of the CMB over the whole sky, with unrivalled angular resolution and sensitivity, pushing the technology to unprecedent limits. In the framework of the highly precision experimental cosmology the legacy Planck results on testing theories of the early universe and the origin of cosmic structure, has provided a major source of information crucial to many cosmological and astrophysical issues. Planck carried out two instruments:

- the High Frequency Instrument (HFI), Principal Investigator: Jean Loup Puget;
- the Low Frequency Instrument (LFI), Principal Investigator: Nazzareno Mandolesi.

The instruments were complementary and using different technology to cross check independently final results and systematic errors. They worked together to produce the overall mission results. The Planck space mission (ESA) has been a wonderful example of Team effort in a large international collaboration, involving scientific, technical and managerial aspects. The unprecedented accuracy of the Planck measurements have established new standards in the determination of fundamental cosmological parameters, as well as new insight in Galactic and extragalactic astrophysics. The Planck full-sky maps in temperature and polarization will remain a lasting legacy for at least dozen years to come. More than 100 papers signed by Planck collaboration have already 30 000 citations in scientific literature. The success of Planck HFI and LFI would not have been possible without the contribution of a large number of talented and dedicated scientists and engineers from many countries of Europe, USA and Canada. HFI was designed to produce high-sensitivity, multi-frequency measurements of the diffuse radiation permeating the sky in all directions in the frequency range of 84 GHz to 1 THz cooled at 100 mK. The instrument consisted of an array of 52 bolometric detectors placed in the focal plane of the telescope. LFI, a microwave instrument, was designed to produce high-sensitivity, multi-frequency measurements of the microwave sky in the frequency range of 27 to 77 GHz. The instrument consisted of an array of 22 tuned radio receivers located in the focal plane of the telescope, cooled at 20 K.

*Jean Loup Puget - PI of the HFI.*

*Nazzareno Mandolesi - PI of the LFI.*

## HANSEN EXPERIMENTAL PHYSICS LABORATORY AT STANFORD UNIVERSITY

presented to **Leo Hollberg**, HEPL Assistant Director

*"to HEPL for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology"*

### Brief History of Stanford's HEPL and Ginzton Laboratories

1947: WW Hansen (right) and team with the Mark I linear accelerator

In 1947, working in the Stanford Physics Department's Microwave Lab, Physics Professor, William W. Hansen and his research team, along with Assistant Professor of Physics and microwave expert, Edward L. Ginzton, completed development on the world's first traveling wave electron linear accelerator. Dubbed the Mark I (see photo) it generated a 1.5 million electron volt (MeV) beam. Hansen's entire report to the U.S. Office of Naval Research (ONR) that funded the project was just one sentence: "We have accelerated electrons."

This successful first step in linear electron acceleration spawned the birth of Stanford's High Energy Physics Lab (HEPL) and Ginzton labs. In 1990, HEPL was renamed the WW Hansen Experimental Physics Lab (also HEPL). HEPL and Ginzton were setup as Stanford's first independent labs. They were organized to facilitate cross-disciplinary research, enabling scientists, engineers, staff and students to work towards common research goals using cutting edge lab equipment and technologies on medium-scale projects. For the past 70 years, the HEPL and Ginzton Labs have spearheaded Stanford's leadership in cross-disciplinary physics and become nurturing homes to a variety of physics-based, research projects: including the following examples:

### Robert Hofstadter's Nobel Prize & Later Work

In 1961, Stanford Professor Robert Hofstadter was awarded the Nobel Prize for his HEPL Mark III Linear Accelerator work on nuclear form factors (nucleons). In the 1980s, Hofstadter became interested in astrophysics and helped design the EGRET telescope in the NASA Compton Gamma Ray Observatory (CGRO).

### Gravity Probe B (GP-B)

2003: Francis Everitt (left) and Brad Parkinson holding a GP-B gyro

In 1959, Physics Department Chair, Leonard Schiff, became interested in using gyroscopes in a satellite to measure the Earth's geodetic effect and the miniscule frame-dragging effect predicted by Albert Einstein's general theory of relativity. Schiff discussed this project with Stanford cryogenic physicist, William Fairbank, and gyroscope expert, Robert Cannon (Aero-Astro department).

In 1962, Fairbank invited post-doc, Francis Everitt, to join the research effort. The team sent a proposal to NASA's Office of Space Sciences requesting funding to develop gyroscopes and a satellite to carry out this unprecedented test. It took 40 years of R&D at Stanford and other places to create and ready the cryogenic satellite and all of its cutting-edge technologies for launch. In 1975, Leonard Schiff moved the GP-B program to HEPL, breathing new life into the lab. In 1981, Francis Everitt became Principal Investigator, a position he still holds. In 1984, Brad Parkinson became Project Manager and a Co-PI, along with Co-PI's John Turneaure and Daniel DeBra.

On 20 April 2004, GP-B launched from Vandenberg AFB into a polar orbit. Data collection began on 28 August 2004 and lasted 50 weeks. Data analysis took five years in order to remove confounding factors in the data. The final results, published in PRL on 31 May 2011, yielded highly accurate geodetic and frame dragging measurements, with 0.28% and 19% margins of error, respectively.

### GPS Spinoffs from GP-B

In the 1990s, Brad Parkinson's research on GPS solutions for positioning the GP-B satellite led to two revolutionary spin-off projects: 1) Wide Area Augmentation System (WAAS) provides highly precise positioning accuracy and itegrity for navigation and the automatic landing of airplanes and 2) Precision Farming adding GPS technology to tractors has enabled the automation of many aspects of farming and has spawned a $1 billion/year industry.

### Fermi Gamma Ray Space Telescope (GLAST)

Peter Michelson, Fermi LAT Principal Investigator

Stanford Physics Professor, Peter Michelson, is a former HEPL Director and the Principal Investigator for the Large Area Telescope (LAT) on board NASA's Fermi Gamma Ray Space Telescope, the successor to CGRO/EGRET. Launched on 11 June 2008, Fermi has been highly successful mapping the gamma-ray sky. Under Michelson's guidance, HEPL's collaborations with Italy are noteworthy. The development of cryogenic bar detectors of gravitational waves, in collaboration with Edoardo Amaldi and his colleagues, established new stringent upper limits to the gravitational waves incident on the Earth. Likewise, the Fermi LAT was developed by a collaboration between Italian INFN and ASI, NASA, and international partners in France, Japan, and Sweden, and used tracking detectors developed, integrated, tested, and qualified for the mission by Italy. GP-B provided the first evidence of frame-dragging on a spinning, superconducting gyroscope. The Fermi detector offers the potential of seeing, through the GeV emission in the Binary Driven Hypernova subclass of long GRBs, the emission from a newly born Black Hole, originating in the induced gravitational collapse of a supernova hypercritically accreting on a binary neutron star companion.

### Robert Byer's LIGO and ACHIP Projects

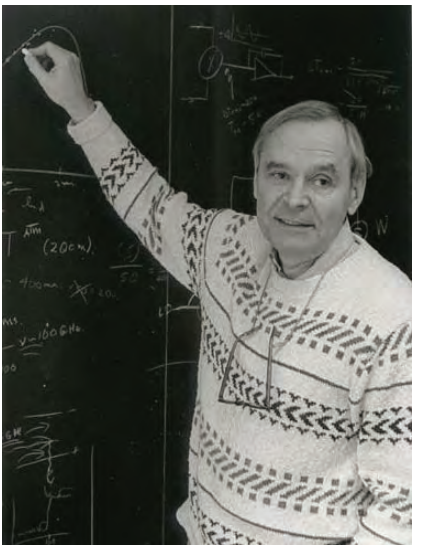
Professor Robert Byer

Robert Byer, former Stanford Dean of Research and former HEPL Director, nurtured the GP-B, GPS and Fermi programs to success during his tenure. He is currently an Applied Physics Professor specializing in lasers and optics. His LIGO Group provided seismic isolation, coatings and materials for the LIGO observatories. His ACHIP project is developing a particle accelerator on a microchip—bringing the HEPL/Ginzton Labs full circle to Hansen's 1947 research.

Professor **LYMAN PAGE**

*"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and as founding director of the Atacama Cosmology Telescope"*

*Lyman Page*



*David Wilkinson*

This award is given in recognition of Lyman Page's pivotal role in transforming cosmic microwave background observations into a high-precision experimental science over the past two decades. In particular Page provided major contributions to the success of the Wilkinson Microwave Anisotropy Probe (WMAP) space mission, which delivered outstanding measurements of the CMB anisotropy and polarization pattern. He is now continuing his effort by promoting a new generation of experiments like the Atacama Cosmology Telescope to study CMB polarization to greater precision.

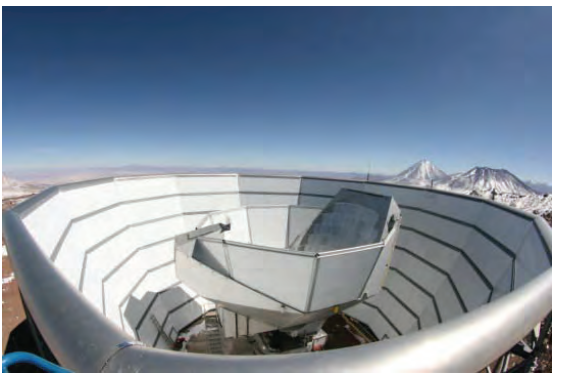


*Photo of the Atacama Cosmology Telescope*

The CMB, the faint afterglow of the Big Bang, is the most powerful probe of the early universe. From its study, we have learned the age of the universe, its major constituents, and have characterized the fundamental fluctuations in gravity that gave rise to cosmic structure. The desire to measure the CMB ever more precisely has driven the development of extraordinary detectors and techniques which will be reviewed in the Lectio Magistralis by Lyman Page. He will describe what we might hope to learn from the CMB in the next decade, including detecting gravitational waves from the birth of the universe if they exist at sufficient amplitude.

Professor **RASHID ALIEVICH SUNYAEV**
*"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe"*

*Rashid Sunyaev*

*Rashid Sunyaev and Yakov Borisovich Zeldovich*

Rashid Sunyaev gave extraordinary contributions to the understanding of physical processes in the universe which identified new and uniquely informative targets for observational cosmology. In particular, the Sunyaev-Zeldovich effect, now observed in thousands of clusters of galaxies over the entire sky, has become a cornerstone of cosmology and extragalactic astrophysics, so much so that it is now considered a research field in its own right. Furthermore, Sunyaev's studies of processes in the early universe responsible for angular anisotropy and frequency distortions of the cosmic microwave background have left a profound and lasting legacy for cosmology. In particular, Sunyaev and Zeldovich predicted the presence of acoustic peaks in the CMB angular fluctuation power spectrum and the existence of baryonic acoustic oscillations.
He is currently the project scientist leading the scientific team of the international high-energy astrophysics observatory Spektr-RG being built under the direction of the Russian Space Research Institute.

*Yakov Zeldovich and Remo Ruffini at the audience with Pope John Paul II*

Professor **SHING-TUNG YAU**
*"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics"*

*Shing-Tung Yau*

Shing-Tung Yau has made fundamental contributions to differential geometry which have influenced a wide range of scientific disciplines, including astronomy and theoretical physics. With Richard Schoen, Yau solved a longstanding question in general relativity by proving that the combined total energy of matter and gravitational field in an asymptotically flat universe is positive. In 1982 Yau was awarded the Fields Medal, the highest award in mathematics, and in 1994 he shared with Simon Donaldson the Crafoord Prize of the Royal Swedish Society in recognition of his development of nonlinear techniques in differential geometry leading to the solution of several outstanding problems.

Another outstanding achievement of Yau is his proof of the Calabi conjecture which allowed physicists to show that string theory is a viable candidate for a unified theory of nature. Furthermore in 2008 Yau (with M.T. Wang) introduced the concept of "quasi-local mass" in general relativity which can be of help to get around the old conundrum — the non-locality of the energy density in relativistic gravity.

During his scientific carrier Yau had more than 50 successful PhD students. At present he is a professor of mathematics at Harvard University where along with research he continues many pedagogical activities. For example, he has created the "Black Hole Initiative", an interdisciplinary center at Harvard University involving a collaboration between principal investigators from the fields of astronomy (Sheperd Doeleman, Avi Loeb and Ramesh Narayan), physics (Andrew Strominger), mathematics (Shing-Tung Yau) and philosophy (Peter Galison). This "Black Hole Initiative" is the first center worldwide to focus on the study of the many facets of black holes.

MG16 in 2021 will mark the $50^{th}$ anniversary of the mass-energy formula for black holes based on the Kerr metric. This timing is an omen that Yau and his school will soon further enlarge our knowledge of this formula with their powerful mathematical analysis.

# PREFACE

The Marcel Grossmann Meetings on Recent Developments in Theoretical and Experimental General Relativity, Astrophysics and Relativistic Field Theories have always had the goal of bringing together scientists from all over the world enabling them to share recent developments in general relativity and cosmology, paying attention to the interplay between physical predictions and mathematical foundations.

More than 800 scientists met at the University of Rome "la Sapienza" for the Fifteenth Marcel Grossmann Meeting (MG15) during the week of July 1–7, 2018 to discuss theoretical topics and the status of the experimental testing and observations of Einstein's theory of gravitation together with the broad spectrum of gravitational physics related phenomena. The topics discussed ranged from classical and quantum aspects of gravity, relativistic astrophysics, branes and strings, inflation theory, the thermal history of the Universe, to more concrete astrophysics experiments, observations, and modeling, reviewing the current state of the art in theory, observations, and experiments related to relativistic gravitation.

The meeting featured 39 plenary talks during the six mornings of the meeting, plus 6 public lectures given by experts in gravitation and cosmology. 73 parallel sessions, some of which were split over multiple days, kept participants busy with the crucial support of 33 students from Sapienza who managed the coordination of each parallel session and offered technical help.

Three scientists and two collaborations were presented with Marcel Grossmann awards. These were: Lyman Page, Rashid Alievich Sunyaev, Shing-Tung Yau, the Planck Scientific Collaboration (ESA) represented by Jean-Loup Puget, and the Hansen Experimental Physics Laboratory (HEPL) at Stanford University, represented by Leo Hollberg,

The detailed program of plenary and public talks is as follows:

**Shing-Tung Yau** (Harvard University): Quasi-local mass at null infinity
**Malcolm J. Perry** (University of Cambridge): Black hole entropy and soft hair
**Thomas Hertog** (KU Leuven): A smooth exit form eternal inflation
**Jean-Luc Lehners** (Max Planck Institute for Gravitational Physics): No smooth beginning for spacetime
**Ivan Agullo** (Louisiana State University): Loop quantum cosmology and the cosmic microwave background
**Elena Pian** (IASF Bologna):Kilonovae: the cosmic foundries of heavy elements
**Nial Tanvir** (University of Leicester): A new era of gravitational-wave / electromagnetic multi-messenger astronomy
**Tsvi Piran** (Hebrew University of Jerusalem): Mergers and GRBs: past present and future
**Stephan Rosswog** (Stockholm University): Neutron star mergers as heavy element production site

**David Shoemaker** (MIT LIGO Laboratory): LIGO's past and future observations of black hole and neutron star binaries
**Yu Wang** (ICRANet): On the role of binary systems in GW170817/ GRB170817A/AT2017gfo
**Hao Liu** (University of Copenhagen): An independent investigation of gravitational wave data
**Stefano Vitale** (University of Trento): Gravitation wave astronomy in ESA science programme
**Takaaki Kajita** (University of Tokyo): Status of KAGRA and its scientific goals
**Masaki Ando** (University of Tokyo): DECIGO : Gravitational-Wave observations from space
**Jun Luo** (Sun Yat-Sen University): TianQin: a space-borne gravitational wave detector
**Jo Van Den Brand** (Dutch National Institute for Subatomic Physics Nikhef, and VU University Amsterdam): Gravitational wave science and Virgo
**Ernst Maria Rasel** (Leibniz Universität Hannover): Science fiction turns into reality: Interferometry with Bose-Einstein condensates on ground and in space
**Manuel Rodrigues** (Université Paris Saclay): The first results of the MICROSCOPE test of the equivalence principle in space
**Victoria Kaspi** (McGill University): Fast radio bursts
**Bing Zhang** (University of Nevada): From gamma-ray bursts to fast radio bursts: unveiling the mystery of cosmic bursting sources
**Jean-Loup Puget** (CNRS): The Planck mission
**Jorge Armando Rueda Hernandez** (ICRANet): Binary-driven hypernovae and the understanding of gamma-ray bursts
**Remo Ruffini** (ICRANet): The essential role of the nature of the binary progenitors for understanding gamma ray bursts
**Heino Falcke** (Radboud University Nijmegen): Imaging black holes now and in the future
**Luc Blanchet** (Institut d'Astrophysique de Paris): Post-Newtonian theory and gravitational waves
**Jean-Loup Puget** (Université Paris): Frome Planck to Atacama Cosmology Telescope
**Razmik Mirzoyan** (Max Planck Institute for Physics): Gamma-ray and multimessenger highlights with MAGIC
**Elisa Resconi** (Technical University Munich): Neutrino astronomy in the multimessenger era
**Francis Halzen** (University of Wisconsin-Madison): IceCube: opening a new window on the universe from the South Pole
**James Lattimer** (Stony Brook University): The history of R-process
**Ralph Engel** (Karlsruhe Institute of Technology): What have we learned about ultra-high-energy cosmic rays from the Pierre Auger Observatory?

**Paolo De Bernardis** (Sapienza - University of Rome):
**Fabio Gargano** (INFN Bari): DAMPE and its latest results
**Markus Arndt** (University of Vienna): Experiments to probe quantum linearity at the interface to gravity & complexity
**Tobias Westphal** (University of Vienna): Micro-mechanical measurements of weak gravitational forces
**Shu Zhang** (Institute of High Energy Physics, Chinese Academy of Sciences):
**Lorenzo Amati** (INAF - OAS Bologna): Cosmology and multi-messenger astrophysics with Gamma-Ray Bursts
**Elisabetta Cavazzuti** (ASI): Gev LAT observations from GRBs and active galactic nuclei
**Remo Ruffini** (ICRANet): Concluding Remarks
**Roy Kerr** (University of Canterbury): Towards MG16

**Public Lectures**

**Jeremiah Ostriker** (Columbia University): Ultra-light scalars as cosmological dark matter
**Malcolm Longair** (University of Cambridge): Ryle and Hewish: 50 and 100 year anniversaries [Radio astrophysics and the rise of high energy astrophysics]
**Lyman Page** (Princeton University): Measuring the Cosmic Microwave Background
**Marc Henneaux** (Université Libre de Bruxelles): The cosmological singularity
**Anne Archibald** (Newcastle University): Does extreme gravity affect how objects fall?

# Concluding remarks by Prof. Remo Ruffini

For over more than four decades the Marcel Grossmann Meetings have been fostering the interaction between mathematics, relativistic field theories and observations in physics and astrophysics and has witnessed the birth and exponential growth of various new subfields within astrophysics. This has also occurred in 2018 during the MG15 (see Fig. 1), which has seen the participation of approximately one thousand participants from 71 different countries (see Fig. 2). In MG15, as is clear from the above program, we have seen considerable progress in theory on topics ranging from models of quantum gravity to the mathematical structure of Einstein's equations.

Fig. 1. MG15 official Awards Ceremony on Monday, July 2, 2018.

Fig. 2. Group photo of MG15 participants in the Aula Magna, Sapienza University of Rome.

In particular, an MG15 individual award was given to Prof. Rashid Sunyaev, as a member of the relativistic astrophysics school of Zel'dovich-Sunyaev (see Fig. 3) and to Prof. Shing-Tung Yau, as a representative of the Chinese-American school of differential geometry and general relativity (see Fig. 4).

Fig. 4. Shing-Tung Yau receiving the MG15 individual award from Roy Kerr.

This has been accompanied by extensive developments in the exploration of the cosmic microwave background with announcements of the final results of the Planck satellite that followed earlier predecessors, like WMAP. In this sense, particularly meaningful have been the MG15

Awards presented to Prof. Jean-Loup Puget, who has successfully accomplished the ESA Plank mission (see Fig. 5) and to Prof. Lyman Page, one of the main participants of the glorious NASA WMAP mission, successfully lead by David Wilkinson (see Fig. 6). I was very fortunate to be in Princeton as an assistant professor at the time WMAP was initially conceived.

Fig. 6. Lyman Page accepting the MG15 individual award from Roy Kerr.

X-ray astrophysics gradually successfully evolved from the first rockets of Riccardo Giacconi discovering Scorpius X-1 using well tested Geiger counters, moving on to larger missions using X-ray mirrors in the Einstein Observatory, in XMM and on to the NASA Chandra mission, each new mission introducing new technologies based on previous successes. The

Chandra data on GRB 170817A were amply discussed in the MG15 meeting. Analogously, starting from the earlier gamma ray detectors on the Vela satellite, gamma ray astrophysics reached maturity with the Compton Observatory with the BATSE instruments on board. These two fields joined their separate expertise together in the hybrid Beppo SAX satellite. Equally impressive was the transition from Beppo SAX to the Neil Gehrels Swift Observatory and the Fermi Gamma-Ray Space Telescope that followed EGRET and opened up the field of high energy gamma-ray astrophysics, adding further successes to this ongoing story. One of the most significant contributions to the success of the Fermi mission has been the LAT detector, jointly led by the Hansen Experimental Physics Laboratory (HEPL) at Stanford University, which received the MG15 institutional award, presented to Prof. Leo Hollberg (see Fig. 7).

Fig. 7. Leo Hollberg accepting the MG15 institutional award from Roy Kerr on behalf of the Hansen Experimental Physics Laboratory at Stanford University.

More recently we are witnessing the birth of TeV astrophysics springing from the ground-based MAGIC, HESS and Whipple telescopes, as well as neutrino astrophysics associated with underground (ICE Cube) and underwater laboratories. New tantalizing results concerning the spectrum and composition of cosmic rays have been reported by the Alpha Magnetic Spectrometer experiment on the international space station. All of these

together mark the gradual development of the largest observational effort in history, well recorded in these MG meetings (see Fig. 8). Today relativistic astrophysics is offering us the possibility of utilizing all of these multi-wavelength observations simultaneously in the study of GRBs and active galactic nuclei. Indeed the description of the distinct temporally discrete episodes for the GRB 130427A, one of the most complex astrophysical objects ever observed, requires the simultaneous knowledge of observations from all of these various wavelengths. This exponential growth in all these areas of astrophysics has been accompanied by attempts at data acquisition of gravitational wave signals arriving on the Earth. After the failure of the initial attempt by Misner and Weber in 1972, the new attempt by LIGO-VIRGO was discussed extensively in this MG15 meeting.

Fig. 8. From the left to right: Leo Hollberg, Rashid Sunyaev, Shing-Tung Yau and Remo Ruffini during the MG15 official awards ceremony.

Indeed in addition to the many topics discussed in the plenary lectures, there was a special session dedicated to kilonova and gravitational waves chaired by Enrico Costa on July 3 and a session on gravitational waves chaired by Claus Lämmerzahl on July 4. Many intense discussions took place at the meeting, both in the plenary and parallel sessions, bringing together different points of view, at times controversial, which stimulated a large number of articles published in leading scientific journals in the months following the meetings. The impossibility of finding these discussions in these proceedings is simply explained: it is due to the incomprehensible decision by Sapienza University not to renew the collaboration agreement with ICRANet. What is incomprehensible is that both the research and teaching activities of ICRA and ICRANet are

recognized internationally at a worldwide level, in more than 70 nations. Locks were put on the ICRA Offices (see Fig. 9).

Fig. 9. Remo Ruffini shows to Barry Barish the locked offices of ICRA at Sapienza University.

The preparation of the proceedings was halted. It was not possible to follow up with post-conference interactions and the impossibility of access to our offices and interact with our students. The invited lecturers, clearly indicated in the conference program and some of the world leaders in their fields who had just presented their extremely interesting lectures stimulating widespread interest, mostly chose to publish their results in international journals giving rise to some of the most highly cited articles in recent times. Only a minority were published here. This was also the case for some of the ICRA-ICRANet lectures, which appeared in:

- J.F. Rodriguez, J.A. Rueda, R. Ruffini, *On the final gravitational wave burst from binary black hole mergers*, Astron. Rep. 62, 940 (2018).
- J.A. Rueda, R. Ruffini, Y. Wang, Y. Aimuratov, U. Barres de Almeida, C.L. Bianco, Y.C. Chen, R.V. Lobato, C. Maia, D. Primorac, R. Moradia, and J.F. Rodriguez, *GRB 170817A-GW170817-AT 2017gfo and the observations of NS-NS, NS-WD and WD-WD mergers*, JCAP 10, 006 (2018); and J.A. Rueda, R. Ruffini, Y. Wang, C.L. Bianco, J.M. Blanco-Iglesias, M. Karlica, P. Lorén-Aguilar, R. Moradi and N. Sahakyan, *Electromagnetic emission of white dwarf binary mergers*, JCAP 03, 044 (2019).

- R. Ruffini, R. Moradi, J. A. Rueda, L. Becerra, C. L. Bianco, C. Cherubini, S. Filippi, Y. C. Chen, M. Karlica, N. Sahakyan, Y. Wang, and S. S. Xue, *On the GeV Emission of the Type I BdHN GRB 130427A*, The Astrophysical Journal, 886, 82 (2019).

The dialogue we had started at MG15 undoubtedly had a very stimulating effect on the community which have been followed up and expanded upon in the subsequent MG16 meeting in 2021. Paradoxically, the moments of greatest difficulty for ICRA members have coincided with the flow of new ideas which promoted the steps forward towards the final identification of some fundamental laws of black hole electrodynamics. The very night ICRA offices were locked up and its electronic communications cut, we had submitted a paper to The Astrophysical Journal for publication containing the first fundamental steps for identifying the "inner engine" of GRBs as discussed in talks in this conference. After one year and four months a judge ordered Sapienza to return the ICRA offices.

I am looking forward to a renewed successful collaboration with Sapienza University, enjoyed for more than three decades, to pursue a new common "path" for the rapidly expanding knowledge of the largest distant objects in our Universe. There is still room for improvement: now that the differences have been identified in published articles, a joint effort on an attentive scientific analysis on both sides can lead to the understanding of the nature of these differences and to jointly converge to common solutions. For this to occur, dialogue and not obstruction of office space is needed. As soon as these clarifications will be achieved, we will be able to proceed in a broad scientific effort of common topics of interest in Einstein's theory, in relativistic astrophysics, ranging from the astrophysics of black holes, neutron stars, dark matter and primordial cosmology, observing the rules of basic academic relations.

I am grateful to all members of the IOC and to Carlo Luciano Bianco, Nathalie Deruelle, Rahim Moradi, Tsvi Piran, Jorge Rueda and Narek Sahakyan for advice and discussion.

# Radio Astronomy and the rise of high energy astrophysics: Two anniversaries

Malcolm Longair

*Cavendish Laboratory,*
*University of Cambridge,*
*Cambridge, UK*
** E-mail: msl1000@cam.ac.uk*

This essay celebrates the 100th anniversary of the birth of Martin Ryle and the 50th anniversary of the discovery of pulsars by Jocelyn Bell and Antony Hewish. Ryle and Hewish received the 1974 Nobel Prize in Physics, the first in the area of astrophysics. Their interests strongly overlapped, one of the key papers on the practical implementation of the technique of aperture synthesis being co-authored by Ryle and Hewish. The discovery of pulsars and the roles played by Hewish and Bell are described. These key advances were at the heart of the dramatic rise of high energy astrophysics in the 1960s and led to the realisation that general relativity is central to the understanding of high energy astrophysical phenomena.

*Keywords*: Martin Ryle, Antony Hewish, Jocelyn Bell-Burnell, earth-rotation aperture synthesis, high energy astrophysics, radio sources, neutron stars, supermassive black holes

## 1. Two Anniversaries

2018 is a cause for celebration in the high energy astrophysical community. The two anniversaries are the centenary of the birth of Martin Ryle (1918-1984) and the 50th anniversary of the announcement of the discovery of pulsars in 1968, associated with the names of Antony Hewish and Jocelyn Bell-Burnell. They were all members of the Radio Astronomy Group in the Cavendish Laboratory. I was present as a graduate student and research fellow through the exciting period from 1963 to 1970.

Martin Ryle and Antony Hewish were awarded the Nobel Prize in Physics in 1974, the first to be awarded in astrophysics. The citation reads:

> 'for their pioneering research in radio astrophysics: Ryle for his observations and inventions, in particular of the aperture synthesis technique, and Hewish for his decisive role in the discovery of pulsars.'

Their experimental work was central to the realisation that high energy particles and strong magnetic fields play a major role in modern astrophysics and that general relativity is essential in order to understand high energy astrophysical phenomena.

## 2. The Origins of Radio Astronomy and the Impact of the Second World War

The story begins in 1933 with the discovery of radio waves from our Galaxy by Karl Jansky who was working at the Bell Telephone Laboratories.[1] The discovery arose

from the need to understand sources of radio interference in radio communications. Grote Reber followed up Jansky's discovery with his own home-made radio telescope. By 1940, he had succeeded in making the first map of the radio emission from the Galaxy, the results being published in the *Astrophysical Journal*.[2] Little attention was paid to this work by professional astronomers. The only paper was a discussion which showed that the spectrum of the radiation found by comparing Jansky's and Reber's intensity measurements could not be the thermal emission of hot gas clouds.[3]

Immediately after the Second World War, astronomy was about to be changed out of all recognition as compared with the pre-War era. The contributory causes can be summarised as follows:

- The opening up of the whole of the electromagnetic spectrum for astronomical observation was facilitated by huge advances in radio and electronic techniques as well as by the availability of rockets from which observations could be made from above the Earth's atmosphere.
- Investment in pure science increased dramatically as the benefits of basic research for defence purposes and for the benefit of society were appreciated.
- Scientific electronic computation began in earnest and would provide the means for advancing all scientific disciplines dramatically.
- Astronomy became one of the 'Big Sciences'.

These all contributed to many of the great and unexpected astronomical discoveries of the succeeding years.[a]

After the Second World War, a number of University Groups began to investigate the nature of the cosmic radio emission discovered by Jansky. The principal groups involved were at Cambridge, Manchester and Sydney, all of them led by scientists who came from a background in radar. The science of radio communication and detection developed at a great pace during the War under the combined pressures of defending the UK from incoming enemy aircraft and rockets and developing air-borne radar and radio location techniques. The Cambridge efforts were led by Martin Ryle who assembled a brilliant team of young physicists to attack these problems. The Radio Astronomy Group was remarkably tight-knit and everyone contributed to the various technical challenges.

Two of these were of particular importance. The first was the need to achieve higher angular resolution and sensitivity of the antennae and receiver systems. The second was the need to understand the origin and nature of the 'twinkling' or 'scintillation' of the radio sources. Ryle and Hewish worked on both problems, as can be appreciated from a list of some of their joint papers.

[a]For more details, see my book *The Cosmic Century: A History of Astrophysics and Cosmology*. Cambridge: Cambridge University Press (2006). For the high energy astrophysical aspects of the story, see also my book *High Energy Astrophysics: third edition*. Cambridge: Cambridge University Press (2011).

- Scott, P. F., Ryle, M. and Hewish, A. (1961), The First Results of Radio Star Observations using the Method of Aperture Synthesis. [7]

Immediately after the Second World War, there was very little money, but Ryle and his colleagues were able to make very good use of surplus war equipment, including high quality radio antennae, a large amount of coaxial cable and other items brought back to the UK as German war booty. It was quickly understood that the way to achieving the goals of higher angular resolution and greater sensitivity was to use radio interferometry and, in particular, to implement the techniques of aperture synthesis in which both the amplitude and phase of the interferometric observations are preserved. Martin Ryle's contribution of genius was the practical implementation of Earth-rotation aperture synthesis which resulted in both high angular resolution and high sensitivity images of the radio sky.

Optical telescopes reflect the light of a distant object from a parabolic mirror which has the property that the signals from a distant object reflected from all parts of the mirror surface travel the same distance to the focus. The radio astronomers realised that the reflecting surfaces do not need to be part of the same surface. If

the path lengths to the focus from the source are the same, the interferometric data provide the necessary amplitude and phase information to begin the reconstruction of the image on the sky. To ensure that the waves travel the same distance, delay lines needed to be introduced so that the signals from the two telescopes were combined in phase. Increasing the number of antennae increases the number of possible pairings of antennae, the short baselines providing the large-scale structure and the long baselines the fine detail.

These techniques were exploited in a series of radio interferometers constructed, first of all, at the Rifle Range site just behind the Cambridge University Rugby Ground and then at the Lord's Bridge Observatory which was opened in 1957 once the full significance of radio astronomy for astrophysics and cosmology had become apparent. Radio astronomy hit the headlines in 1955 with the first results of the Second Cambridge (2C) Survey. The dramatic result was that there is a large excess of extragalactic radio sources at large distances, implying that these objects had evolved strongly with cosmic epoch. This was initially a controversial result but it led to the need for deeper surveys and the continued development of radio interferometric techniques. The first large interferometer on the Lord's Bridge site was the 4C radio telescope completed in about 1960. The surveys of the Northern sky carried out by the telescope showed convincingly the evolutionary nature of the radio source population. These radio surveys were carried out with fixed telescopes which mapped the sky by allowing the Earth's rotation to provide a scan of the sky above the telescope.

To sample the two-dimensional structure of the sources, Ryle and his colleagues pioneered the concept that it is simplest to build a one-dimensional interferometer and then use the Earth's rotation to carry one telescope about another as viewed from a point on the sky. In this way information is obtained corresponding to the annulus of a large telescope with diameter equal to the maximum separation of the elements of the interferometer. By adding together a number of baselines with different spacings, the equivalent of a single large telescope with diameter equal to the longest baseline separation can be synthesised with much improved sensitivity. Ryle and Ann Neville used the 4C telescope system in 1962 to create the first fully two-dimensional map of a region about the North Celestial Pole using the Earth-rotation synthesis technique.[8] Every available receiver in the Observatory was needed to make the observations.

The implementation of fully-steerable aperture-synthesis radio telescopes was realised with the construction of the Cambridge One-Mile Telescope (OMT). It required a great deal of innovation in electronics, path compensation and computation. The new generation of electronic computers, the Cambridge EDSAC-1 and 2 machines, was essential to carry out the Fourier transforms to convert the interferometric data into two-dimensional maps. The Fast Fourier transform was implemented to make these computations feasible in a reasonable time.

Fig. 2. The Cambridge One-Mile Telescope, the world's first fully-steerable, general purpose, Earth-rotation aperture synthesis radio telescope.

In 1965, the first radio images from the One-Mile Telescope, the world's first fully-steerable, general purpose, Earth-rotation aperture synthesis radio telescope (Fig. 2), were made of the radio galaxy Cygnus A and the supernova remnant Cassiopaeia A.[9] I was there in the EDSAC control room when the first maps came out of the computer printer. The next step was to extend these techniques to higher frequencies with larger numbers of telescopes and this was achieved with the 5-kilometre (Ryle) in the early 1970s. This resulted in much higher angular resolution and sensitivity. The success of these telescopes led to the construction of even more powerful instruments such as the Very Large Array in the USA.

It is remarkable that over the 25 year period from the end of the Second World War, the sensitivity of radio astronomical observations increased by a factor of about one million and the imaging capability of the telescope system improved from several degrees to a few arcseconds, comparable to that of ground-based optical telescopes. This was Martin Ryle's legacy to radio astronomy. After 1972, his health declined and his interest changed to wind power, sustainability and opposition to nuclear power.

The major impact of radio astrophysics upon astrophysics and cosmology in general cannot be overstated. The discovery of Galactic and extragalactic radio sources revealed the importance of relativistic astrophysics for astronomy in general. To summarise the change of perspective:

- Enormous energies in relativistic particles and magnetic fields were needed to account for the synchrotron radio emission of the radio sources and involved the conversion of $10^6\, M_\odot c^2$ of mass into these forms of energy, at the same time ejecting them far beyond the confines of the host galaxy.
- The role of relativistic jets in powering the huge energies in relativistic particles and magnetic fields became apparent.
- The discovery of the quasars and the BL-Lac objects opened up quite new challenges for the astrophysics of these objects in all wavebands.
- The extreme variability of some of the quasars and BL-Lac objects led to the realisation that supermassive black holes had to be involved in the most extreme active galactic nuclei.
- Evidence for the cosmological evolution of extragalactic radio sources, both radio galaxies and quasars, showed that major changes had taken place in the properties of these objects over the last 75% of the age of the Universe.

These discoveries were first reviewed internationally at the first Texas Symposium on *Relativistic Astrophysics* held in Dallas, Texas in 1963. At the closing dinner, Thomas Gold remarked:

> 'Everyone is pleased: the relativists who feel they are being appreciated, who are suddenly experts in a field which they hardly knew existed; the astrophysicists for having enlarged their domain, their empire by the annexation of another subject - general relativity.'

This was the beginning of high energy astrophysics in its modern guise.

## 3. The Discovery of Pulsars

The discovery of pulsars in 1967 is associated with the names of Antony Hewish and Jocelyn Bell-Burnell, but the seeds of their achievement were sown long before during the immediate post-War years. During that period, part of Hewish's research involved understanding the nature of the scintillations of the intensities of radio sources caused by intervening moving plasma clouds. Just as stars twinkle even on the clearest nights, so point sources of radio emission are observed to scintillate, particularly at long radio wavelengths. Their cause is the deflections of radio rays when they pass through irregularities in the ionospheric plasma.

The theory of the process of scintillation was worked out in detail by Hewish in 1951 in a paper entitled 'The diffraction of radio waves in passing through a phase-changing ionosphere'.[10] The paper set out the theoretical background needed to understand the short-term fluctuations in the intensities of radio sources due to irregularities in an ionised plasma. The same concepts could be used to understand the physics of fluctuations due to ionospheric, interplanetary and interstellar electron density fluctuations. This theoretical paper was followed in 1952 by another entitled 'The Diffraction of Galactic Radio Waves as a Method of Investigating the

Irregular Structure of the Ionosphere'.[11] Applying these concepts to observations of the fluctuating radio signals, Hewish showed that the scale of the irregularities ranged from 2 to 10 km, that the variation of the electron content was about $5 \times 10^9$ electrons cm$^{-2}$ and that the irregularities are at a height of about 400 km. These irregularities moved with a steady wind-like motion at a velocity of the order 100 to 300 m s$^{-1}$.

The same technique could be used to study the solar corona, the region of hot plasma surrounding the Sun. The radio source Taurus A (the Crab Nebula) was observed at varying angular distances from the Sun and the variability of the signal could be accounted for by scattering because of the presence of fluctuations of the electron density in the solar corona. In his paper of 1955 'The Irregular Structure of the Outer Regions of the Solar Corona', Hewish derived the sizes and electron densities of coronal irregularities in the distance range 5 to 15 solar radii.[12]

In 1954, Hewish had remarked in his notebooks that, if the angular sizes of the extragalactic radio sources were small enough, they would illuminate the solar corona with a coherent radio signal and so give rise to rapid time variations in their intensities. This idea was forgotten until about 1962 when Margaret Clarke showed that two of the compact 3CR radio sources ($\theta \lesssim 2$ arcsec) varied very rapidly in intensity. Hewish realised that his old idea was the answer.

By 1964, a number of radio quasars were known and some of these radio sources had small angular sizes. With Paul Scott and Derek Wills, Hewish showed that the radio scintillations were due to scattering of the radio waves by inhomogeneities in the ionised plasma flowing out from the Sun, the Solar Wind. This wind had been predicted by Eugene Parker in 1958 and observed by the Soviet Luna satellites in 1959 and by the US Mariner-2 satellite in 1962. The paper by Hewish, Scott and Wills showed how radio source scintillations could be used to map the outflowing Solar Wind.[13]

Hewish realised that a large, low-frequency array dedicated to the measurement of the scintillations of compact radio sources would provide a new approach to the study of three important astronomical areas:

- it would enable many more quasars to be discovered,
- their angular sizes could be estimated,
- the structure and velocity of the Solar Wind could be determined.

In 1965, he designed a large array to undertake these studies and was awarded a grant of £17,286 by the UK Department of Scientific and Industrial Research to construct it, as well as outstations for measuring the velocity of the Solar Wind. To obtain adequate sensitivity at the low observing frequency of 81.5 MHz (3.7 m wavelength), the array had to be large, 4.5 acres (1.8 hectares) in area, in order to record the rapidly fluctuating intensities of bright radio sources on time-scales as short as one tenth of a second.

Jocelyn Bell joined the 4.5 acre array project as a graduate student in October 1965. She was involved in the construction of the telescope, including knocking the posts into the ground, and then became responsible for the network of cables connecting the dipoles. The telescope was commissioned during July 1967 with the objective of mapping the whole sky once a week so that the variation of the scintillation of the sources with solar elongation could be studied. The array consisted of 2,048 full-wave dipoles arranged in 16 rows of 128 elements. Each row was 470 m long and the north-south extent of the array was 45 m.

A key aspect of the array was that it had to measure the fractional scintillations of the radio sources in real time. Before the days of high speed digital computers, this was achieved by electronic processing of the incoming signals. On a strip chart, the top trace showed the intensity of the source as it passed through the beam of the telescope. This signal was then passed through a high-pass filter so that only the fluctuating component was registered in the middle trace, from which the noise power in the fluctuating component could be displayed in the bottom trace.

While the array was being constructed, Leslie Little and Hewish carried out a theoretical investigation of the strength of the scintillations as a function of heliocentric coordinates. They demonstrated how the angular sizes of the sources could be estimated from measurements of the amplitudes of the scintillations when sources were observed at different solar elongations.[14] A key point was that the scintillations decrease to very small amplitudes when observed at large angles from the Sun.

The commissioning of the 4.5 acre array proceeded through the summer of 1967. Hewish suggested that Bell create sky charts for each strip of the sky each day, noting all the scintillating sources. If the scintillating sources were present on successive weeks at the same astronomical coordinates, they were likely to be real sources, whereas if they were simply interference, for example caused by a nearby unsuppressed tractor or motorcycle, they would not recur at the same astronomical coordinates. This was a very demanding task requiring great persistence, patience and attention to detail on Bell's part since she had to keep up with the very high rate at which the charts were being produced by the telescope, over 200 metres per week.

The discovery of the pulsar CP 1919 was made by Bell on 6 August 1967, the story of the discovery being contained in Appendix 1 of her PhD dissertation. The remarkable feature of CP1919 was that the source scintillated at roughly the 100% level in the anti-solar direction, quite contrary to the expectations of the scintillation models of Little and Hewish. Furthermore, the source was highly variable and not always present. It was not observed again until 28 November 1968, this time with a much short time-constant in the receiver system – the pulses were detected separately for the first time. To everyone's astonishment, the signal consisted entirely of a sequence of pulses with repetition period 1.33 sec, the period being stable to better than one part in $10^6$.

The following two months were what Hewish described as the most exciting of

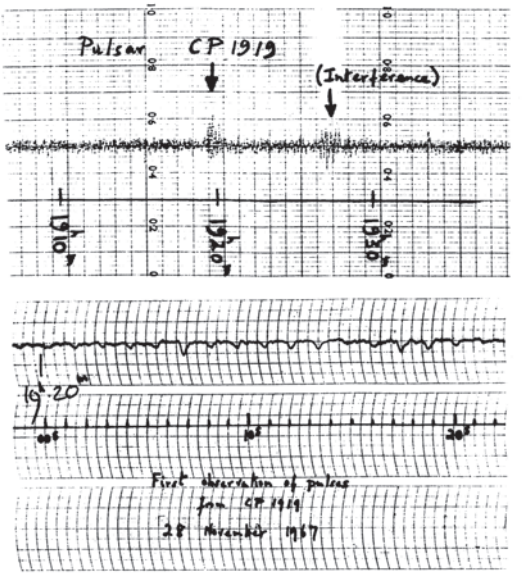

Fig. 3. The discovery record of CP 1919 taken on 6 August 1967. (Courtesy and copyright the Cavendish Laboratory, University of Cambridge and Churchill College Archives.)

his scientific career. Nothing like this had been observed in astronomy before and Hewish and his colleagues had to be absolutely certain of the correctness of the observations. It was essential to carry out follow-up observations and experiments:

- All sources of terrestrial inference had to be excluded.
- If the source was associated with extraterrestrial emissions, including the notorious 'Little Green Men (LGM)', the motion of a planet about the parent star would be easily detectable. The motion of the Earth about the Sun was observed, but no orbital motion of the source.
- The low frequency signals displayed dispersion, the high frequency signals arriving earlier than the low frequencies. This enabled a rough distance of 65 parsec (about 200 light years) to be estimated for the source.
- Three other similar sources were discovered by Bell including one with a period of only 0.25 seconds.

The discovery was kept under tight wraps until Hewish and his colleagues were absolutely convinced that they had discovered a new type of astronomical phenomenon. I was in the next door office to Hewish at the time and I knew nothing about what was going on until he gave a lecture about the discovery in the week before the *Nature* paper was published. The paper 'Observation of a Rapidly Pulsating Radio Source' was submitted for publication in *Nature* on 9th February 1968 and published on 24th February 1968.[15]

Within a few months, Thomas Gold convincingly associated the pulsars with magnetised, rotating neutron stars.[16] The radio pulses are caused by beams of very high energy particles emitting coherent radiation of extraordinarily high brightness temperature escaping from the poles of a magnetised rotating neutron star. When the beam passes across the line of sight to the observer, an intense burst of radio emission is observed.

Very soon after the discovery, large numbers of pulsars were discovered. By now, well over 2000 radio pulsars are known and they are of the greatest astrophysical importance as the last stable stars before collapse to a black hole ensues. The neutron stars represent matter in bulk at nuclear densities and offer many challenges for physicists and astrophysicists. Perhaps most significant was the fact that relativistic stars really exist in nature — general relativity is essential in working out their stability.

In 1972, neutron stars were discovered as the compact X-ray emitting sources in X-ray binary systems by Riccardo Giacconi and his colleagues from observations with the UHURU X-ray observatory.[17] In these sources, the energy source is the accretion of matter from the normal primary star onto the poles of the neutron star.

In 1975, Russell Hulse and Joseph Taylor discovered that the pulsar PSR 1913+16 is a member of a binary neutron star system.[18] This was a fabulous gift to relativists since it can be considered to be a perfect clock in a rotating frame of reference. The binary neutron star system loses energy by the radiation of gravitational waves and one of the great discoveries was the measurement of the speeding up of the binary due to this process. The remarkable agreement between theory and experiment shows that general relativity is the best theory of relativistic gravity we possess.

The discovery of the pulsars resulted in the award of the Nobel prize to Hewish in 1974. Hewish continued his research on the use of the scintillation technique to chart 'interplanetary weather', work which is of the considerable importance because of its impact upon the GPS system. Bell went on to become a distinguished member of the UK scientific community and has received many awards recognising her role in the discovery of pulsars, most recently the $3 M Special Breakthrough Prize in Fundamental Physics in 2018 — she has generously donated this remarkable prize to the Institute of Physics to support research studentships. In June 2007, she was created Dame Jocelyn Bell-Burnell in the UK honours list. She has been President of the UK Institute of Physics and of the Royal Society of Edinburgh. She has recently been appointed Chancellor of the University of Dundee.

# The CMB then and now with snapshots of Dave Wilkinson

Lyman A. Page Jr.

*Department of Physics, Princeton University, Princeton, NJ 08544-0708, USA*
**E-mail: page@princeton.edu*

We comment on the advance in measurements of the anisotropy of the CMB spanning from when Remo Ruffini was starting his academic career and watching the field's development to the present.

*Keywords*: Cosmic Microwave Background, Cosmology, David T. Wilkinson.

## 1. Ruffini and Wilkinson at Princeton

Remo Ruffini and Dave Wilkinson and were faculty colleagues at Princeton in the early 1970s. Remo was working in the group established by John Wheeler on theoretical aspects of general relativity: gravitational radiation, black holes, neutron stars, and the coupling of electromagnetic and gravitational radiation process to name a few topics. Dave on the other hand was working with colleagues in Bob Dicke's "gravity research group" on experimental aspects of gravity: tests of the equivalence principle, lunar laser ranging, pulsar timing, measurements of the CMB, and the search for primeval galaxies. Just this simple listing gives a sense for what the intellectual atmosphere must have been like. So many possibilities were just about within reach but yet beyond the limits of the empirical tests of the times. Peebles describes the environment at Princeton in these days, and what led Dicke and Wheeler, quite independently, to pursue general relativity [1]. The topics with which Remo and Dave were engaged are, of course, at the forefront of modern physics and as exciting as ever. In the following I'll focus on just one element of the activity in the 1970s, the cosmic microwave background (CMB), and give a brief update on the status of observations.

## 2. The CMB anisotropy in the 1970s

Figure 1 shows the state of measurements of the anisotropy as of 1979. It is taken from "Finding the Big Bang" [2]. It was known that the anisotropy should be present at some level because there are galaxies and clusters of galaxies. They formed via gravitational instability and the same instability affects the CMB. But the level was uncertain and it was not known whether foregrounds or, for example, an early epoch of reionization would mask the anisotropy. The number of groups who were measuring the anisotropy was small. Those who had published results between 1965 and 1979 are shown in the figure. The year 1967, not long after the initial discovery, was particularly active, with limits coming from the "Isotropometer,"

the first instrument designed explicitly to measure the anisotropy [3,4], "Stanford" [5,6], "Crawford Hill" [7], and "Aerospace" [8].

"White Mountain" [9] was also run by the Stanford group. Conklin was searching for evidence of the CMB dipole. It was not appreciated until many years later that his was probably the first experiment to detect anomalous microwave emission [10]. With "RATAN" [11–13] the Soviets were limiting the anisotropy with a highly asymmetric beam while Steve Boughn published his senior thesis at Princeton, "KaDip" [14], on a search for the quadrupole. "XBal" [15] was the first CMB balloon experiment for measuring the anisotropy. Additional limits came from "NRAO-P" [16], "Goldstone" [17], and "Parkes" [18]. The "U2" [19] experiment made a big splash because of its novel platform, a modified U2 spy plane, and a clear detection of the CMB dipole, although at least one other measurement of the dipole had already been presented at a conference [20]. In addition, the U2 was a testing ground for the DMR experiment aboard COBE that discovered the anisotropy [21]. "Testa-Griga" [22] is of special note. It was the first experiment to use bolometers on the ground to search for the anisotropy. Today, all active CMB anisotropy experiments use bolometers. Towards the end of the decade came "GBank-R" [23] and then "MIT" [24,25], a balloon-borne bolometric radiometer.

These were small experiments (or small observing programs on existing telescopes) by today's standards. The total number of separate authors in all the sixteen different measurements spanning this fifteen-year period is about thirty. By comparison, the Planck mission began around 1996 and the number of authors on the most recent parameters paper [26] is just over 175.

## 3. Wilkinson in the 1990s

Before the MAP collaboration formed, Dave had been thinking about a satellite to follow on from COBE. Not much more than a decade had passed since the results in Figure 1 but the field was advancing rapidly. Figure 2 shows what Dave had on his mind. One day when I was walking by his office he called out and asked if I was interested in working on a satellite project. I said "sure!" Dave formed a small group of Ed Wollack, one of his graduate students (affectionally called "Waveguide Wollack" by Ken Ganga, Michael Joyce, and José Gonzalez), Norm Jarosik, a research scientist in the group, and me. When we weren't working on other experiments, we'd iterate on the design shown in the figure. Telling of the times, Dave called the satellite PIE, the Princeton Isotropy Experiment. The anisotropy had yet to be discovered. His vision, though, was far from "PIE in the sky." After pursuing a few different paths [2], we ended up collaborating with the group at NASA Goddard Space Flight Center with Chuck Bennett as the PI. The Goddard group had independently been thinking about a space mission. The proposal, submitted in 1995, was a partnership between Princeton and Goddard. Although Dave passed away in 2002, he saw the first maps from the mission he

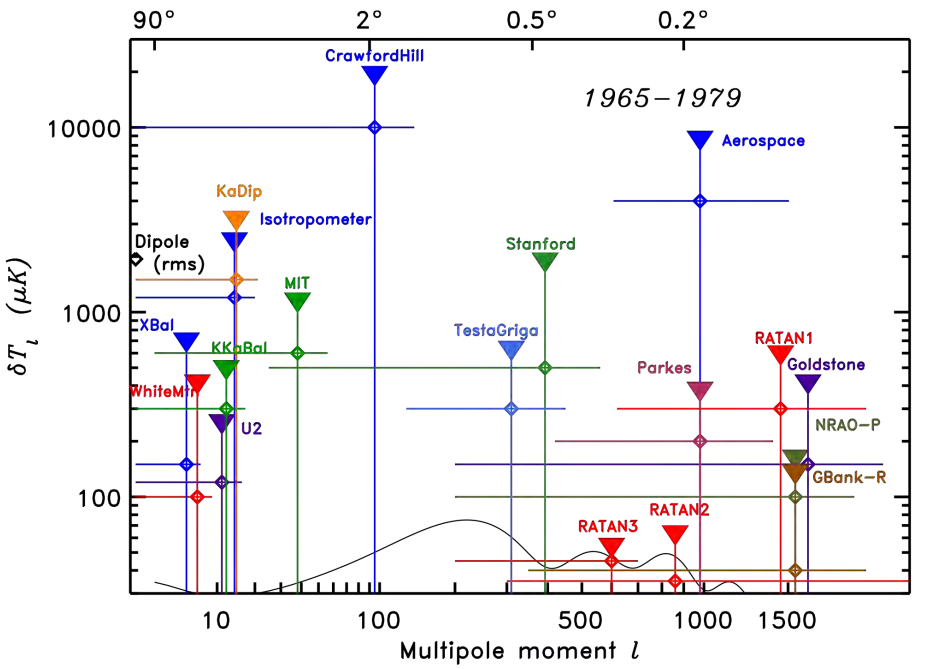

Fig. 1. Status of anisotropy measurements as of 1979. The quantity on the y-axis is $\delta T_\ell = (\ell(\ell+1)C_\ell/2\pi)^{1/2}$ where $C_\ell$ is the angular power spectrum of the CMB. At the time of the measurements, different conventions were used. The original data were converted to the modern standard format as discussed in "Finding the Big Bang" [2]. The triangles show $1\sigma$ upper limits; the horizontal lines show the range of $\ell$ corresponding to the limit. The smooth curve near the bottom of the plot shows the LCDM model in the same units.

had dreamed about just a decade earlier. The satellite was renamed the Wilkinson Microwave Anisotropy Probe (WMAP) in his honor.

## 4. The state of the art

Figure 3 shows the state of the art in anisotropy measurements from groups that have published in the past few years. Since the discovery of the anisotropy by COBE in 1992 a whole field has been born and matured. We have learned more than we ever thought, or even knew, possible in the early 1990s. Although I don't think Dave would have been surprised by the advance in instrumentation, I think he might have been surprised at how kind Nature has been in revealing her secrets through the CMB.

There is a lot captured in Figure 3. For the temperature anisotropy (TT), Planck has the smallest error bars up to about $\ell = 2000$. The higher resolution ground-based ACT and SPT data fill in from $\ell = 500$ up to about $\ell = 8000$. For those in the field, there are important differences between the measurements, but if one takes a step back the agreement is a major success for the field. It is important

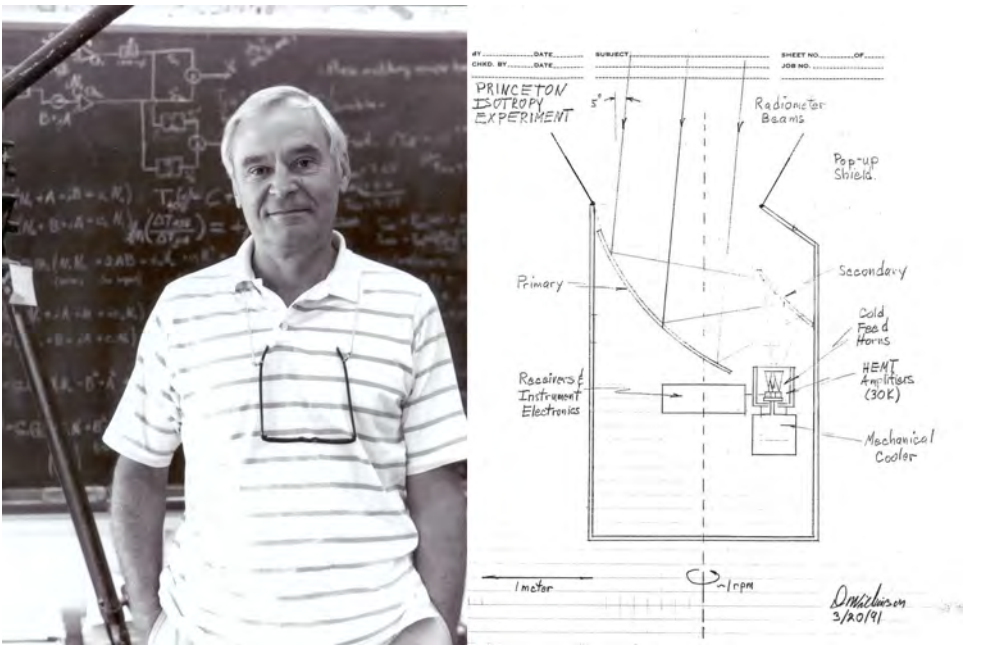

Fig. 2. Dave Wilkinson in front of the blackboard and his 1991 vision for a dedicated CMB satellite.

to note that the agreement is not just in the power spectrum but is in the maps. Different competing teams with different methods of analysis measure the same thing when compared. Both ACT and SPT calibrate off of the Planck maps in a range of $\ell$s near $\ell \sim 1000$.

The two lines through the TT spectrum are the WMAP and Planck basic six-parameter LCDM models. The first thing to note is their similarity. Two completely different satellites, based on different technologies, and analyzed with different methods give the same results.

Sometimes the LCDM model is characterized as just the six parameter fit to cosmological data but it is, of course, more than that. To the limits of measurement, the anisotropy is Gaussian and the fluctuations are adiabatic. In addition, the fluctuations are super horizon. As the universe expands, we sample ever more of a pre-existing sea of primordial fluctuations outside our current Hubble volume.

The Planck/WMAP agreement is especially notable because the data sets are considerably different. Although Planck was the union of two different technologies so that it could cover, importantly, from 30-800 GHz, the following will just address the HFI. On the one hand, Planck is much more sensitive than WMAP. For example the Planck 143 GHz channels, their most sensitive, have a combined instantaneous sensitivity[a] of 14 $\mu$Ks$^{1/2}$ relative to the CMB whereas for WMAP, the instantaneous

[a]All quoted sensitivities are relative to the CMB and for the temperature anisotropy, as opposed to the polarization.

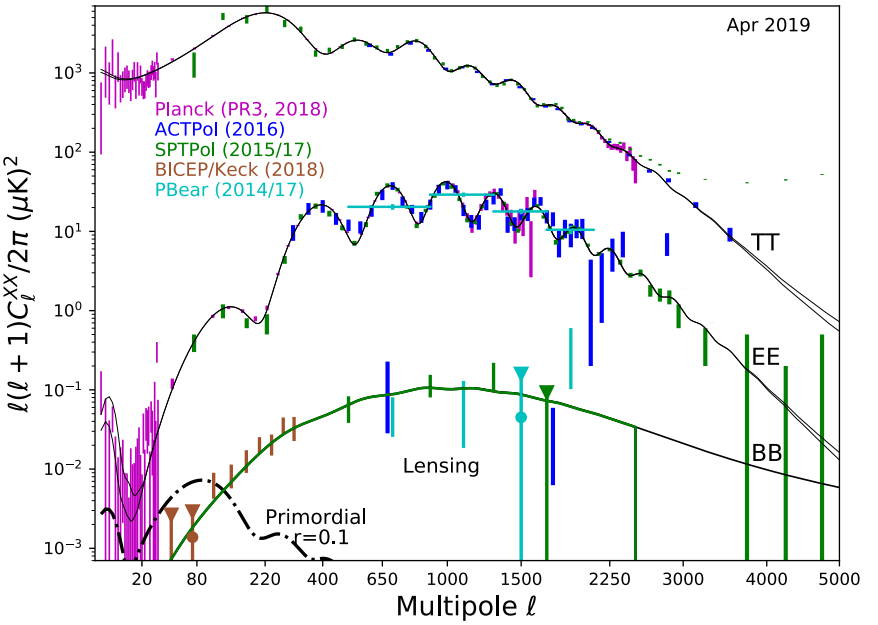

Fig. 3. Recent CMB anisotropy measurements. The y-axis in this plot is the square of the quantity in Figure 1. The TE spectrum is not shown. The data come from Planck, ACTPol, SPTPol, BICEP2/Keck, and Polarbear/Simons Array. Maps from ACT, SPT (and of course WMAP) are publicly available through NASA's LAMBDA site (https://lambda.gsfc.nasa.gov) and Planck's are available through https://wiki.cosmos.esa.int/planck-legacy-archive/index.php/CMB_maps. The *rms* fluctuations for the full range of $\ell$s are TT: 113 $\mu$K, EE 6.4 $\mu$K, BB lensing: 0.43 $\mu$K, and BB primordial: 0.12 $\mu$K for the full range for $r = 0.1$ but 0.09 $\mu$K for $30 < \ell < 160$.

sensitivity in any band is a factor of 30 or more higher[27]. On the other hand, the WMAP data are much cleaner. There are no A/D non-linearities, no long detector time constants, and barely any cosmic rays or glitches to excise. The distribution of WMAP's raw data is Gaussian[28] so that the noise in the sky pixels can be characterized simply by the number of observations.

The HFI sensitivity is notable. Planck still holds the record for the single most sensitive detector that has observed the CMB[29], 50 $\mu$Ks$^{1/2}$. These bolometers came through the efforts of Andrew Lange and Paul Richards, and their power was dramatically demonstrated with the Boomerang experiment[30], led by Lange and La Sapienza's Paolo deBernardis. WMAP was based on the much different broad-band coherent amplifiers developed by NRAO's Marian Pospieszalski.

The next line down on the plot shows the EE spectrum. To minimize "clutter," the TE spectrum is not plotted. The largest discrepancy between WMAP and Planck is on the optical depth, $\tau$. This is a difficult parameter to pin down because it is manifest at large scales, where the foreground emission is large and instrumental systematic errors can have an outsized effect. In Figure 3 the discrepancy is seen as

the difference between the two thin solid curves at $\ell < 20$ for the EE polarization. Planck simply does not see as much low-$\ell$ power as WMAP did. The Planck value is $\tau = 0.054 \pm 0.0076$ [26]. Weiland *et al.*, [31] taking into account WMAP and a range of systematic errors recommends $\tau = 0.07 \pm 0.02$. Reionization is process that is begging to be measured better. Among other things our understanding of it impacts how well one can determine the sum of neutrino masses from the CMB [32].

The LCDM model has a number of built-in cross checks. The same model that fits TT predicts the TE spectrum, the EE spectrum, and the lensing BB spectrum. The physics of these spectra are different. For example, the polarization is produced in a relatively short time right around decoupling as opposed to the longer time over which the temperature anisotropies are produced. As can be seen in the plot, the EE pattern is in excellent agreement with the model that fits TT. The adjustable parameters between them are the polarization efficiency and detector angles.

In Figure 3 one can also see that the Planck TT spectrum runs out of statistical power near $\ell \sim 2300$ and the EE spectrum does so at $\ell \sim 1500$. Both ACT and SPT are more sensitive in this range. In particular, this means that with increased sensitivity the cosmological parameters can be redone using only CMB polarization. This program is in the works.

The bottom curve shows the lensing BB spectrum. The signal is produced by gravitational lensing of the CMB E-modes [33] as the CMB propagates to us from the decoupling surface through the matter fluctuations in the volume of the universe. The fluctuations in matter density arise from the same primordial power spectrum that gives rise to the TT/TE/EE CMB spectra. Thus the lensing ties together two manifestations of the primordial power spectrum. Lensing also affects TT and TE and, to within a few $\sigma$, the lensing effects agree with the those of the primary anisotropy.

The much-discussed primordial B-modes are shown on the bottom left. If they exist at measurable levels, they will give us new insights into the physics of the birth of the universe and to how gravitational waves couple to fundamental fields. The plotted data are from the BICEP2/Keck experiment [34].

## 5. Challenges

Between the COBE discovery in 1992 and 1995, there were half dozen groups publishing measurements of the anisotropy. Most of the results were in the form of power spectra and only a few could be confirmed through cross correlation with another experiment or through a repeated independent measurement in, say, a subsequent year. This prompted Dave Wilkinson, who often admonished the community to "show our warts," to write "A warning label for cosmic microwave background anisotropy experiments." [35]. The abstract is still relevant:

*It is demonstrated that there may be undetected systematic errors or foreground sources lurking in measurements of anisotropy in the cosmic microwave background radiation (CMBR). The elaborate statistical analysis techniques used to identify tiny*

*signals in hours of noisy data are discussed. The important errors in the results are probably not generated by Gaussian noise, but by spurious signals and unknown foreground sources that are hiding in that noise, along with whatever CMBR signal is being detected. It is likely that among the many reports of statistically significant sky signals there are some real detections of CMBR anisotropy. However, given the number of ways that results can be contaminated, and the modest level of candor and quantitative assessment of possible systematic effects in the experimental papers, theorists should treat most current "detections" with skepticism.*

The field has advanced enormously since then. We routinely produce *maps* of the temperature anisotropy and *maps* of the polarization that can be compared between experiments. In contrast to reporting power spectra, maps allow one to check both the amplitude and phase of any purported signal. This gives faith in the results, but also assumes that the maps are public. There are still claims of different, beyond LCDM, phenomena at the 2-3$\sigma$ level and time will tell if these turn into something real. The statistical methods are now much more sophisticated but at the same time Dave's "tiny signals" have been redefined. In 1995, a typical error bar was $10 - 20$ $\mu$K for $\delta\ell \sim 50$; today it is an order of magnitude or more smaller. The warning label still obtains: one must be skeptical of new unconfirmed claims based on coadding months and months of data.

The overall challenge of the measurement can be appreciated from a few numbers. On the ground, the best sites are at the South Pole and Chile. At 150 GHz, the physical temperature of the surroundings is 250 K and the atmosphere is 10 K. The *rms* of the E-mode polarization is 6 $\mu$K. To measure this to an accuracy of 1% requires control/understanding of the environment to better than a part in $10^6$. The advances over the years have not only been in detector sensitivity but in technique. In the mid-1990s we did not know how best to extract such small signals.

The field is entering a new era. For example, when one measures B-mode polarization at large angular scales, one is measuring foregrounds. Thus understanding, measuring, and modeling polarized foregrounds has become an active area of research. So far, the only measured polarized foregrounds are from synchrotron and dust emission. In temperature these components show spatial variations in their spectra indices and they are non-Gaussian. The polarized emission comes from different regions of the interstellar medium and a definitive departure from power law behavior has not been published. Though we might get lucky in modeling them, the field is prepared for the challenge of dealing with a complicated sky. To measure primordial B-modes with say $r = 0.001$ with a S/N of a few entails measuring a 10 nK level signal with a few nK precision. The lensing produces a corresponding *rms* of roughly 65 nK. In a clean part of the sky, the *rms* level of dust emission of the sweet spot for ground observing at $30 < \ell < 160$ is roughly 220 nK.

At smaller angular scales, gains can still be made with only modest cleaning. Figure 4 shows the dust foregrounds at 150 GHz, one of the prime observing frequencies. The top grey line is for TT. The bottom two swaths are for the polarization

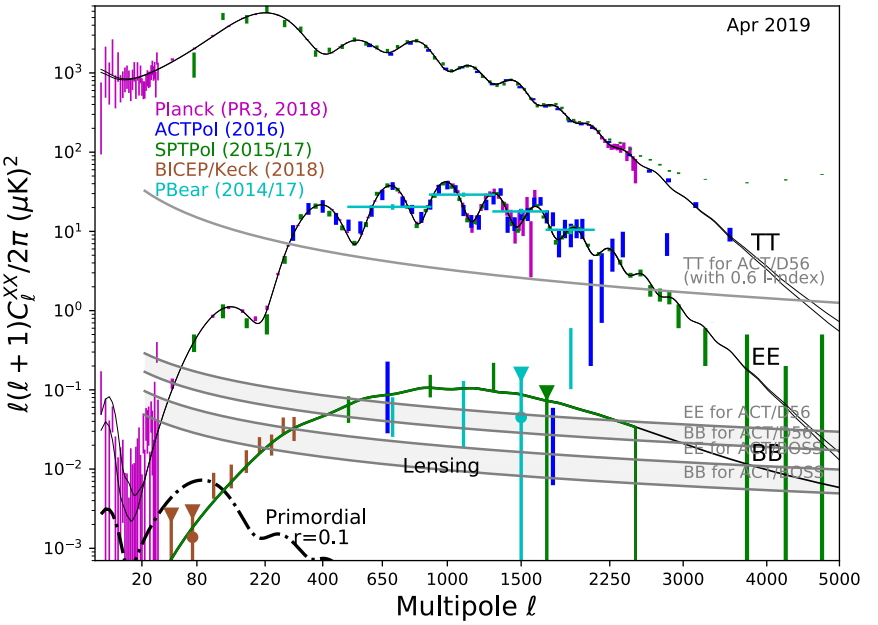

Fig. 4. Foreground emission from dust at 150 GHz for different regions of sky. The top grey line is for TT and the bottom two swaths are for polarized emission in a typical off-plane (top) and a relatively clean (bottom) region. Cleaner parts of the sky exist.

in different regions. The BB foreground levels are typically a factor of two smaller than the EE levels as indicated by the width of the various bands.

## 6. The future

The CMB is the gift that keeps on giving. We are far from learning all we can from it. Largely driven by the different demands of measuring large and small angular scales, there are two broad classes of instruments: "small telescopes" for large angular scales, particularly primordial B-modes, and "large telescopes" for smaller angular scales corresponding to $\ell > 300$. The Polarbear/Simons Array instrument[b] straddles these two broad classes.

### 6.1. *Large angular scales*

On the ground, the leading large-angular scale experiment is BICEP2/Keck which operates from the South Pole. It's advantages are the relatively stable atmospheric conditions at the South Pole, a large array of detectors, and the nearby SPT to help

[b]The Polarbear/Simons Array project is distinct from the Simons Observatory project.

delens the signal. The limitation is access to large clean, perhaps even the cleanest, areas of sky. The current results are from $400\,\mathrm{deg}^2$. As can be seen in Figure 3, delensing will be needed before too long.

The CLASS experiment is operating in Chile with the most sensitive array yet at 40 GHz: $32\,\mu\mathrm{Ks}^{1/2}$. (The previous record holder was the QUIET experiment[36] at $69\,\mu\mathrm{Ks}^{1/2}$.) Higher frequencies are fielded and observing. Their strategy is to cover a large area of sky, currently 75%, to search for primordial B-modes and measure the optical depth[37].

The QUBIC[38] team is building a novel bolometric interferometer to search for B-modes. It will be situated in northern Argentina, not too far from the ACT/SO/PB-SA/CLASS site. This is the most novel of the current generation of experiments. It is the sort of thing I think Dave would have liked to try. Other examples of him taking a direction different from the rest of the field are his dual-horn correlation receiver experiment done with Peter Timbie[39] and his development of a mm-wave detector based on Rydberg atoms which was never published. The first of these presaged the successful compact interferometric arrays of CBI and DASI.

The Simons Observatory collaboration is in the process of building three "Small Aperture Telescopes" (SATs)[40] that will be situated in Chile. As of this writing, the first is scheduled to be fielded in 2020. In contrast to BICEP2/Keck, they will observe roughly 4000 $\mathrm{deg}^2$. For this area, delensing is not needed to reach a sensitivity of $\sigma_r = 0.002$. (See Table 1 ). The CMB-S4 collaboration envisions a collection of 14 half-meter aperture receivers.

There are a number of balloon-borne experiments in various stages of development. Currently the most advanced is SPIDER[41]. It has completed one balloon flight mapping 4000 $\mathrm{deg}^2$ of the sky at 90 and 150 GHz. The preliminary in-flight net sensitivity is $7.1\,\mu\mathrm{Ks}^{1/2}$ at 90 GHz and $5.3\,\mu\mathrm{Ks}^{1/2}$ at 150 GHz. The LSPE[42], EBEX-IDS[43] (next generation EBEX[44]), and PIPER[45] experiments (with first flight in Oct. 2017) are in various stages of testing. There are also some recent proposals for measuring the optical depth from balloons. During the conference, La Sapienza's OLIMPO experiment was launched. While its science goal is the characterization of SZ clusters, it has advanced detector technology relevant to B-mode measurements. In particular, it gave the first demonstration of KID detectors in a space environment[46].

Space is the ultimate environment for CMB measurements. For a measurement as important B-modes, a new satellite mission is a natural and arguably necessary next step. There have been a number of proposals that have reached various stages of review. They include COrE, COrE+, PRISM, PIXIE, EPIC, EPIC-IM, CMB-Bharat, PICO, and LiteBIRD. The number of proposals indicates the general realization of the importance of such a mission. One clear advantage of space is the ability to look at a wide range of frequencies to clean foreground emission as assessed, for example, by Remazeilles et al.[47]. The most developed of the satellite missions is LiteBIRD, which has already passed a number of review milestones.

Table 1. Comparison of some projections for future large experiments

| | Existing | Simons Observatory | CMB-S4 | LiteBIRD | PICO |
|---|---|---|---|---|---|
| Estimated first light | Current | 2021 | 2027 | 2027 | TBD |
| Angular scale | | $\ell > 30$ | $\ell > 30$ | $\ell < 200$ | $\ell < 4000$ |
| $\sigma_r$ | 0.03 | $2 \times 10^{-3}$ | $0.5 \times 10^{-3}$ | $1 \times 10^{-3}$ | $1 \times 10^{-4}$ |
| $\sigma_{N_{eff}}$ | 0.2 | 0.05 | 0.03 | | 0.06 (95% cl) |
| $\sigma_\tau$ | 0.0076 | | | | 0.002 |
| $\sigma_{\Sigma m_\nu}$ (meV) | 100 | 30 | 26 | | 15 |

*Note*: The current values of $\sigma$ are from BICEP2/Keck [34] for the tensor to scalar ratio, $r$, and from Planck [26] for the other parameters. The Simons Observatory values [48] are the "goals" and include foreground cleaning. The CMB-S4 projections [49] for $\sigma_{\Sigma m_\nu}$ were originally 15 meV but are here modified according to Allison et al. [32]. The other projection are from the LiteBIRD [50] and PICO [51] projects. See references for constraints on additional parameters.

### 6.2. *Small angular scales*

At angular scales where one can measure multiple SZ clusters as well as the high $\ell$ part of the CMB ($200 < \ell < 8000$) the two major telescopes are ACT and SPT. There are both in their third generation of receiver and continue to produce great science. ACT, of which I am a part, has mapped half the sky with receivers that have a combined sensitivity, for just two of three arrays, of about $8\,\mu\mathrm{Ks}^{1/2}$ at 90 GHz and $11\,\mu\mathrm{Ks}^{1/2}$ at 150 GHz [52] in nominally good (pwv=1.3 mm) observing conditions. In other words, they exceed the sensitivity of Planck even though they are observing through the atmosphere.

The next generation of large telescopes are already in the works. The Simons Foundation has made a significant award for a new effort, called the Simons Observatory [c], to be built in Chile. Not only are there the three SATs mentioned above, but there will be a new 6-m telescope based on the CCAT-prime design [53]. The telescope and the associated receiver are currently under construction. The currently scheduled delivery date for the telescope is late 2020. There are yet further plans for additional large telescopes under the CMB-S4 umbrella. Table 1 shows projections for what these new efforts aim to achieve.

The CMB field is alive and growing. There is steady progress on new techniques and on improving the detector sensitivity. The more we learn, the more we know what we can learn. Through the CMB, and the CMB combined with other observations, we are piecing together an interlocking picture of the universe that combines high energy theory, particle physics, general relativity, and a host of exciting astronomical phenomena. The potential for discovery is high and the future prospects exciting.

We give a brief review of the definition of the Wang-Yau quasilocal mass and discuss the evaluation of which on surfaces of unit size at null infinity of an axi-symmetric spacetime in Bondi-van der Burg-Metzner coordinates.

## 1. Introduction

As is well known, it is not possible to find the mass density of gravity in general relativity. The expression for the mass density would have to consist of first derivatives of the metric tensor which are zero in suitable chosen coordinates at a point. But we still desire to measure the total mass in a spacelike region bounded by a closed surface. The mass due to gravity should be computable from the intrinsic and the extrinsic geometry of the surface. It has been considered to be one of the important questions to find the right definition. Penrose gave a talk [24] at the Institute for Advanced Study in 1979 and listed it as the first one in his list of major open problems. The quantity is called quasilocal mass.

Many people including Penrose, [25] Hawking, [16] Brown-York, [5] Hawking-Horowitz, [17] Bartnik [2] and others worked on this problem and various definitions have been given. Several important contributions have also been made by Bartnik, [1] Shi-Tam, [29] and Liu-Yau. [20,21] This article discusses the Wang-Yau quasilocal mass definition discovered in 2009 [33,34].

## 2. The definition of Wang-Yau quasilocal mass

Quasilocal mass is attached to a 2-dimensional spacetime surface which is a topological 2-sphere (the boundary of a spacelike region). But with different intrinsic geometry and extrinsic geometry, we expect to read off the effect of gravitation in the spacetime vicinity of the surface. Suppose the surface is spacelike, i.e., the induced metric $\sigma$ is Riemannian. An essential part of the extrinsic geometry is measured by the mean curvature vector field $\mathbf{H}$, which is a normal vector field of the surface such that the null expansion along any null normal direction $\ell$ is given by the paring of $\mathbf{H}$ and $\ell$.

To evaluate the quasilocal mass of a 2-surface $\Sigma$ with the physical data $(\sigma, \mathbf{H})$, one solves the *optimal isometric embedding system* (see (1) in the next paragraph), which gives an embedding of $\Sigma$ into the Minkowski spacetime with the image surface $\Sigma_0$ that has the same induced metric $\sigma$ as $\Sigma$. We then compare the extrinsic geometries of $\Sigma$ and $\Sigma_0$ and evaluate the quasilocal mass from $\sigma, \mathbf{H}$, and $\mathbf{H_0}$.

The physical surface $\Sigma$ with physical data $(\sigma, \mathbf{H})$ gives $(\sigma, |\mathbf{H}|, \alpha_{\mathbf{H}})$, where $|\mathbf{H}|$ is the norm of the mean curvature vector field and $\alpha_{\mathbf{H}}$ is the connection one-form determined by the mean curvature gauge. As long as the mean curvature vector field $\mathbf{H}$ is spacelike, $|\mathbf{H}|$ is positive and $\alpha_{\mathbf{H}}$ is well-defined. Given an isometric embedding $X : \Sigma \to \mathbb{R}^{3,1}$ of $\sigma$, let $\Sigma_0 = X(\Sigma)$ be the image and $(\sigma, |\mathbf{H_0}|, \alpha_{\mathbf{H_0}})$ be the corresponding data of $\Sigma_0$. Let $T$ be a future timelike unit Killing field of $\mathbb{R}^{3,1}$ and define $\tau = -\langle X, T\rangle$ as a function defined on the surface $\Sigma$ where $\langle \cdot, \cdot \rangle$ is the Minkowski metric on $\mathbb{R}^{3,1}$.

The optimal isometric embedding system and the quasilocal mass can be expressed in terms of a function $\rho$ and a 1-form $j_a$ on $\Sigma$ given by

$$\rho = \frac{\sqrt{|\mathbf{H_0}|^2 + \frac{(\Delta\tau)^2}{1+|\nabla\tau|^2}} - \sqrt{|\mathbf{H}|^2 + \frac{(\Delta\tau)^2}{1+|\nabla\tau|^2}}}{\sqrt{1+|\nabla\tau|^2}}$$

$$j_a = \rho\nabla_a\tau - \nabla_a\left(\sinh^{-1}(\frac{\rho\Delta\tau}{|\mathbf{H_0}||\mathbf{H}|})\right) - (\alpha_{\mathbf{H_0}})_a + (\alpha_{\mathbf{H}})_a,$$

where $\nabla_a$ is the covariant derivative with respect to the metric $\sigma$, $|\nabla\tau|^2 = \nabla^a\tau\nabla_a\tau$ and $\Delta\tau = \nabla^a\nabla_a\tau$.

The optimal isometric embedding system seeks for a solution $(X, T)$ that satisfies

$$\begin{cases} \langle dX, dX\rangle & = \sigma \\ \nabla^a j_a & = 0. \end{cases} \tag{1}$$

We note that the first equation is the isometric embedding equation into the Minkowski spacetime $\mathbb{R}^{3,1}$. The quasilocal mass is then defined to be

$$E(\Sigma, X, T) = \frac{1}{8\pi}\int_\Sigma \rho. \tag{2}$$

Several remarks are in order:

(1) $\Sigma_0$ is the "unique" surface in the Minkowski spacetime that best matches the physical surface $\Sigma$. If $\Sigma$ happens to be a surface in the Minkowski spacetime, the above procedure identifies $\Sigma_0 = \Sigma$ up to a global isometry.

(2) A prototype form of the quasilocal mass which corresponds to the special case $\tau = 0$ in (2) (due to Brown-York,[5] Liu-Yau,[20] Booth-Mann,[4] Kijowski[19]) is

$$\frac{1}{8\pi}\int_{\Sigma}\left(|\mathbf{H_0}| - |\mathbf{H}|\right).$$

The positivity is proved by Shi-Tam[29] and Liu-Yau.[21] However, for a surface in the Minkowski spacetime, the above expression may not be zero.[22]

The optimal isometric embedding system gives the necessary correction, so that the Wang-Yau definition is positive in general and zero for surfaces in the Minkowski spacetime.[33,34]

The derivation of the Wang-Yau definition (2) relies on both physical theory and mathematical theory. From the Hamilton-Jacobi analysis of the Einstein-Hilbert action (Brown-York,[5] Horowitz-Hawking[17]) a surface Hamiltonian $\mathfrak{H}(\Sigma)$ is obtained and the quasilocal energy should be $\mathfrak{H}(\Sigma) - \mathfrak{H}(\Sigma_0)$ for a reference surface $\Sigma_0$ in the reference Minkowski spacetime. The precise definitions of the surface Hamiltonians still depend on the choices of a normal gauge and a timelike vector field along the surface $\Sigma$ as an observer.

On the other hand, the mathematical theory of isometric embeddings (Nirenberg,[23] Pogorelov[26]) is used to find the reference surface $\Sigma_0$ and a variational approach leads to a canonical gauge that anchors the choices of the gauge of the surface Hamiltonian.

In general, the optimal isometric embedding system is difficult to solve. Suppose $(X, T)$ is a solution and suppose the corresponding $\rho$ is positive, then $E(\Sigma, X, T)$ is a local minimum[8] and the nearby optimal isometric embedding system is solvable by an inverse function theorem argument. In a perturbative configuration, when a family of surfaces limit to a surface in the Minkowski spacetime, then the optimal isometric embedding system is solvable, again subject to the positivity of the limiting mass. This applies to the case of large sphere limits[7] and small sphere limits.[12]

## 3. Quasilocal mass at null infinity

### 3.1. *Large sphere limit at null infinity*

Consider an isolated system surrounding a source. In terms of the Bondi-Sachs coordinate system $(u, r, x^2 = \theta, x^3 = \phi)$,[3,27,31,32] near future null infinity $\mathfrak{I}^+$ the spacetime metric takes the form:

$$-Vdu^2 - 2Ududr + \sigma_{ab}(dx^a + W^a du)(dx^b + W^b du), a, b = 2, 3$$

such that each $V$, $U$, $W^a$ admit expansions in terms of integral powers of $r$ with

$$\begin{aligned} V &= 1 - \frac{2m(u,\theta,\phi)}{r} + O(r^{-2}) \\ U &= 1 + O(r^{-2}) \\ \sigma_{ab}dx^a dx^b &= r^2(d\theta^2 + \sin^2\theta d\phi^2) + 2r(cd\theta^2 - c\sin^2\theta d\phi^2 + 2\underline{c}\sin\theta d\theta d\phi) + O(1) \\ W^a &= O(r^{-2}) \end{aligned}$$

The Bondi-Trautman mass is

$$M_{BT}(u) = \frac{1}{4\pi}\int_{S^2} m(u,\theta,\phi), \tag{3}$$

where $m(u,\theta,\phi)$ is the mass aspect function defined at $\mathfrak{I}^+$. As a result of the vacuum Einstein equation, the mass loss formula states

$$\frac{d}{du}M_{BT}(u) = -\frac{1}{4\pi}\int_{S^2}\left(c_u^2 + (\underline{c}_u)^2\right) \leq 0. \tag{4}$$

This important formula represents the first theoretical verification of gravitational wave/radiation in the nonlinear setting.

In Ref. 7, we evaluate the large sphere limit of quasilocal mass which recovers the Bondi-Trautman mass. At a retarded time $u = u_0$, we consider the family of large spheres $\Sigma_r$ parametrized by an affine parameter $r$. The positivity of the Bondi-Trautman mass guarantees the unique solvability of the optimal isometric embedding system (1) with a solution $(X_r, T_r)$. Suppose $X_r$ and $T_r$ admit expansions:

$$T_r = T^{(0)} + \sum_{k=1}^{\infty} T^{(-k)} r^{-k}$$

$$X_r = rX^{(1)} + X^{(0)} + \sum_{k=1}^{\infty} X^{(-k)} r^{-k},$$

then $T^{(0)}$ is shown to be proportional to the Bondi-Sachs energy-momentum and $T^{(0)}$ being future timelike makes $T^{(-k)}$ and $X^{(-k+1)}$ solvable inductively for $k = 1, 2\cdots$.

### 3.2. *Unit sphere limits at null infinity*

Both the Bondi-Trautman mass and the mass loss formula are global statements about $\mathfrak{I}^+$, i.e. they require the knowledge of all directions of $(\theta,\phi)$. The limit of quasilocal mass introduced in the following provides a quasilocal quantity along a single direction $(\theta,\phi)$ at $\mathfrak{I}^+$.

Consider a null geodesic $\gamma(d)$ that approaches $\mathfrak{I}^+$. Around each point on $\gamma(d)$, consider a geodesic 2-sphere $\Sigma_d$ of unit radius. The geometry of $\Sigma_d$ approaches the geometry of a standard unit round sphere of $\mathbb{R}^3$.

In the limit $d \to \infty$, we obtain two quantities. The first one is $\lim_{d\to\infty} E(\Sigma_d)$ which is of the order of $\frac{1}{d^2}$ with $E(\Sigma_d) \geq 0$. The second one is obtained by exploiting the vanishing of the $\frac{1}{d}$ term and appears as a loop integral on the limiting surface that is of the order of $\frac{1}{d}$.

Several cases have been computed:

(1) Linear gravitational perturbation of the Schwarzschild black hole à la Chandrasekhar. The linearized vacuum Einstein equation is solved by separation of variables and solutions of linearized waves are obtained. The optimal isometric embedding system can be solved and the quasilocal mass can be evaluated by solving

$$\begin{aligned} \Delta(\Delta+2)\tau &= \text{physical data}, \\ (\Delta+2)N &= \text{physical data}, \end{aligned} \tag{5}$$

where $\tau$ and $N$ are functions on the standard 2-sphere and $\Delta$ is the Laplace operator. All distinctive features of the waves such as frequency and mode parameters are recovered.

(2) The Vaidya spacetime [a]

$$-(1-\frac{2m(u)}{r})du^2 - 2dudr + r^2(d\theta^2 + \sin^2\theta d\phi^2)$$

The quasilocal mass of a unit sphere approaching null infinity is

$$E(\Sigma_d) = -\frac{1}{8\pi d^2}\int_{S^2} (\partial_u m)\sin^2(\hat{\theta}) + l.o.t. \geq 0 \tag{6}$$

The positivity of quasilocal mass corresponds to the mass loss formula in the Vaidya case.

One may expect that the limit of quasilocal mass in the direction of $(\theta_0, \phi_0)$ will recover the value of the mass aspect function $m(u, \theta_0, \phi_0)$. But notice that the mass aspect function is not pointwise positive, only the integrated Bondi-Trautman mass is positive by Schoen-Yau [28] and Horowitz-Perry. [18] In the Vaidya case, the mass aspect is recovered from the loop integral.

## 4. Unit sphere limit in BVM coordinate near null infinity

The Vaidya spacetime is a model for the Einstein-null dust system. In particular, the condition $-\partial_u m \geq 0$ in (6) can be interpreted as local energy condition for matters. In order to study the contribution of quasilocal mass at the purely gravitational level, we study the null infinity of a vacuum spacetime. We discuss the case of an axi-symmetric spacetime in the Bondi- van der Burg-Metzner coordinates near null infinity. The leading terms of the spacetime metric are of the form:

$$-(1-\frac{2\mathbf{M}}{r})du^2 - 2dudr - 2\mathbf{U}dud\theta + (r^2 + 2r\mathbf{C})d\theta^2 + (r^2 - 2r\mathbf{C})\sin^2\theta d\phi^2,$$

where $\mathbf{M}, \mathbf{U}, \mathbf{C}$ are functions of $u$ and $\theta$.

[a] The mass aspect function used here differs to that of Ref. 13 by a factor of 2.

The $\frac{1}{d^2}$ term of the quasilocal mass of a unit sphere approaching null infinity is (up to a constant factor)

$$\int_{B^3}[(\partial_u \mathbf{C})^2 + \det(h_0^{(-1)} - h^{(-1)})] + \frac{1}{4}\int_{S^2}[(tr_\Sigma k^{(-1)})^2 - \tau^{(-1)}\tilde{\Delta}(\tilde{\Delta}+2)\tau^{(-1)}], \quad (7)$$

in which $h^{(-1)}$ and $k^{(-1)}$ depend on the physical data and $h_0^{(-1)}$ and $\tau^{(-1)}$ depend on the solution of the optimal isometric embedding system. A priori, the expression may depend on all $\mathbf{M}, \mathbf{U}$, and $\mathbf{C}$. However all occurrences of $\mathbf{M}$ and $\mathbf{U}$ are cancelled and the final answer only involves the function $\mathbf{C}$ and is completely independent of the mass aspect function $\mathbf{M}$. The expression (7) is manifestly positive by Wang-Yau's theorem.

### 4.1. *Final remark*

Given a spacetime surface $(\Sigma, \sigma, \mathbf{H})$, we find the reference surface $(\Sigma_0, \sigma, \mathbf{H_0})$ through the optimal isometric embedding equation and evaluate the quasilocal mass. This is a nonlinear and coordinate independent theory. The procedure is canonical and is accompanied by a uniqueness statement. In particular, the definition does not involve any ad hoc referencing or normalization. The calculation of the quasilocal mass does not assume any a priori knowledge of null infinity.

The positivity of the unit sphere limit should correspond to a "quasilocal" mass loss formula, or "quasilocal gravitational radiation" at null infinity. The evaluation in the full generality of Bondi-Sachs coordinates (without assuming axi-symmetry) will appear in an upcoming paper.

We start by looking at why we believe that black holes have entropy. According to Boltzmann, the entropy is a measure of the number of microstates of a system. We suggest here that the entropy arises from a holographic conformal field theory on the black hole horizon. Finally, we discuss some of the implications for the information paradox.

*Keywords*: Black holes. Thermodynamics, Holography. Information Paradox.

## 1. Introduction

Black holes were first thought about by John Michell back in 1784.[1] He reasoned that if the escape velocity from an object like a star exceeded the speed of light, then it would give rise to an object that cannot be seen optically but whose gravitational field would betray its existence. These ideas were given substance by Einstein's general theory of relativity and the subsequent discovery of solutions of the field equations that represented stationary black holes.[2–6] One puzzling feature of stationary black holes is that they are completely characterised by just a few parameters; their mass $M$, angular momentum $\mathbf{J}$ and electric charge $Q$.[7–11] It is this observation that is the basis for the information paradox.[12]

The thermodynamics of black holes in general relativity has a history starting in 1972. The first relevant discovery, the area theorem, was made by Hawking.[13] He found that the area of a black hole horizon could never decrease provided the null convergence condition $R_{ab}k^ak^b \geq 0$ holds for every null vector $k^a$. Shortly after this, Jacob Bekenstein suggested[14] that the entropy of a black hole must be proportional to the area of its event horizon. His reasoning was based on three observations. The first was that if a Kerr-Newman black hole increased its mass by an amount $dM$, then

$$dM = \frac{\kappa dA}{8\pi} + \Phi dQ + \mathbf{\Omega}\cdot d\mathbf{J} \tag{1}$$

where $\kappa$ is the black hole surface gravity, $A$ the area of the event horizon, $\Phi$ the electrostatic potential of the black hole and $\mathbf{\Omega}$ its angular velocity. $\kappa$, $A$, $\Phi$ and $\mathbf{\Omega}$ are all determined in terms of $M$, $\mathbf{J}$ and $Q$. The second piece of evidence was that he reasoned that a black hole must have some kind of internal structure that

resulted from it method of formation. That would give rise to an entropy

$$S = -\sum_n p_n \ln p_n \tag{2}$$

arising from the probability of the occupation of the $n^{th}$-state being $p_n$. Finally, he showed that it was necessary for this black hole entropy to be added to the thermodynamic entropy of the rest of the universe in order to have a consistent theory of thermodynamics. This came about because otherwise dropping a box of radiation into a black hole would cause the entropy of the universe to decrease, in contradiction to the second law of thermodynamics.

His ideas were met with a certain amount of scepticism because black holes were thought to have vanishing temperature. Despite that, Bardeen, Carter and Hawking[15] pointed out the similarities between the first law of thermodynamics and (1) and also the second law of thermodynamics and the area theorem.

In 1974, Hawking[16,17] showed that black holes had a temperature $T_H$ of $\hbar\kappa/(2\pi)$. Unlike previous work, his calculation was quantum mechanical in nature. Black holes would emit particles with a thermal spectrum at a temperature given by $T_H$. By identifying (1) with the first law of thermodynamics, one can immediately infer that the entropy must be given by $A/(4\hbar)$. The area theorem is thereby identified with the second law of thermodynamics. A somewhat different view of entropy was taken in Ref. 18. The idea here was to use the path integral for gravity to derive black hole entropy. Although gravity is unrenormalizable, there is no obstacle to using the path integral to lowest order as the uncontrollable divergences only occur at one loop or beyond. The action for pure gravity is, including the Gibbons-Hawking-York boundary terms[18,19]

$$I[g,h] = \frac{1}{16\pi}\int_{\mathcal{M}} R(g)\sqrt{\| g \|}d^4x + \frac{1}{8\pi}\int_{\partial\mathcal{M}} K\sqrt{\| h \|}d^3x + C[h] \tag{3}$$

where now $\mathcal{M}$ is the spacetime manifold with metric $g$ and Ricci scalar $R(g)$. The boundary of $\mathcal{M}$ is $\partial\mathcal{M}$ with metric $h$ and second fundamental form $K$. $C[h]$ is any functional of $h$ and is designed to make the action of flat spacetime vanish. Suppose one wants to find the partition function for a black hole spacetime. Then one wants to compute $Z = \mathrm{tr}(e^{-\beta\mathcal{H}})$ where $\beta$ is the inverse temperature and $\mathcal{H}$ the Hamiltonian. This can be done by realising that $e^{i\mathcal{H}t}$ is the time evolution operator and so if $t$ is identified with $t + i\beta$ then $Z$ is given by

$$Z = \int D[g]e^{-I[g,h]/\hbar}, \tag{4}$$

where now the integral is over all metrics $g$ of positive definite signature and that approach flat space at infinity and are periodic in imaginary time $t$ with period $\beta = T_H^{-1}$.

The Schwarzschild metric is

$$ds^2 = -(1 - \frac{2M}{r})dt^2 + (1 - \frac{2M}{r})^{-1}dr^2 + r^2 d\Omega^2\,, \tag{5}$$

where $M$ is the mass of the static black hole with horizon at $r = 2M$ and $d\Omega^2$ is the metric on the unit 2-sphere. Taking $t = i\tau$ so that the geometry is as described above gives the Euclidean metric

$$ds^2 = (1 - \frac{2M}{r})d\tau^2 + (1 - \frac{2M}{r})^{-1}dr^2 + r^2 d\Omega^2 \tag{6}$$

Now, $r = 2M$ is a conical singularity that is resolved provided that $\tau$ is identified with period $8\pi M$.[20] This periodicity is precisely the same periodicity expected from the Hawking calculation of the black hole temperature. Interpreting the exponential of the action as the partition function, reproduces the black hole entropy. In this calculation, the region $r < 2M$ has been removed from consideration. Implicitly this means that the internal degrees of freedom have been traced over. One is thereby led to believe that the black hole does have some kind of internal structure that cannot be probed by external observers who just look at the classical geometry. The same kind of reasoning can be applied to the Kerr-Newman metric too.

Black holes evaporate. The black hole uniqueness theorems suggest that the only properties that a stationary black hole has are just the mass, charge and spin. As a consequence, there is a tension with the ideas of quantum mechanics. If a black hole completely disappears, then the final state should be unitarily equivalent to the initial state. Obviously, there are enormous number of ways in which the black hole could form. The black hole, once it has settled down to a more or less equilibrium state, is described by just those three parameters. The Hawking radiation is thermal and characterised by the Hawking temperature. Such a final state consisting of Hawking radiation will not be unitarily related to the initial state that gave rise to the black hole. This is the information paradox. It might be that quantum mechanical information really is lost in gravitational collapse. But then, the whole edifice of quantum mechanics would need to be rethought. The incredible success of quantum mechanics would seem to discourage such a viewpoint. Alternatively, there might be something wrong with the uniqueness theorems. It is this latter possibility that we will investigate here.

In what follows, we will use covariant phase space methods[21–27] to understand the nature of charges in general relativity and the consequences for the physics of black holes. The reason for using the covariant phase space method is to preserve as much as possible of the covariance of theory. Had we picked the more conventional canonical methods, we would be forced to pick a particular time coordinate which would obscure matters. Furthermore, it would it impossible to understand what happens on null surfaces such as the event horizon. Our aim now is to try to understand something about the microscopic origin of black hole entropy. The hope is that this will aid a resolution of the information paradox.

In pure general relativity, one can start with the Einstein-Hilbert action $I$ given by

$$I = \frac{1}{16\pi}\int_{\mathcal{M}} R(g)\sqrt{\| g \|}d^4x. \tag{7}$$

This action omits the boundary terms, but these are not germane to the discussion that follows. One finds the Einstein equation by performing a variation of the action induced by a variation of the metric $g_{ab} \to g_{ab} + h_{ab}$. This results in the variation $\delta I$ given by

$$\delta I = \int_{\mathcal{M}} \; (R_{ab} - \frac{1}{2} R \, g_{ab}) \; h^{ab} \, \sqrt{\| \; g \; \|} d^4x + \int_{\partial \mathcal{M}} \theta \tag{8}$$

The three-form on the boundary $\theta(g, h)$ is known as the presymplectic potential and has components

$$(*\theta)_a = \frac{1}{16\pi} \left( \nabla_b h^b_a - \nabla_a h \right) \tag{9}$$

where $h = h_{ab} g^{ab}$. In canonical general relativity, the boundary term would be thought of

$$\int_{\partial \mathcal{M}} \; \sum_i \; p_i \delta q^i \tag{10}$$

where $q^i$ are the generalised coordinates, $p_i$ are the generalised momenta and $i$ represent the tensor indices of these fields.

The presymplectic density $\omega(g; h, h')$ is defined by a second variation $g_{ab} \to g_{ab} + h'_{ab}$

$$\omega(g; h, h') = \delta\theta(g, h') - \delta'\theta(g, h) \tag{11}$$

Finally, the symplectic form for general relativity is

$$\Omega_\Sigma = \int_\Sigma \omega \tag{12}$$

where $\Sigma$ is any partial Cauchy surface in the spacetime. In the language of the canonical theory, $\Omega_\Sigma$ would be

$$\int_\Sigma \; \sum_i \; \delta p_i \wedge \delta q^i. \tag{13}$$

One property that $\omega$ has is that if the background metric $g_{ab}$ obeys the Einstein equation and both $h_{ab}$ and $h'_{ab}$ obey the linearised Einstein equations, then $\omega$ is closed. Thus $\Omega_\Sigma$ is constant under variations of $\Sigma$ as long as the boundaries of $\Sigma$ are fixed.

In general relativity, the symmetry group is the group of diffeomorphisms. An infinitesimal coordinate transformation is specified by a vector field $\zeta^a$. This induces a variation in any tensor field given by the Lie derivative of that field. Thus, for example, the variation of the metric is given by

$$\delta g_{ab} = \mathcal{L}_\zeta g_{ab} = g_{ab} + \nabla_a \zeta_b + \nabla_b \zeta_a. \tag{14}$$

The bulk term in the variation of the action $\delta I$ is invariant under such a transformation but the boundary term is not. The infinitesimal co-ordinate transformations obey an algebra whose composition law is

$$\mathcal{L}_\zeta \mathcal{L}_\eta - \mathcal{L}_\eta \mathcal{L}_\zeta = \mathcal{L}_{[\zeta, \eta]} \tag{15}$$

where $\zeta$ and $\eta$ are two (smooth) vector fields and

$$[\zeta, \eta] = \mathcal{L}_\zeta \eta = -\mathcal{L}_\eta \zeta \tag{16}$$

Suppose now that in $\Omega$ one makes $h'_{ab}$ a gauge transformation given by the vector field $\zeta$. Then $\Omega$ can be written as a boundary integral. Explicitly,

$$Q_\zeta = \frac{1}{16\pi} \int_{\partial\Sigma} F_{ab}\ dS^{ab} \tag{17}$$

with

$$F_{ab} = -2\zeta_{[a}\nabla_{b]}h + 2\zeta_{[a}\nabla^c h_{b]c} - 2\zeta^c \nabla_{[a} h_{b]c} - h\nabla_{[a}\zeta_{b]} + 2h_{c[a}\nabla^c \zeta_{b]}. \tag{18}$$

Let $\partial\Sigma$ is a closed 2-surface $S$, for example the celestial sphere or a black hole event horizon. One would like to interpret $Q_\zeta$ as the variation in the Noether charge conjugate to $\zeta$ that is enclosed in the interior of $S$ as one moves between the metric $g_{ab}$ and $g_{ab} + h_{ab}$. There is a complication with this idea because in such a change, there might be a flux of charge crossing $S$. To take account of this possibility, one needs to examine $Q_\zeta$ and identify such terms and subtract them out. In more mathematical language, one we want $Q_\zeta$ to be a function of state. As such it must be a 1-form on the infinite-dimensional phase space of the theory. This 1-form needs to be exact so that if one goes along a path $\Gamma$ between $g_{ab}$ and $g_{ab} + h_{ab}$, then $Q_\zeta$ is independent of the path $\Gamma$, and therefore dependent only the end-points of that path. The definition on $Q_\zeta$ thus needs to be modified by the ddition of a suitable counterterm $Q_\zeta \to Q_\zeta + Q^{ct}_\zeta$. Finding $Q^{ct}_\zeta$ needs to be done on a case by case basis as has been elegantly explained in detail by Wald and Zoupas.[26]

In the case that $\zeta$ were a time translation, then $Q_\zeta$ would be the quasi-local mass enclosed in $S$.[28] If it were a spatial translation then the momentum. If $\zeta$ were a Killing vector, then $Q_\zeta$ would be the same as the Komar integral.[29] If $\zeta$ were a supertranslation or super-rotation at null infinity, then $Q_\zeta$ would be the corresponding supertranslation or super-rotation charge. Equally, one can define charges on the black hole horizon and these are the soft charges or soft black hole hair.[30]

Diffeomorphism invariance of general relativity means that the charges $Q_\zeta$ lie in some representation of group of coordinate transformations. Thus

$$\delta_\zeta Q_\eta - \delta_\eta Q_\zeta = Q_{[\zeta,\eta]} \tag{19}$$

Were this relation not to hold, general coordinate invariance would be violated, in gross contradiction to our expectations of what should be true in physics. However, what we find is that this relationship does not hold for charges on black hole event horizons. Instead, we find

$$\delta_\zeta Q_\eta - \delta_\eta Q_\zeta = Q_{[\zeta,\eta]} + K(\zeta, \eta) \tag{20}$$

where $K(\zeta, \eta)$ is a central extension of this algebra.[31] We will now explore a particular example and move on to its interpretation.

We start from the Kerr metric in Boyer-Lindquist coordinates.

$$ds^2 = \rho^2(\frac{dr^2}{\Delta} + d\theta^2) + (r^2 + a^2)\sin^2\theta d\phi^2 - dt^2 + \frac{2Mr}{\rho^2}(a\sin^2\theta d\phi - dt)^2 \quad (21)$$

where

$$\Delta = r^2 - 2Mr + a^2 \quad (22)$$

and

$$\rho^2 = r^2 + a^2\cos^2\theta. \quad (23)$$

$M$ is the mass of the black hole and $J = Ma$ is its angular momentum. $\Delta = 0$ at $r_\pm$ with $r_+$ being the location of the outer horizon, $r_-$ the location of the inner horizon and

$$r_\pm = M \pm \sqrt{M^2 - a^2} \quad (24)$$

Now we will define "conformal" coordinates[32] and assume that the black hole is not extreme so that $m^2 > a^2$.

$$w^+ = \sqrt{\frac{r - r_+}{r - r_-}}\, e^{2\pi T_R \phi} \quad (25)$$

$$w^- = \sqrt{\frac{r - r_+}{r - r_-}}\, e^{2\pi T_L \phi - t/2M} \quad (26)$$

$$y = \sqrt{\frac{r_+ - r_-}{r - r_-}}\, e^{\pi(T_L + T_R)\phi - t/4M} \quad (27)$$

where

$$T_L = \frac{r_+ + r_-}{4\pi a} \quad \text{and} \quad T_R = \frac{r_+ - r_-}{4\pi a} \quad (28)$$

The future outer horizon is $w^- = 0$ and the past outer horizon is $w^+ = 0$. The azimuthal coordinate $\phi$ is identified with period $2\pi$ and this induces an identification on $w^+, w^-$ and $y$ as

$$w^+ \to e^{4\pi^2 T_R} w^+, \quad w^- \to e^{4\pi^2 I_L} w^-, \quad y \to e^{2\pi^2(T_L + T_R)} y. \quad (29)$$

The line element close to the horizon bifurcation surface $w^+ = w^- = 0$ is[33]

$$ds^2 = \frac{4\rho_+^2}{y^2} dw^+ dw^- + \frac{16M^2a^2\sin^2\theta}{\rho_+^2 y^2} dy^2 + \rho_+^2 d\theta^2 + O(w^+, w^-) \quad (30)$$

where $\rho_+^2 = r_+^2 + a^2\cos^2\theta$. If one looks at the $w^+, w^-, y-$ plane by setting $\theta$ to be a constant, then this line element is that of $AdS_3/\Gamma$ with $\Gamma$ being some discrete group. So close to the horizon bifurcation surface, the geometry of spacetime is some kind of warped product of the line segment $\theta \in [0, \pi]$ and a deformed portion of three-dimensional anti-de Sitter space. The classic work of Brown and Henneaux[31] shows

that in spacetimes that are asymptotic to anti-de Sitter spacetime, the diffeomorphism algebra has anomalies. One might therefore suspect that something similar happens in the case of the Kerr black hole.

Consider the diffeomorphism given by the vector field $\zeta_n$

$$\zeta_n = \epsilon_n(w^+)\partial_+ + \frac{1}{2}\epsilon'(w^+)y\partial_y \tag{31}$$

with

$$\epsilon_n(w^+) = 2\pi T_R(w^+)^{(1+\frac{in}{2\pi T_R})} \tag{32}$$

and $n$ being any integer. It should be noted that under the identifications of either $w^+ \to w^+ e^{4\pi^2 T_R}$ or $y \to y e^{2\pi^2(T_L+T_R)}$ that $\zeta_n$ is invariant. This vector field is well-defined on the future horizon. These vector fields obey the Witt (or centerless Virasoro) algebra with the commutator

$$[\zeta_n, \zeta_m] = i(m-n)\zeta_{n+m} \tag{33}$$

Similarly, one can find a second vector field $\tilde{\zeta}_n$ given by

$$\tilde{\zeta}_n = \tilde{\epsilon}_n(w^-)\partial_- + \tfrac{1}{2}\tilde{\epsilon}'(w^-)y\partial_y \tag{34}$$

and $\tilde{\epsilon}$ being given

$$\tilde{\epsilon}_n(w^-) = 2\pi T_L(w^-)^{(1+\frac{in}{2\pi T_L})} \tag{35}$$

again with $n$ being any integer. This vector field is well-defined on the past horizon. Again, it is invariant under the identifications $w^- \to w^- e^{4\pi^2 T_L}$ or $y \to y e^{2\pi^2(T_L+T_R)}$. It too obeys the Virasoro algebra

$$[\tilde{\zeta}_n, \tilde{\zeta}_m] = i(m-n)\tilde{\zeta}_{n+m}. \tag{36}$$

Both of these vector fields are well-defined on the bifurcation surface and commute with each other there

$$[\zeta_n, \tilde{\zeta}_m] = 0. \tag{37}$$

These vector fields can be used to generate charges on the bifurcation surface. To do this we need to introduce an appropriate counterterm. This is given by

$$-\frac{1}{8\pi}\int dS^{ab}\ \nabla_a(\zeta^c h^d_b)N_{cd} \tag{38}$$

where $N_{ab}$ are the components of the volume form on the normal bundle to the horizon. There is a precisely similar expression for the fields $\tilde{\zeta}_n$. One then finds that the charges on the bifurcation surface obey the algebra

$$[Q_n, Q_m] = i(n-m)Q_{n+m} + in^3 J\delta_{n,-m} \tag{39}$$

for the right-handed algebra and

$$[\tilde{Q}_n, \tilde{Q}_m] = i(n-m)\tilde{Q}_{n+m} + in^3 J\delta_{n,-m} \tag{40}$$

for the left-handed algebra. Finally, the left and right algebras commute with each other

$$[Q_n, \tilde{Q}_m] = 0. \tag{41}$$

In both cases, the central terms shown here correspond to the conventionally normalised Virasoro algebra with central charges given by $c_L = c_R = 12J$. Thus the diffeomorphism algebra has an anomaly.

We postulate that this anomaly is cancelled by holographic degrees of freedom on the horizon expressed in terms of a two-dimensional conformal field theory. Consider for a moment the expressions for the absorption probabilities for particles incident on a Kerr black hole. Suppose we look at a particle with energy $\delta E$ and angular momentum parallel to the black hole spin $\delta J$. Then we observe that the absorption probability obtains a suggestive factor of

$$|\Gamma(1 + \frac{i\omega_L}{2\pi T_L})|^2 \ |\Gamma(1 + \frac{i\omega_R}{2\pi T_R})|^2 \tag{42}$$

where

$$\omega_L = \frac{2M^3}{J}\delta E \quad \omega_R = \frac{2M^3}{J}\delta E - \delta J. \tag{43}$$

This is precisely what is to be expected for a conformal field theory where the left-handed degrees of freedom are at a temperature of $T_L$ and the right-handed degrees of freedom are at a temperature of $T_R$ and one is asking for the absorption probability for particles of energy $\omega_L$ in the left-handed sector and energy $\omega_R$ in the right-handed sector. We take it that there are no coincidences in nature and therefore we really can attribute our observations to the existence of holographic degrees of freedom on the horizon described by a two-dimensional conformal field theory.

A general property of conformal field theories, provided the central charge is sufficiently large, was first described by Cardy.[34] The entropy for a system with central charges $c_L$ and $c_R$ for the two sectors at temperatures $T_L$ and $T_R$ is given by

$$S = \frac{\pi^2}{3}(c_L T_L + c_R T_R). \tag{44}$$

Plugging in our expressions for $c_L, c_R, T_l$ and $T_R$ gives

$$S = \frac{1}{4}A. \tag{45}$$

It is hard to believe that this is a coincidence. It appears therefore we have identified the degrees of freedom responsible for black hole entropy.[33]

Subsequent to the conference, it has been shown that the same methods reproduce the entropy for the Kerr-Newman family of black holes[35] and for uncharged black holes in anti-de Sitter spacetime.[36]

A key question is to ask how this affects our view of the information paradox. We have shown how to account for black hole entropy in terms of a holographic two-dimensional conformal field theory living on the black hole horizon. It is however far from clear that the states of such a theory can record all of the quantum mechanical information that is pertinent to black hole formation from ordinary matter. We are therefore left with a collection of problems that need exploration and solution before there can be any claim of solving the information paradox. We conclude this essay with a summary of outstanding issues. Does the horizon conformal field theory contain a complete description of the black hole formation process? How does the Hawking radiation encode this information so as to preserve unitary time evolution? Why is it that the black hole entropy is independent of the spectrum of elementary particles when the number of ways a black hole can be formed is highly dependent on that spectrum. For example, if there were a million different species of electron, the number of ways a black hole could form would be vastly higher than if there a single type of electron. Nevertheless, the Hawking entropy would be same.

Suppose a particle falls into a black hole. Classically, a co-moviong observer sees it pass through the horizon without anything obvious happening. In the case of a Schwarzschild black hole, it will reach the singularity in a finite amount of proper time. The singularity is a boundary of spacetime and so we believe the particle to have disappeared. In the case of rotating black holes, it seems plausible that it will also inevitably reach a singularity as the inner horizon of a Kerr black hole is unstable and is presumed to become singular once any energy-momentum arrives there. However, if the particle is to leave an imprint on the state of the horizon conformal field theory, it appears to have violated the quantum no-cloning theorem. Roughly speaking, the no-cloning theorem says that you cannot duplicate the state of a particle by unitary time evolution. A number of technical assumptions go into this amongst which is a notion of locality, a dubious assumption in the case of gravitation.

Then there are some more challenging issues. What happens to the singularity? It is a classical concept and shows that classical general relativity is an incomplete theory. What happens quantum mechanically? There is no satisfactory answer at present. What are the final stages of black hole evaporation? The picture presented seems to suggest that all symmetries in nature are gauge symmetries and not global symmetries. For example in the standard model, baryon number is a global symmetry, but it is hard to see how this could be encoded in the picture presented here. There is one ambitious theory that predicts that all symmetries are gauge symmetries and that is string theory. Although string theory is successful in resolving the divergence problems of quantum gravity, and potentially geometrizing the spectrum of elementary particles, it is far from being a theory of spacetime. Hopefully, the picture here will provide a guide to the true nature of quantum gravity, but there are immense and exciting challenges to the construction of such a theory. Eventually, we hope that the construction of such a theory will lead to deep insights into the nature of our Universe.

**Acknowledgements**

The work presented here was joint with the late Stephen Hawking, Andy Strominger and Sasha Haco. We hope that it is a fitting memory to Stephen who was a dear friend for almost forty years.

We are grateful to Sangmin Choi, Geoffrey Comp‘ere, Peter Galison, Monica Guica, Dan Harlow, Roy Kerr, Alex Lupsasca, Juan Maldacena, Alex Maloney, Suvrat Raju and Maria Rodriguez for useful conversations. This paper was supported in part by DOE de-sc0007870, the John Templeton Foundation, the Black Hole Initiative at Harvard, the Radcliffe Institute for Advanced Study and the UK STFC. We would also like to thank the George and Cynthia Mitchell Foundation, whose generous support allowed for over a decade of scientific workshops, spanning Cooks' Branch in Texas and Great Brampton House and Brinsop Court in England, without which this collaboration would not have been possible. The work began at a Mitchell Foundation retreat and was completed at another. We are profoundly grateful to the Foundation and personally to Sheridan Lorenz and George Mitchell for their contribution to the development of fundamental science.

# No smooth beginning for spacetime

Jean-Luc Lehners

*Max-Planck-Institute for Gravitational Physics (Albert-Einstein-Institute)*
*Am Mühlenberg 1, Potsdam, Germany*
*E-mail: jlehners@aei.mpg.de*

In these proceedings, I will review an obstruction for theories of the beginning of the universe which can be formulated as semiclassical path integrals. Hartle and Hawking's no boundary proposal and Vilenkin's tunneling proposal are examples of such theories. Each may be formulated as the quantum amplitude for obtaining a final 3-geometry by integrating over 4-geometries. The result is obtained using a new mathematical tool – Picard-Lefschetz theory – for defining the semiclassical path integral for gravity. The Lorentzian path integral for quantum cosmology with a positive cosmological constant is mathematically meaningful in this approach, but the Euclidean version is not. Framed in this way, the resulting framework and predictions are unique. Unfortunately, the outcome is that primordial gravitational wave fluctuations are unsuppressed.

*Keywords*: Quantum cosmology; Big bang; MG15 Proceedings.

## 1. Introduction

There is an old and attractive idea that the universe could have been created out of "nothing" via a quantum creation event. More specifically, since in a closed universe all total charges are zero, there is the intuition that no conservation law can prevent such an event from happening – and since everything that is not forbidden will eventually occur, so goes the logic, such a process must be possible. One could object to this line of reasoning by saying that in the absence of time, it is not at all clear that such a process must "eventually" occur. A more pertinent line of enquiry however is to first see if such an idea can be made concrete. This has indeed been attempted, in particular with the "no-boundary" proposal of Hartle and Hawking[1–3] and the tunneling wavefunction of Vilenkin[4–6]. These proposals have been heuristically formulated within the path integral approach to quantisation, but now with gravity included. The idea then is that the big bang is replaced by a closed and regular geometry corresponding to the Euclidean version of de Sitter space (for an illustration see Fig. 7). Such a geometry can arise as a saddle point of the path integral for gravity with a cosmological constant $\Lambda$, as we shall see in more detail below. What was left unspecified in these proposals is how to properly and precisely define the original path integral itself. Here Hartle and Hawking implicitly had in mind a Euclidean version of the path integral, since they hoped that this would lead to better convergence properties. Meanwhile Vilenkin stated that his proposal was to be viewed in the framework of a Lorentzian path integral. However, neither approach was made very precise, and thus the true consequences of these proposals remained somewhat heuristic.

The object of our work was to make both proposals mathematically precise. The outcome of this clarification was however rather negative: we discovered that both

proposals lead to unstable fluctuations, and that consequently the replacement of the big bang by a smooth geometry remains an untenable proposition at present.

The present review is based on Refs.[7–11]

## 2. Path Integral

In this overview we consider a universe with a positive cosmological constant $\Lambda$, described by the action

$$S = \frac{1}{2}\int_{\mathcal{M}} \mathrm{d}^4x\sqrt{-g}\,(R - 2\Lambda) + \int_{\partial\mathcal{M}} \mathrm{d}^3y\sqrt{g^{(3)}}K\,, \tag{1}$$

where we have set $8\pi G = 1$. The second term, involving the 3-metric $g^{(3)}_{ij}$ and the trace of the second fundamental form $K$ of the boundary $\partial\mathcal{M}$, renders the variational principle well posed. We start by truncating the theory to the simplest cosmologies, with line element

$$\mathrm{d}s^2 = -N(t)^2\mathrm{d}t^2 + a(t)^2\mathrm{d}\Omega_3^2\,, \tag{2}$$

with $\mathrm{d}\Omega_3^2$ the metric of a homogeneous, isotropic 3-sphere. Later on, we will add gravitational wave perturbations.

The Feynman path integral for the reduced theory is

$$G[a_1;a_0] = \int \mathcal{D}N\mathcal{D}\pi\mathcal{D}a\mathcal{D}p\mathcal{D}C\mathcal{D}\bar{P}\, e^{\frac{i}{\hbar}\int_0^1\left[\dot{N}\pi+\dot{a}p+\dot{C}\bar{P}-NH\right]\mathrm{d}t}\,, \tag{3}$$

where, in addition to $a$, $N$ and the fermionic ghost $C$, we have introduced the conjugate momenta $p, \pi$ and $\bar{P}$, and the corresponding Liouville measure. Without loss of generality, we can choose the range of the time coordinate to be $0 \leq t \leq 1$. The Hamiltonian constraint $H[a,p;N,\pi;C,\bar{P}] = H_{EH}[a,p] + H_g[N,\pi;C,\bar{P}]$ consists of the Einstein-Hilbert Hamiltonian $H_{EH}$, in our case a minisuperspace Hamiltonian, and a Batalin, Fradkin and Vilkovisky (BFV) ghost Hamiltonian $H_g$. The ghost term breaks time reparametrization symmetry and fixes the proper-time gauge $\dot{N} = 0$.[12] For minisuperspace models, most of the path integrals can be performed analytically, yielding

$$G[a_1;a_0] = \int_{0^+}^{\infty}\mathrm{d}N\int_{a=a_0}^{a=a_1}\mathcal{D}a\, e^{iS(N,a)/\hbar}\,, \tag{4}$$

which has a very simple interpretation. The path integral $\int \mathcal{D}a e^{iS(N,a)/\hbar}$ represents the quantum mechanical amplitude for the universe to evolve from $a_0$ to $a_1$ in a proper time $N$. The integral over the lapse function indicates that we should consider paths of every proper duration $0 < N < \infty$. Teitelboim[13] showed that this choice of integration domain leads to the causal ordering of the $a_0$ and $a_1$, *i.e.* $a_0$ precedes $a_1$. This allows us to describe both an expanding $a_1 > a_0$ and a contracting $a_1 < a_0$ universe, since the direction of the arrow of time is determined by the Feynman propagator and not by the choice of boundary conditions.

The action in (4) reduces to

$$S = 2\pi^2 \int_0^1 \mathrm{d}t N \left( -3a\frac{\dot{a}^2}{N^2} + 3a - a^3\Lambda \right) . \tag{5}$$

We are faced with a functional integral over $a(t)$, and an ordinary integral over the proper time $N$. In fact, we can simplify the calculation by noticing that redefining the lapse function $N(t) \to N(t)/a(t)$ renders the action (5) quadratic in $q(t) \equiv a(t)^2$, allowing the path integral over $q(t)$ to be performed exactly[14]. In these new variables, the action (5) becomes

$$S = 2\pi^2 \int_0^1 \mathrm{d}t \left( -\frac{3}{4N}\dot{q}^2 + N(3 - \Lambda q) \right) . \tag{6}$$

The equation of motion and the constraint following from this action are

$$\ddot{q} = \frac{2\Lambda}{3}N^2; \quad \frac{3}{4N^2}\dot{q}^2 + 3 = \Lambda q \, . \tag{7}$$

With boundary conditions $q(0) = q_0$ and $q(1) = q_1$, the general solution to the first equation (before imposing the constraint) is

$$\bar{q} = \frac{\Lambda}{3}N^2 t^2 + \left( -\frac{\Lambda}{3}N^2 + q_1 - q_0 \right) t + q_0 \, . \tag{8}$$

Writing the full solution as

$$q(t) = \bar{q}(t) + Q(t) \, , \tag{9}$$

the path integral becomes

$$G[q_1; q_0] = \int_0^\infty \mathrm{d}N e^{2\pi^2 i S_0/\hbar} \int_{Q[0]=0}^{Q[1]=0} \mathcal{D}Q e^{2\pi^2 i S_2/\hbar} \, , \tag{10}$$

with

$$S_0 = \int_0^1 \mathrm{d}t \left( -\frac{3}{4N}\dot{\bar{q}}^2 + 3N - N\Lambda\bar{q} \right) , \quad S_2 = -\frac{3}{4N}\int_0^1 \mathrm{d}t \, \dot{Q}^2 \, . \tag{11}$$

The path integral over $Q$ is Gaussian and can be evaluated exactly:

$$\int_{Q[0]=0}^{Q[1]=0} \mathcal{D}Q e^{2\pi^2 i S_2/\hbar} = \sqrt{\frac{3\pi i}{2N\hbar}} \, . \tag{12}$$

The propagator thus reduces to an ordinary integral

$$G[q_1; q_0] = \sqrt{\frac{3\pi i}{2\hbar}} \int_0^\infty \frac{\mathrm{d}N}{N^{1/2}} e^{2\pi^2 i S_0/\hbar} . \tag{13}$$

with

$$S_0 = N^3 \frac{\Lambda^2}{36} + N\left( -\frac{\Lambda}{2}(q_0 + q_1) + 3 \right) + \frac{1}{N}\left( -\frac{3}{4}(q_1 - q_0)^2 \right) . \tag{14}$$

Equation (13) is an oscillatory integral, implying that it is only conditionally convergent. Below, we will use Picard-Lefschetz theory to show that it is indeed convergent, and to evaluate it. However, it is instructive to see that an elementary

proof of convergence may be provided, without the use of analytic continuation. We will sketch it here.

For many oscillatory integrals, convergence can be demonstrated with the Leibniz convergence test for alternating series. A real alternating series is defined as

$$a = \pm \sum_{i=0}^{\infty} (-1)^i a_i \,, \tag{15}$$

with $a_i$ positive real numbers. The Leibniz convergence test states that the series is convergent when the arguments decrease monotonically, i.e. $a_{i+1} \leq a_i$ for sufficiently large $i$, and the argument goes to zero in the limit of large $i$, i.e. $\lim_{i\to\infty} a_i = 0$. To see the relation to oscillatory integrals, consider the integral

$$I = \int_0^\infty \mathrm{d}x \; e^{if(x)} \,, \tag{16}$$

for a real valued polynomial $f$ (for the Fresnel integrals $f(x) = x^2$). The real and imaginary parts of $I$ are given by

$$\mathrm{Re}[I] = \int_0^\infty \mathrm{d}x \;\; \cos(f(x)) \,, \quad \mathrm{Im}[I] = \int_0^\infty \mathrm{d}x \;\; \sin(f(x)) \,. \tag{17}$$

For simplicity we concentrate on the real part. Let us assume that the leading term of $f$ goes like $x^n$ in the limit $x \to \infty$ for $n \in \mathbb{N}$. A change of coordinates $u = x^n$ gives the integral

$$\mathrm{Re}[I] = \int_0^\infty \frac{\mathrm{d}u}{n u^{1-1/n}} \;\; \cos(f(\sqrt[n]{u})) \,, \tag{18}$$

and ensures that $f(\sqrt[n]{u}) \sim u$ for large $u$. Now let the zero crossings of the argument be given by $z_i$ for $i \in \mathbb{N}$. The real part of the integral can be written as an alternating series

$$\mathrm{Re}[I] = \left[ \int_0^{z_0} + \sum_{i=0}^{\infty} \int_{z_i}^{z_{i+1}} \right] \frac{\mathrm{d}u}{n u^{1-1/n}} \;\; \cos(f(u^{1/n})) \,, \tag{19}$$

$$= c \pm \sum_{i=0}^{\infty} (-1)^i \left| \int_{z_i}^{z_{i+1}} \frac{\mathrm{d}u}{n u^{1-1/n}} \;\; \cos(f(u^{1/n})) \right| \,, \tag{20}$$

$$= c \pm \sum_{i=0}^{\infty} (-1)^i a_i \,, \tag{21}$$

without changing the order of summation, with $c$ the integral over the interval $(0, z_0)$, either the positive or the negative sign for $\pm$ depending on the details of $f$, and the positive real numbers

$$a_i = \left| \int_{z_i}^{z_{i+1}} \frac{\mathrm{d}u}{n u^{1-1/n}} \;\; \cos(f(u^{1/n})) \right| \,. \tag{22}$$

The argument of the alternating series can be dominated with a simple approximation

$$a_i = \left| \int_{z_i}^{z_{i+1}} \frac{\mathrm{d}u}{n u^{1-1/n}} \cos(f(u^{1/n})) \right| \tag{23}$$

$$< \int_{z_i}^{z_{i+1}} \frac{\mathrm{d}u}{n u^{1-1/n}} = \sqrt[n]{z_{i+1}} - \sqrt[n]{z_i} = b_i \,. \tag{24}$$

In the limit of large $u$ the function $f(\sqrt[n]{u})$ asymptotes to a function proportional to $u$. For this reason, in the limit of large $i$, the zero crossings $z_i$ in $u$ will asymptote to a regular spacing, leading to the conclusion that for $n > 1$ and for sufficiently large $i$, the coefficients $b_i$ satisfy the conditions of the Leibniz convergence test. Since $a_i < b_i$ for all $i$ we conclude that $\mathrm{Re}[I]$ converges when $n > 1$. A similar argument can be given for the imaginary part of $I$, making $I$ conditionally convergent. This discussion applies to a more general class of integrals. When the integral function $f(x)$ diverges as $x^{-n}$ in the limit $x \to 0$ with $n \in \mathbb{N}$, the change of coordinates $u = x^{-n}$ leads to convergence for $n > 1$. More generally, when $f$ is not a polynomial but dominates some polynomial $x^n$ with $n > 1$, the oscillatory integral can be shown to converge due to cancellations from oscillations at large $x$. Our integral above, when expressed in terms of the canonically normalised integration variable $M \equiv N^{1/2}$, involves the asymptotic behaviour $\sim \int dM e^{i(\Lambda^2 M^6 - q_1^2/M^2)/\hbar}$, and hence is manifestly convergent. In order to evaluate its value, however, Picard-Lefschetz theory is a preferable tool to which we turn our attention now.

### 2.1. *Picard-Lefschetz theory*

Picard-Lefschetz theory deals with oscillatory integrals like

$$I = \int_D \mathrm{d}x \, e^{iS[x]/\hbar}, \tag{25}$$

where $\hbar$ is a real parameter, the action $S[x]$ is a real-valued function and the integral is taken over a real domain $D$, usually defined by the singularities of the integrand or, in higher dimensional or path integral cases, its partial integrals (see e.g.[15] for a more complete overview). One is typically interested in the behavior of the integral for small values of the parameter $\hbar$: in quantum mechanical applications, taking $\hbar$ to zero is a nice way to study the classical limit.

When faced with an integral in the form of (25), the idea of Picard-Lefshetz theory is to interpret $S[x]$ as a holomorphic function of $x \in \mathbb{C}$, the complex plane. Cauchy's theorem allows us to deform the integration contour from the real domain $D$ on the real $x$-axis into a contour we now call $\mathcal{C}$ in the complex $x$-plane, while keeping its endpoints fixed. In particular, we seek to deform $\mathcal{C}$ into a "steepest descent" contour passing through one or more critical points of $S[x]$, *i.e.* points where $\partial_x S = 0$. By the Cauchy-Riemann equations, the real part of the exponent, $\mathrm{Re}[iS[x]]$, which controls the magnitude of the integrand, has a saddle point in the real two-dimensional (Re[$x$],Im[$x$])-plane there. The steepest descent contour

through the saddle point is defined as the path along which $\mathrm{Re}[iS[x]]$ decreases as rapidly as possible.

A simple example is provided by $S[x] = x^2$, with a critical point at $x = 0$. Writing $x = \mathrm{Re}[x] + i\,\mathrm{Im}[x]$, we have $\mathrm{Re}[iS[x]] = -2\,\mathrm{Re}[x]\mathrm{Im}[x]$. The magnitude of the integrand decreases most rapidly along the contour $\mathrm{Im}[x]=+\mathrm{Re}[x]$ which is the steepest descent contour. Conversely, it increases most rapidly along the contour $\mathrm{Im}[x] = -\mathrm{Re}[x]$, which is the steepest ascent contour. As we shall discuss, steepest descent contours generically lead to convergent integrals, and in this case they are known as Lefschetz thimbles $\mathcal{J}_\sigma$.

In more detail, we write the exponent $\mathcal{I} = iS/\hbar$ and its argument $x$ in terms of their real and imaginary parts, $\mathcal{I} = h + iH$ and $x = u^1 + iu^2$. Downward flow is then defined by

$$\frac{\mathrm{d}u^i}{\mathrm{d}\lambda} = -g^{ij}\frac{\partial h}{\partial u^j}\,, \tag{26}$$

with $\lambda$ a parameter along the flow and $g_{ij}$ a Riemannian metric introduced on the complex plane. The real part of the exponent $h$ (known as the Morse function) decreases on such a flow away from its critical points, because $\frac{\mathrm{d}h}{\mathrm{d}\lambda} = \sum_i \frac{\partial h}{\partial u^i}\frac{\mathrm{d}u^i}{\mathrm{d}\lambda} = -\sum_i \left(\frac{\partial h}{\partial u^i}\right)^2 < 0$, with the fastest rate of decrease occuring in the direction of "steepest descent", which maximises the magnitude of the gradient. Defining the latter requires that we introduce a metric.

For the simple examples we discuss here, the obvious metric $\mathrm{d}s^2 = |\mathrm{d}x|^2$ is sufficient. Defining complex coordinates, $(u, \bar{u}) = \big((\mathrm{Re}([x] + i\mathrm{Im}[x]), (\mathrm{Re}[x] - i\mathrm{Im}[x])\big)$, the metric is $g_{uu} = g_{\bar{u}\bar{u}} = 0$, $g_{u\bar{u}} = g_{\bar{u}u} = 1/2$. Then $h = (\mathcal{I} + \bar{\mathcal{I}})/2$ and (26) becomes

$$\frac{\mathrm{d}u}{\mathrm{d}\lambda} = -\frac{\partial\bar{\mathcal{I}}}{\partial\bar{u}}, \quad \frac{\mathrm{d}\bar{u}}{\mathrm{d}\lambda} = -\frac{\partial\mathcal{I}}{\partial u}\,. \tag{27}$$

The imaginary part of the exponent $H = \mathrm{Im}[iS/\hbar]$ is conserved along these flows, since

$$\frac{\mathrm{d}H}{\mathrm{d}\lambda} = \frac{1}{2i}\frac{\mathrm{d}(\mathcal{I} - \bar{\mathcal{I}})}{\mathrm{d}\lambda} = \frac{1}{2i}\left(\frac{\partial\mathcal{I}}{\partial u}\frac{\mathrm{d}u}{\mathrm{d}\lambda} - \frac{\partial\bar{\mathcal{I}}}{\partial\bar{u}}\frac{\mathrm{d}\bar{u}}{\mathrm{d}\lambda}\right) = 0\,. \tag{28}$$

Thus the integrand $e^{iS[x]/\hbar}$ – which was a purely oscillatory factor in the original integral – does not oscillate at all when evaluated along a downward flow (see Fig. 1). Instead, it decreases monotonically so that the integral converges absolutely and "as rapidly as possible." For a downward flow originating at a saddle, $\lambda$ runs from $-\infty$ at the saddle point to positive values as $h$ decreases. The Lefschetz thimble associated with a given saddle is defined as the set of downward flows leaving the saddle in this way.

Analogously, upward flows are defined via

$$\frac{\mathrm{d}u^i}{\mathrm{d}\lambda} = +g^{ij}\frac{\partial h}{\partial u^j}\,, \tag{29}$$

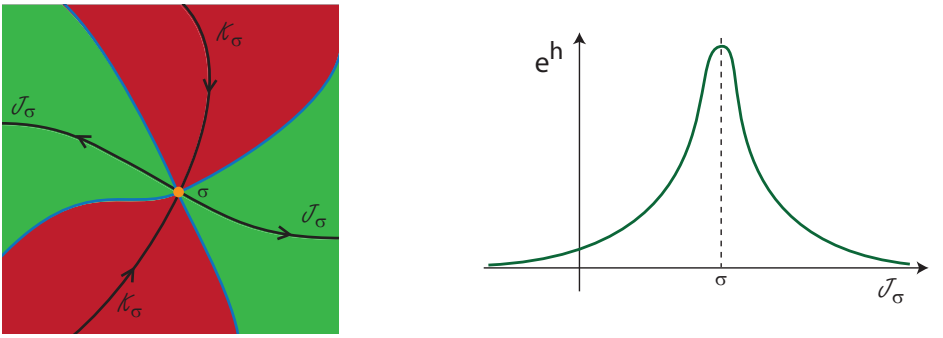

Fig. 1. *Left panel:* From a saddle point $\sigma$ emanate upward ($\mathcal{K}_\sigma$) and downward ($\mathcal{J}_\sigma$) flows, which are located in the wedges $J_\sigma$ (in green) and $K_\sigma$ (in red) respectively, defined as the regions where the Morse function $h$ is lower (higher) than its value at the saddle, respectively. The arrows along the flows indicate the direction of descent, and the downward flow $\mathcal{J}_\sigma$ is known as a Lefschetz thimble. The wedges are separated by blue lines along which $h$ is constant and equal to the value at the saddle point $h(p_\sigma.)$ *Right panel:* Along a Lefschetz thimble the real part $h$ of the exponent decreases as fast as possible, ensuring an absolutely convergent integral.

with $H$ likewise being conserved along these flows. Every critical point has an upward flow which, in analogy to the downward flow, is labelled $\mathcal{K}_\sigma$.

Lefschetz thimbles and upward flows only intersect at a single critical point (in case of a degeneracy, a small perturbation may be added), the one where both are defined. With a suitable choice of orientation, we can write for the intersection number

$$\mathrm{Int}(\mathcal{J}_\sigma, \mathcal{K}_{\sigma'}) = \delta_{\sigma\sigma'}. \tag{30}$$

Our objective is to deform the original integral (25) into one evaluated over a sum of Lefschetz thimbles. That is, we would like to write

$$\mathcal{C} = \sum_\sigma n_\sigma \mathcal{J}_\sigma, \tag{31}$$

in a homological sense, for some integers $n_\sigma$ which may take the values 0 or $\pm 1$ when accounting for the orientation of the contour over each thimble. It follows from these equations that $n_\sigma = \mathrm{Int}(\mathcal{C}, \mathcal{K}_\sigma) = \mathrm{Int}(D, \mathcal{K}_\sigma)$, since the intersection number is topological and will not change if we deform the contour $\mathcal{C}$ back to the original, real domain $D$. Thus a necessary and sufficient condition for a given thimble $\mathcal{J}_\sigma$ to be relevant is that a steepest *ascent* contour from the critical point $p_\sigma$ intersects the original, real integration domain $D$. In this circumstance, intuitively, there is no obstacle to smoothly "sliding" the intersection point from the real axis along $\mathcal{K}_\sigma$ down to $p_\sigma$, and in the process deforming the original integration contour onto the the thimble $\mathcal{J}_\sigma$. This is an argument that shows that if one starts from a real Lorentzian theory, then as long as the action is analytic one *never* obtains semiclassical enhancement factors such as are found in the Euclidean approach.

Once we have deformed the contour from the real axis to run through a set of thimbles associated with the contributing critical points, we have:

$$I = \int_D \mathrm{d}x\, e^{iS[x]/\hbar} = \int_{\mathcal{C}} \mathrm{d}x\, e^{iS[x]/\hbar} = \sum_\sigma n_\sigma \int_{\mathcal{J}_\sigma} \mathrm{d}x\, e^{iS[x]/\hbar}. \tag{32}$$

As (32) indicates, typically more than one Lefschetz thimble contributes to the Lorentzian path integral, with given boundary conditions, even in mini-superspace quantum cosmology.

The integral taken over a thimble is absolutely convergent if

$$\left| \int_{\mathcal{J}_\sigma} \mathrm{d}x e^{iS[x]/\hbar} \right| \leq \int_{\mathcal{J}_\sigma} |\mathrm{d}x| \left| e^{iS[x]/\hbar} \right| = \int_{\mathcal{J}_\sigma} |dx| e^{h(x)} < \infty\,. \tag{33}$$

Defining the length along the curve as $l = \int |dx|$, the integral will converge if $h(x(l)) < -\ln(l) + A$, for some constant $A$, as $l \to \infty$, which is a rather weak requirement.

We have then expressed the original integral as a sum of absolutely convergent steepest descent integrals. In an expansion in $\hbar$, we have

$$I = \int_D \mathrm{d}x\, e^{iS[x]/\hbar} = \sum_\sigma n_\sigma\, e^{i\,H(p_\sigma)} \int_{\mathcal{J}_\sigma} e^h \mathrm{d}x \approx \sum_\sigma n_\sigma\, e^{iS(p_\sigma)/\hbar} \left[A_\sigma + \mathcal{O}(\hbar)\right], \tag{34}$$

where $A_\sigma$ represents the result of the leading-order Gaussian integral about the critical point $p_\sigma$. Sub-leading terms may be evaluated perturbatively in $\hbar$.

### 2.2. *Relevant and irrelevant saddle points*

The action $S_0$ has four saddle points in the complex plane, which are solutions of

$$\partial S_0/\partial N = \Lambda^2 N_s^4 + (-6\Lambda(q_0+q_1)+36)\, N_s^2 + 9(q_1-q_0)^2 = 0\,, \tag{35}$$

given by

$$N_s = c_1 \frac{3}{\Lambda} \left[ \left( \frac{\Lambda}{3} q_0 - 1 \right)^{1/2} + c_2 \left( \frac{\Lambda}{3} q_1 - 1 \right)^{1/2} \right], \tag{36}$$

with $c_1, c_2 \in \{-1, 1\}$. The action evaluated at these saddle points is given by

$$S_0^{saddle} = -c_1 \frac{6}{\Lambda} \left[ \left( \frac{\Lambda}{3} q_0 - 1 \right)^{3/2} + c_2 \left( \frac{\Lambda}{3} q_1 - 1 \right)^{3/2} \right]. \tag{37}$$

Each of these four saddle points corresponds to a Lefschetz thimble $\{\mathcal{J}_\sigma\}$, and a steepest ascent contour $\{\mathcal{K}_\sigma\}$. Each is also associated with wedges $J_\sigma, K_\sigma$ in which the real part of the exponent $iS/\hbar$ is respectively lower and higher than the saddle point value. Writing the original integration contour in terms of the Lefschetz thimbles

$$(0^+, \infty) = \sum_\sigma n_\sigma \mathcal{J}_\sigma\,, \tag{38}$$

we approximate the propagator using the saddle point approximation in the limit $\hbar \to 0$,

$$\begin{aligned} G[q_1;q_0] &= \sum_\sigma n_\sigma \sqrt{\frac{3\pi i}{2\hbar}} \int_{\mathcal{J}_\sigma} \frac{\mathrm{d}N}{N^{1/2}} e^{2\pi^2 i S_0/\hbar} \\ &\approx \sum_\sigma n_\sigma \sqrt{\frac{3\pi i}{2\hbar}} \frac{e^{2\pi^2 i S_0^{saddle}/\hbar}}{N_s^{1/2}} \int_{\mathcal{J}_\sigma} \mathrm{d}N e^{\frac{i\pi^2}{\hbar} S_{0,NN}(N-N_s)^2} \left[1 + \mathcal{O}\left(\hbar^{1/2}\right)\right] \\ &\approx \sum_\sigma n_\sigma \sqrt{\frac{3\pi i}{2\hbar}} \frac{e^{2\pi^2 i S_0^{saddle}/\hbar}}{N_s^{1/2}} e^{i\theta_\sigma} \int_{\mathcal{J}_\sigma} \mathrm{d}n e^{-\frac{\pi^2}{\hbar}|S_{0,NN}|n^2} \left[1 + \mathcal{O}\left(\hbar^{1/2}\right)\right] \\ &\approx \sum_\sigma n_\sigma \sqrt{\frac{3i}{2N_s|S_{0,NN}|}} e^{i\theta_\sigma} e^{2\pi^2 i S_0^{saddle}/\hbar} \left[1 + \mathcal{O}\left(\hbar^{1/2}\right)\right] , \end{aligned} \tag{39}$$

where we defined $N - N_s \equiv n e^{i\theta}$ with $n$ real and $\theta$ being the angle of the Lefschetz thimble with respect to the positive real $N$ axis.

Earlier approaches amount to choosing a particular contour in the complex $N$ plane "by hand," on the basis of some preconceived notions. However, the virtue of the Lorentzian path integral combined with Picard-Lefschetz theory is that the proper combination of saddle points and relative phases between them is completely fixed.

The "no-boundary" conditions were proposed by Hartle and Hawking as a theory of initial conditions for the universe[1–3]. The idea is that in the path integral one should sum only metrics whose only boundary is provided by the final spatial hypersurface (corresponding to the current state of the universe). To implement "no-boundary" conditions, we must take $q_0 = 0$ and find a 4-metric which is regular there. This is possible for positive spatial curvature, as assumed here. The "no-boundary" condition is supplemented with the constraint equation (7) evaluated at $q = 0$,

$$\dot{q}^2 = -4N^2 \qquad (q = 0) \ . \tag{40}$$

We will take the final boundary to correspond to a late time configuration, where the universe has become large, $q_1 > \frac{3}{\Lambda}$. The saddle points of the action are given by

$$N_{s,nb1} = +\frac{3}{\Lambda}\left[i \pm \left(\frac{\Lambda}{3}q_1 - 1\right)^{1/2}\right] , \quad N_{s,nb2} = -\frac{3}{\Lambda}\left[i \pm \left(\frac{\Lambda}{3}q_1 - 1\right)^{1/2}\right] , \tag{41}$$

with corresponding actions

$$S_{0,nb1} = -\frac{6}{\Lambda}\left[-i \pm \left(\frac{\Lambda}{3}q_1 - 1\right)^{3/2}\right] , \quad S_{0,nb2} = +\frac{6}{\Lambda}\left[-i \pm \left(\frac{\Lambda}{3}q_1 - 1\right)^{3/2}\right] . \tag{42}$$

Note that saddle points in the upper half plane lead to a $e^{i2\pi^2 S_0} \sim e^{-12\pi^2/(\hbar\Lambda)}$, while those in the lower half plane lead to $e^{i2\pi^2 S_0} \sim e^{+12\pi^2/(\hbar\Lambda)}$.

Given the saddle points, we can determine the wedges and the curves of steepest descent and ascent emanating from them. We use the fact that curves with $\mathrm{Re}(iS_0)$

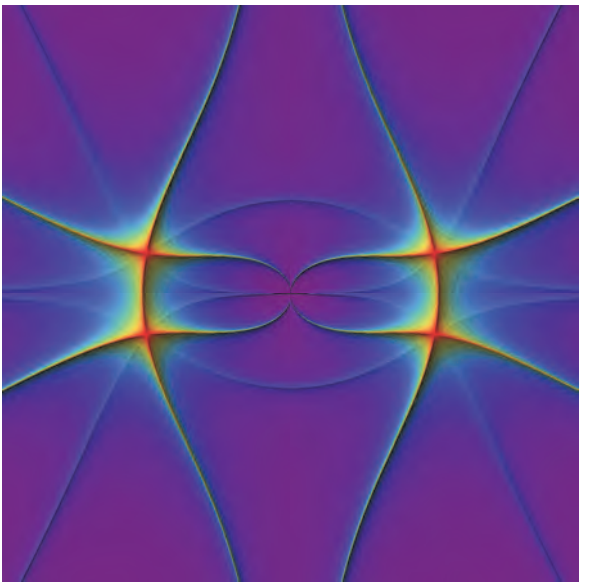

Fig. 2. For this numerical example we have chosen $\Lambda = 3, q_0 = 0, q_1 = 10$. The saddle points then lie at $\pm 3 \pm i$. Shown in the present figure are both the boundaries of wedges (lines of constant real part of the integrand/imaginary part of the action – light blue lines) and the flow lines (lines of constant real part of the action – red/green lines). More specifically, the plot shows both $Abs[\mathrm{Im}(S(N) - S(N_s))]$ and $Abs[\mathrm{Re}(S(N) - S(N_s))]$, where lighter colours correspond to smaller values. The four saddle points are located at the intersections of the flow lines. More details are provided in Fig. 3.

specify the boundaries of the wedges, and that $\mathrm{Im}(iS_0)$ is constant along the flow lines to determine them numerically – see also[16]. For the case of interest to us, the wedge boundaries and flow lines are shown in Fig. 2, while the directions of the flows are sketched in Fig. 3.

Note that the downward flow lines (Lefschetz thimbles) of the upper saddle points can indeed be deformed to the real $N$ line, while the downward flow lines of the lower saddle points cannot. Moreover, only saddle point 1 can be linked to the original integration contour (the positive real half line) via an upward flow, and hence the appropriate integration contour, along which the integral will be manifestly convergent, is given by the Lefschetz thimble $\mathcal{J}_1$ also indicated by the dashed orange line in Fig. 3. Saddle point 1 lies at

$$N^{+}_{s,nb1} = +\frac{3}{\Lambda}\left[i + (\frac{\Lambda}{3}q_1 - 1)^{1/2}\right], \tag{43}$$

and the action evaluated on the saddle point is

$$S^{+}_{0,nb1} = -\frac{6}{\Lambda}\left[-i + (\frac{\Lambda}{3}q_1 - 1)^{3/2}\right]. \tag{44}$$

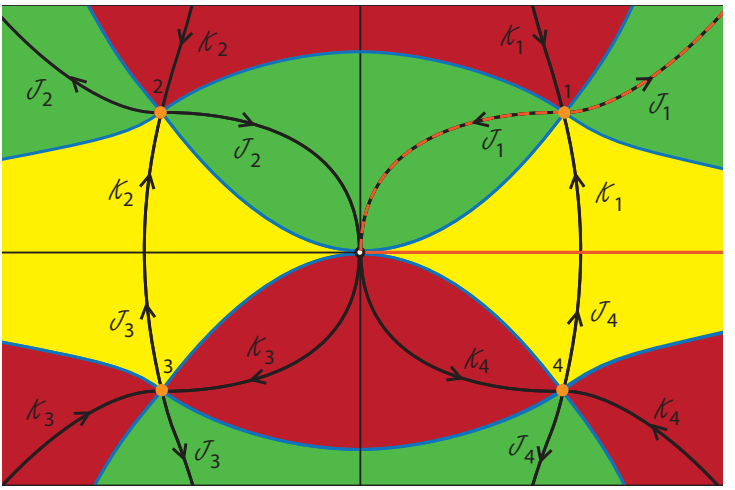

Fig. 3. A sketch of the wedges and flow lines emanating from the saddle points in the complex $N$ plane, for "no-boundary" conditions $q_0 = 0, q_1 > \frac{3}{\Lambda}$. The loci of the steepest ascent/descent flows (in black) and of the boundaries between wedges (in blue) were determined numerically in Fig. 2. Here the arrows indicate the direction of steepest descent. We have coloured the wedges such that regions $J_\sigma$ with a lower value of the magnitude of the integrand than the corresponding saddle point are green, and regions $K_\sigma$ with a higher value are red, with the exception of the yellow regions which have a value intermediate between the two saddle point values. Comparing with the adjacent colours then avoids any ambiguity. The original integration contour along the positive real axis is shown in orange, and the deformed contour which Picard-Lefschetz theory picks out as the preferred integration cycle is marked in dashed orange. Again neither the flow lines, nor the original or final integration contours, include the point at $N = 0$. Only saddle point 1 in the upper right quadrant can be linked to the original integration contour via an upward flow, and this implies that the (orange-dashed) downward flow from this saddle point is the correct Lefschetz thimble along which the path integral should be performed.

For saddle points of the form (36), we have

$$S_{0,NN} = \frac{2c_2}{N_s} \left(\Lambda q_0 - 3\right)^{1/2} \left(\Lambda q_1 - 3\right)^{1/2} , \tag{45}$$

implying that $Arg(N_s) = -\alpha + Arg\left[\left(\Lambda q_0 - 3\right)^{1/2} \left(\Lambda q_1 - 3\right)^{1/2}\right]$. For the "no-boundary" conditions we thus find $Arg(N_s) + \alpha = \frac{\pi}{2}$, and this implies $\theta - \frac{1}{2} Arg(N_s) = 0$. In the saddle point approximation, we thus obtain the wavefunction

$$G_{nb}[q_1; 0] \approx e^{i\frac{\pi}{4}} \frac{3^{1/4}}{2(\Lambda q_1 - 3)^{1/4}} e^{-12\pi^2/(\hbar\Lambda) - i4\pi^2\sqrt{\frac{\Lambda}{3}}(q_1 - \frac{3}{\Lambda})^{3/2}/\hbar} . \tag{46}$$

Note that the real part of the classical action for the dominant saddle point is negative, as expected from the general arguments presented earlier. This concludes the explicit derivation of our result that the relevant saddle point contributes a weighting $e^{-12\pi^2/(\hbar\Lambda)}$, the inverse of the Hartle-Hawking result.

## 3. Unstable Perturbations

We now turn our attention to the perturbations, treated in general relativistic linear perturbation theory. The second order action for a linearized (tensor) perturbation $\phi_l$ with principal quantum number $l$ is given in terms of the background squared scale factor $q(t)$ as

$$S^{(2)}[q,\phi;N] = \frac{1}{2}\int_0^1 \left[q^2\frac{\dot{\phi}_l^2}{N} - Nl(l+2)\phi_l^2\right]\mathrm{d}t$$
$$= \frac{1}{2}\int_0^1 \left[\frac{\dot{\chi}_l^2}{N} + N\left(\frac{\ddot{q}}{q} - \frac{l(l+2)}{q^2}\right)\chi_l^2\right]\mathrm{d}t - \frac{1}{2N}\left[\frac{\dot{q}}{q}\chi_l^2\right]_0^1, \qquad (47)$$

where we have re-expressed the dimensionless tensor metric perturbation $\phi_l$ in terms of the canonically normalized field $\chi_l = q\,\phi_l$. Note that we have orthonormalized the modes on the unit sphere (thus no prefactor of $2\pi^2$ appears in the action). Also, to avoid needless complexity in the equations we only consider a single mode. It is straightforward to amend all the formulae we derive by replacing $l(l+1)(l+2)\phi_l^2$ with $\sum_{lmn} l(l+1)(l+2)\phi_{lmn}^2$ where the $\phi_{1,lmn}$ are the expansion coefficients expressing in the final tensor perturbation in terms of orthonormal tensor spherical harmonics on the three sphere. For ease of notation, where there is no danger of confusion, we will also usually drop the subscript $l$. Note that the perturbation of the lapse $N$ is non-dynamical in the absence of matter and may be set to zero.

If we neglect the backreaction of the linear perturbations on the background, such as is certainly reasonable for small final amplitude $\phi_1$, then we can evaluate the path integral first for $q$ and then for $\phi$, using the classical solution for the background $q$ in the action (47) for $\phi$. To integrate out the perturbations, we again just find the classical solution and use this to evaluate the classical action. The total semiclassical exponent is then given by $S^{(0)}[q_1;N] + S^{(2)}[q_1,\phi_1;N]$ and we then perform the final ordinary integral over $N$ using saddle point methods. We shall not calculate any functional determinants here, although this is perfectly possible. These should not alter any conclusions about the Picard-Lefschetz flow, nor the final semiclassical exponent, in any regime where the semiclassical expansion is valid.

The no boundary path integral on a contour $\mathcal{C}$ is then given, in this leading semiclassical approximation, by

$$G_{\mathcal{C}}[q_1,\phi_1;0] \propto \int_{\mathcal{C}} \frac{\mathrm{d}N}{\sqrt{D(N,q_1,\hbar)}} e^{i\bar{S}^{(0)}[q_1;N]/\hbar + i\bar{S}^{(2)}[q_1,\phi_1;N]/\hbar}\,, \qquad (48)$$

where $\bar{S}^{(2)}[q_1,\phi_1;N]$ is the classical action for the perturbation, in the background $\bar{q}$, satisfying $\phi(1) = \phi_1$ as well as a second condition we shall define shortly. The quantity $D(N,q_1,\hbar)$ is the functional determinant which is in principle calculable in terms of the classical modes and as a series expansion in $\hbar$.

In the leading semiclassical approximation, we can perform the path integral by the saddle point method, *i.e.*, by solving the equations of motion and computing the classical action. The boundary condition on the perturbations at $t = 0$ is delicate

because the background geometry is sufficiently singular for a range of real values of the lapse, that the perturbations obey a singular equation of motion. We shall find that, nevertheless, for generic complex $N$, the criterion of finite classical action selects a unique perturbation mode.

At fixed $N$, the classical equation for $\chi$ following from (47) is

$$\ddot{\chi} = \left( \frac{\ddot{\bar{q}}}{\bar{q}} - \frac{N^2 l(l+2)}{\bar{q}^2} \right) \chi \,. \tag{49}$$

Near $t = 0$, this becomes

$$\ddot{\chi} \approx -\frac{N^2 l(l+2)}{(q_1 - \Lambda N^2/3)^2} \frac{\chi}{t^2} \equiv \frac{\gamma^2 - 1}{4} \frac{\chi}{t^2} \,, \tag{50}$$

from which we see $\chi \sim t^{\frac{1}{2}(1 \pm \gamma)}$, as $t \to 0$. Notice that the equation of motion for $\chi$ is singular and this results in some unusual properties of the perturbations, as we explain below.

For small real $N$, we take $\gamma$ to be real and positive. Provided $N$ is real and smaller in magnitude than a particular value $N_-$, then both solutions for $\chi$ are monotonic in $t$ and both vanish at $t = 0$. However, only one of them has finite action so it is natural to select that one as the saddle point solution. For real $N$ larger in magnitude than $N_-$ but smaller than another, larger value, $N_+$, $\gamma$ is imaginary and the solutions oscillate an infinite number of times as they approach $t = 0$. In fact, both solutions have a finite regularized action, so the finite action criterion becomes ambiguous for $N$ in this range. Increasing the magnitude of $N$ beyond $N_+$, while keeping $N$ real, we see that $\gamma$ becomes real once again. However, as we explain shortly, in this latter regime, there are *no* finite action classical solutions.

The two critical values are given by

$$N_- = \frac{3}{\Lambda} \sqrt{2l(l+2) + q_1 \Lambda/3 - 2\sqrt{l(l+2)(l(l+2) + q_1 \Lambda/3)}} \,, \tag{51}$$

$$N_+ = \frac{3}{\Lambda} \sqrt{2l(l+2) + q_1 \Lambda/3 + 2\sqrt{l(l+2)(l(l+2) + q_1 \Lambda/3)}} \,, \tag{52}$$

with geometric mean $N_\star \equiv \sqrt{N_+ N_-} = \sqrt{3q_1/\Lambda}$. It follows that we can take

$$\gamma = \frac{\sqrt{(N_-^2 - N^2)(N_+^2 - N^2)}}{(N_\star^2 - N^2)} \,, \tag{53}$$

defined to be real and positive for small $N$ and defining $\gamma$ at complex $N$ by analytic continuation. The branch cuts needed to define the square roots are conveniently placed along the real intervals $-N_+ < N < -N_-$ and $N_- < N < N_+$. On the upper side of the cuts, $\gamma$ is negative imaginary and on the lower sides it is positive imaginary. Away from the cuts, as is evident from (47), the action integral converges at $t = 0$ only for the mode behaving as $t^{\frac{1}{2}(1+\gamma)}$ as $t \to 0$. The complete solution of (49) with this small $t$ behavior is

$$\chi(t) = \bar{q}(t)^{\frac{1}{2}} \left( \frac{t}{3q_1 + (t-1)N^2 \Lambda} \right)^{\frac{\gamma}{2}} \left( (3q_1 - \Lambda N^2)(1+\gamma) + 2\Lambda N^2 t \right) \,, \tag{54}$$

and the corresponding, correctly normalized classical solution is

$$\phi(t) = \phi_1 \frac{\chi(t)}{\bar{q}(t)} \frac{q_1}{\chi(1)}. \tag{55}$$

This solution allows us to calculate the classical action from (47). With an integration by parts and using the equations of motion, we find

$$S^{(2)}[q_1, \phi_1; N] = \left[\bar{q}^2 \frac{\bar{\phi}\dot{\phi}}{2N}\right]_0^1 = \frac{l(l+2)q_1\phi_1^2}{4N(3l(l+2)+q_1\Lambda)} \left(-3q_1 - N^2\Lambda + \gamma(N_\star^2 - N^2)\right), \tag{56}$$

which is real where $\gamma$ is real, but gains a negative or positive imaginary part (meaning that the semiclassical exponent $iS/\hbar$ gains a positive or negative real part) as $N$ approaches the real axis from above or below the branch cuts. This behavior is illustrated in Figure 4.

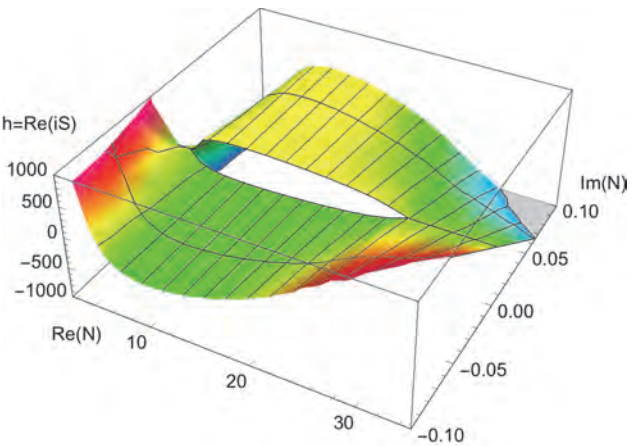

Fig. 4. The Morse function $h = Re(iS/\hbar)$ around a branch cut, in units where $\hbar = 1$ and for the parameters $\Lambda = 3, q_1 = 101, l = 10, \phi_1 = 1$. At the cut, the Morse function reaches its maximum at $N_\star = 10$ coming from the upper half plane, and its minimum also at $N_\star$, though approaching the cut from below.

There is one additional important consideration: for real $N$, the background solution for the scale factor is real and quadratic in $t$. For $N > N_\star$ (or $N < -N_\star$) the background solution starts at $q = 0$, then turns negative before crossing $q = 0$ a second time, at $t_s = 1 - \frac{3q_1}{\Lambda N^2}$, to eventually reach $q_1$ at $t = 1$. Thus there is a second singularity in these real but off-shell-in-$N$ background geometries. It is obvious from (54) that if $\chi$ behaves as $t^{\frac{1}{2}(1\pm\gamma)}$ near $t = 0$, then it behaves as $(t_s - t)^{\frac{1}{2}(1\mp\gamma)}$ near $t = t_s$. Thus, for real $\gamma$ and $N > N_\star$ then if the action integral converges at $t = 0$, it diverges at $t = t_s$, and vice versa. We conclude that for $N > N_+$ or $N < -N_+$ *no* solution of the perturbation equations of motion has finite action. Hence, in performing the integration over $N$ in the last step (48) of our calculation, however

we deform the contour $\mathcal{C}$, we cannot allow it to cross the real $N$-axis for real $N$ beyond the outer ends of the two branch cuts.

Finally, notice that at large $|N|$ in the complex $N$-plane, the background action $\bar{S}^{(0)} \sim N^3$ – dominates over the perturbation action $\bar{S}^{(2)} \sim N$. The same holds in the small $|N|$ limit, where both the background and the perturbation diverge like $1/N$ (the background and the perturbation action have opposite sign). As a consequence the asymptotic regions of convergence are preserved when we add linearized tensor perturbations.

The leading contribution of the perturbations, in the semi-classical approximation, comes from the relevant saddle point of the background. At this saddle points, the parameter $\gamma$ is precisely equal to $l+1$, meaning that the tensor modes $\phi_l$ behave as $t^{l/2}$ near the singularity, which means they are regular there. The value of the classical action at the relevant saddle point is then

$$\bar{S}^{(2)}(N_s^+) = -i\frac{\phi_1^2 q_1}{2}\frac{l(l+2)}{l+1+i\sqrt{q_1\Lambda/3-1}}. \tag{57}$$

There are two simplifying regimes. If the wavelength on the final three-geometry, $\sim \sqrt{q_1}l^{-1}$ is well within the Hubble radius $\sqrt{3/\Lambda}$, we obtain

$$i\frac{\bar{S}^{(2)}(N_s^+)}{\hbar} \approx +\frac{\phi_1^2 q_1}{2\hbar}l, \quad l \gg \sqrt{\frac{\Lambda q_1}{3}}, \tag{58}$$

a result which is independent of $\Lambda$. In the opposite limit, we obtain the result for the "frozen" modes in the expanding de Sitter spacetime, which have passed out of the de Sitter Hubble radius and ceased to evolve. In this case, we obtain

$$i\frac{\bar{S}^{(2)}(N_s^+)}{\hbar} \approx +\frac{3}{2\Lambda}l(l+1)(l+2)\phi_1^2 - i\sqrt{\frac{3q_1}{4\Lambda}}l(l+2)\phi_1^2, \quad \sqrt{\frac{\Lambda q_1}{3}} \gg l. \tag{59}$$

As we can see, the relevant saddle point leads to an inverse Gaussian distribution, meaning that the tensor modes are out of control.

## 4. Comments

In view of the unsettling nature of our result, one may ask whether our approximations have broken down, or whether we have somehow incorrectly implemented the idea of the no-boundary proposal. In this section we will address these issues and show that our result, to the best of our knowledge, really is robust.

### 4.1. *Backreaction*

First one may wonder whether the instability which we have demonstrated only occurs for very small perturbations, and whether it will be cured for larger perturbations. The $l = 2$ modes are particularly interesting in this regard, as a possible non-linear completion of the metric exists in the form of the Bianchi IX line element

$$ds_{IX}^2 = -N_p^2(t)dt_p^2 + \sum_m \left(\frac{l_m(t)}{2}\right)^2 \sigma_m^2\,, \tag{60}$$

where $N_p$ is the physical lapse function and $\sigma_1 = \sin\psi d\theta - \cos\psi\sin\theta d\varphi$, $\sigma_2 = \cos\psi d\theta + \sin\psi\sin\theta d\varphi$, and $\sigma_3 = -(d\psi + \cos\theta d\varphi)$ are differential forms on the three sphere such that $0 \leq \psi \leq 4\pi$, $0 \leq \theta \leq \pi$, and $0 \leq \phi \leq 2\pi$. For ease of notation we will denote a derivative w.r.t. physical time $t_p$ by an overdot in this section (and only in this section). Employing the original definition of Misner, we can re-write the three scale factors as

$$l_{1,2}(t_p) = a(t_p)\exp\left[\frac{1}{2}\left(\beta_+(t_p) + \pm\sqrt{3}\beta_-(t_p)\right)\right], \tag{61}$$

$$l_3(t_p) = a(t_p)\exp\left[-\beta_+(t_p)\right], \tag{62}$$

which makes it clear that $a$ is the average scale factor while the $\beta$s quantify anisotropic perturbations. In these coordinates the action becomes

$$S = 2\pi^2\int dt_p N_p a\left[\frac{1}{N_p^2}\left(-3\dot{a}^2 + \frac{3}{4}a^2\left(\dot{\beta}_+^2 + \dot{\beta}_-^2\right)\right) - U(\beta_+,\beta_-)\right], \tag{63}$$

where the full non-linear potential is given by

$$\begin{aligned} U(\beta_+,\beta_-) = -2\left(e^{2\beta_+} + e^{-\beta_+ - \sqrt{3}\beta_-} + e^{-\beta_+ + \sqrt{3}\beta_-}\right) \\ + \left(e^{-4\beta_+} + e^{2\beta_+ - 2\sqrt{3}\beta_-} + e^{2\beta_+ + 2\sqrt{3}\beta_-}\right) \end{aligned} \tag{64}$$

The equations of motion for $a, \beta_+, \beta_-$ are given by

$$\frac{\ddot{a}}{a} + \frac{1}{2}\frac{\dot{a}^2}{a^2} + \frac{3}{8}\left(\dot{\beta}_+^2 + \dot{\beta}_-^2\right) - \frac{N_p^2}{6a^2}U(\beta_+,\beta_-) = 0\,, \tag{65}$$

$$\ddot{\beta}_\pm + 3\frac{\dot{a}}{a}\dot{\beta}_\pm + \frac{2}{3}\frac{N_p^2}{a^2}U_{,\beta_\pm} = 0\,. \tag{66}$$

Expanding the last equation to linear order we obtain

$$\ddot{\beta}_\pm + 3\frac{\dot{a}}{a}\dot{\beta}_\pm + 8\frac{N_p^2}{a^2}\beta_\pm = 0\,. \tag{67}$$

A comparison with Eq. (49) confirms that the $\beta$s are non-linear versions of the $l = 2$ modes – more specifically, they are non-linear versions of two $l = 2$ modes which are such that they preserve the Bianchi IX symmetry. To match with our earlier normalization conventions, one has to re-scale

$$\beta_\pm = \frac{1}{\sqrt{3}\pi}\phi_\pm\,, \tag{68}$$

where $\phi_\pm$ denote two separate $l = 2$ modes. The structure of the potential $U$ shows that when going beyond linear order, the equations of motion lead to direct couplings between these two $l = 2$ modes.

In the present section we work in a gauge where $N_p = 1$ and where one then has to determine the value of the time coordinate of the final hypersurface on which the boundary conditions $q_0 = 0, q_1 = a_1^2, \phi_\pm = \phi_{1\pm}$ are satisfied. This is done using the shooting method discussed in[17]. In this method, the (generally complex valued) second time derivatives of $\phi_\pm$ at the no boundary point $a = 0$ are adjusted using an

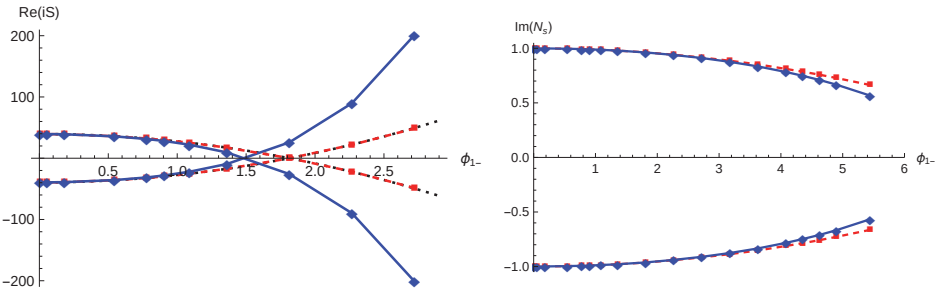

Fig. 5. These graphs show the weighting at the saddle points (left panel) and the imaginary part of the saddle point locations (right panel) as a function of the $l = 2$ anisotropy mode amplitude $\phi_{1-}$, for $\Lambda = 3$. In the plot of the action (left) the line starting at $+12\pi^2/\Lambda = +4\pi^2$ for $\phi_{1-} = 0$ corresponds to the saddle points in the lower half $N$ plane, while the line starting at $-4\pi^2$ corresponds to the saddle points in the upper half plane. In black (mostly hidden behind the red line) are the linear results without backreaction, in red the results including backreaction but still in linear perturbation theory, and in blue the results stemming from solving the fully backreacted Einstein equations. For values of $\phi_{1-}$ below 1 the linear and non-linear results agree to high precision, while one can see that at larger values of the anisotropy the non-linear corrections enhance the instability of the fluctuations, and move the saddle points further towards the real $N$-axis. Note that the weighting of the upper saddle points surpasses that of the lower ones when backreaction is still entirely negligible. Moreover, the non-linear effects of the full Einstein equations imply that the (unstable) upper saddle points come to dominate already for smaller amplitudes of the fluctuations.

optimization algorithm such that at a final time $t_f$ the desired real values $q_1, \phi_{1\pm}$ are simultaneously reached. The total time interval $\int N_p \mathrm{d}t_p = t_f$ can then also be related to the lapse function $N$ using the change of coordinates $N_p \mathrm{d}t_p = N q^{-1/2} \mathrm{d}t$,

$$N = \int_0^1 N \mathrm{d}t = \int_0^{t_f} a(t_p) \mathrm{d}t_p \,. \tag{69}$$

Our results are shown in Fig. 5. For ease of comparison with linear perturbation theory, we only show results for the case where a single $l = 2$ mode (here chosen to be $\phi_{1-}$) takes on a non-trivial value on the final hypersurface. The left panel shows how the weighting of the saddle point solution (for saddles in the upper half plane) increases as the perturbation amplitude is increased. The opposite behavior is seen for the saddle points in the lower half plane. As is evident from the figure, backreaction at second order in perturbation theory is utterly negligible. Even more importantly, the effects of the instability are even stronger when non-linear terms are included, and the dominance of the upper saddle point over the lower ones occurs already for smaller values of $\phi_{1-}$ than in the linear theory. Also, as shown in the right panel, the saddle point moves faster towards the real $N$-axis in the non-linear theory. These results consolidate our analytic results, and indicate that the inclusion of non-linear terms only reinforces the instability that we have identified.

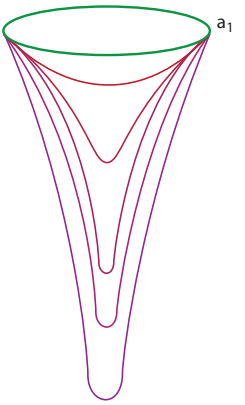

Fig. 6. We may consider a path integral over purely regular geometries, having as their only boundary a large late time universe with scale factor $a_1$. The integral can be pictured as a sum over complexified 4-spheres, bearing in mind that a complexified 4-sphere contains a Lorentzian de Sitter section. One may argue that such a restricted sum is closest in spirit to the original idea of the no-boundary proposal[1,2].

### 4.2. *Sums over regular metrics*

The idea of the no-boundary proposal is to sum over compact and regular metrics. However, as we have seen, in the minisuperspace example discussed so far there were many singular metrics off-shell, although the saddle point geometries were regular. One may wonder if one should restrict the sum in the path integral even furthst, so as to allow only regular metrics off- and on-shell. Could this lead to a different result? Following[18] we can consider the simplest and most symmetric possibility, namely a sum over 4-spheres with given boundaries $a_0 = 0$ and $a_1 > 0$ and arbitrary radius,

$$a(t) = \pm r \sin\left(\frac{N_E\, t}{r}\right) \tag{70}$$

with $a_1 = \pm r \sin\left(\frac{N_E}{r}\right)$ and $\dot{a}_1 = \pm N_E \cos\left(\frac{N_E}{r}\right)$. Accordingly, one should think of $N_E$ as being fixed by the boundary conditions and the sum to be over $r$. Given that $N_E$ will in general be a complex number, we should also expect $r$ to be complex, and that the integral will be over a contour in the complex $r$ plane. As discussed in[11], in fact the relevant saddle point geometry remains the same, and the associated perturbations remain unstable. Moreover, one can also explicitly check that in this calculation backreaction effects are small, so that the instability is confirmed.

## 5. Outlook

Despite the fact that intuitively, the idea of a smooth beginning for spacetime is very attractive, and of clear aesthetic appeal, our results have shown that upon closer inspection it does not work, as it leads to unsuppressed fluctuations (see Fig. 7).

One lesson to be drawn from this result is that it is worthwhile analysing the mathematical setup of a physical theory in some detail, as heuristic arguments can be misleading in unexpected ways. Moreover, quantum gravity appears to be much more restrictive than naively thought. This is in fact an extremely encouraging thought, as it may allow us to make progress regarding the unification of quantum theory and general relativity.

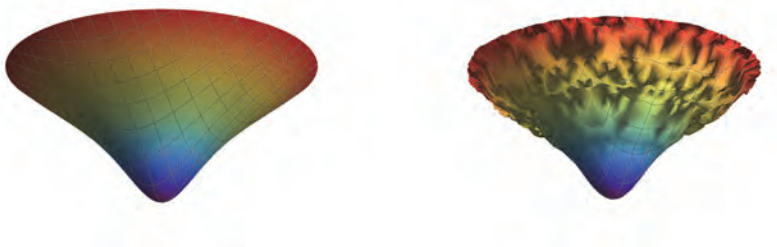

Fig. 7. The beginning of the universe is depicted at the bottom, while our current state of the universe should be thought of as the boundary at the top. *Left panel:* The originally hoped for situation of a smooth beginning. *Right panel:* A detailed investigation of the path integral shows that fluctuations are unstable, and the probability for large perturbations is unsuppressed. Thus the no-boundary and tunneling proposals are untenable in their current forms.

The most important result of our investigations is probably that the Lorentzian path integral is well defined: it gives sensible results for other types of boundary conditions, in particular for classical boundary conditions[7], and it is in fact simply the no-boundary condition that fails. Moreover, our analysis clearly shows that the Euclidean path integral does not exist (see Fig. 3 where one can see that integral along imaginary lapse direction necessarily diverges, either near $N = 0$ or towards imaginary infinity). Other, intrinsically complex integration contours for the lapse were proposed in reaction to our work[19,20], but these ultimately lead to inconsistent results[9,10]. Thus one may take the Lorenztian path integral as a solid basis for further investigations into quantum cosmology, allowing us to explore questions such as: what are the conditions for quantum field theory in curved spacetime to be a good approximation? Are the complex big-crunch-avoiding solutions that were found heuristically in[21] of physical relevance or not? How severe is the trans-Planckian problem of inflation? Which assumptions must be modified in order to obtain a consistent theory of initial conditions? The search remains wide open!

In this work, we extend our previous blind GW signal estimation method [1] to the case of multiple detectors and show that, with a full use of redundancy, it gives promising results, e.g. a faster decay of fluctuations than that expected from the central limit theorem. This method, whose design explicitly accounts for redundancy in multiple measurements, considerably improves the efficiency of signal extraction in a multi-detector network.

## 1. Introduction

Given that detector noise is several orders of magnitude larger than expected gravitational wave (GW) signals from black hole mergers, the analysis of LIGO's data is challenging. This is one reason why LIGO consists of two independent detectors separated by 3000 km. It is reasonable to divide the task into three relatively distinct parts. These include event detection, waveform extraction, and the identification of its physical origin. Here, we will be concerned with the two final steps in this process, focusing on black hole mergers like GW150914. Since thermal and seismic effects lead to substantial low frequency noise and since quantum noise is dominant at high frequencies, it is possible to reduce the effects of noise by band-pass filtering (or equivalent operations) to a restricted frequency range e.g., 30 – 300 Hz. LIGO extracts waveforms by comparing the data from the Livingston and Hanford detectors with (suitably time-shifted) elements of a bank of templates describing the merger of two black holes with various masses, spins and initial conditions. A satisfactory level of agreement would then lead to the acceptable conclusion that the data is *not inconsistent* with a black hole merger. An equally satisfactory conclusion would be that, *if* the event is due to a black hole merger, it has the parameters corresponding to the best-fit template. However, in our view, the far stronger conclusion that such agreement proves that the event actually *is* due to a black hole merger with the corresponding parameters is unwarranted.

Moreover, there are disturbing features in the noise associated with LIGO's events. Although this noise is complex, its two essential characteristics are clear and unambiguous. First, LIGO noise is neither stationary nor Gaussian.[2] In fact, both stationarity and Gaussianity are implicitly assumed in the Bayesian likelihood analysis as a diagonal approximation for the noise covariance matrices for both the Hanford and Livingston detectors.[3] Second, the LIGO "residuals" (defined as the cleaned data minus the best-fit template) for the two detectors should not be correlated. In fact, the residuals associated with GW150914 are strongly correlated when shifted by the same time lag as the template itself and considerably larger than the expected level of "accidental" correlations for LIGO data.[4,5] Since the Hanford (H) and Livingston (L) detectors are assumed to be completely independent except for a possible GW signal, this correlation in the residuals tells us that a template-based analysis does not provide a reliable description of the common signal seen by the H and L detectors.

Template-based analyses have a strong tendency to be self-fulfilling, this alone should be sufficient to emphasize the importance of maintaining a clean separation between the extraction of a signal and attempts to divine its physical origin.

In order to make optimal use of the independence of the H and L detectors and to quantify the uncertainties in previously extracted waveforms, we have constructed a template-free method that includes minimization of residual correlations in order to determine a "best common signal" for GW150914.[1] Since the residual for an individual detector is a complicated function of time (or frequency), there are many ways to realize the desired absence of correlations. This means that our algorithm yields a family of best common signals that enable us to estimate the probability, $p$, that the best common signal is a black hole merger template. For GW150914, we find $p = 0.008$. It is unclear whether this small probability is indicative of inadequacies in the gravitational wave templates, imperfect knowledge of the acceptance of the instruments, or of a completely different physical explanation — either astrophysical or terrestrial — of this event. As the amplitude of the signal becomes smaller with respect to the noise level, the relative width of the envelope of best common solutions obtained by this method grows and eventually covers the line of zero signal. The signal to noise ratio (SNR) for other possible black hole merger events is smaller than that found for GW150914, and we find that all of these subsequent events are consistent with a best common signal of precisely zero.

The fact that LIGO does not make use of the only relevant information available about noise properties (i.e., the fact that L and H residuals must be uncorrelated) also suggests that their analysis does not optimally exploit the benefits of redundancy that should accrue from two independent measurements of the same signal. Since the power of redundancy becomes clearer as the degree of redundancy is increased, our primary concern in this paper is to extend the results of Ref. 1 to the case of an arbitrary number of GW detectors. We emphasize that this approach is not merely a pedagogic exercise. There is considerable current discussion about adding additional detectors to the GW network. Since the effects an additional

detector can have on the accuracy of signal attraction depends sensitively on the degree to which redundancy is exploited, we believe that the present work can be of practical relevance in deciding the extent to which such an investment is justified.

We begin in section 2 by presenting simple schematic models that illustrate the dramatic differences found when analyzing multi-detector events with or without consideration of the effects of redundancy. These models will provide a gauge of the extent to which redundancy is realized in practice. The extension of our earlier model for the blind estimation of the common signal to the case of many detectors will be described in section 3 along with the results of realistic simulations. Finally, section 4 contains a discussion based on these results.

## 2. The value of redundancy and its price

We all have an intuitive understanding of the important role that redundancy can play in the accurate determination of a signal transmitted in the presence of noise. When told an important telephone number in a noisy environment, our immediate reaction is to ask for it to be repeated. Hearing the same number twice greatly increases our confidence that it has been transmitted correctly. Clearly, redundancy is equally important in a scientific context, and it was surely one of the primary reasons that LIGO wished to have multiple GW detectors. In the analysis of GW170814, LIGO makes use of the Virgo detector as a consistency check for the results from Hanford and Livingston.[6] The additional information from Virgo improves the false-alarm rate compared to the two detector case. In general, the SNR of the LIGO/Virgo network is defined as a sum in quadrature of the individual detector SNRs, i.e.[7]

$$\rho^2_{\text{network}} = \sum_{i=1}^{M} \rho_i^2. \tag{1}$$

The precondition for this definition is ideal detector noise uncorrelated between detectors, with off-diagonal terms of the noise covariance matrix neglected. Furthermore, the addition of detector SNRs in this way fails to properly exploit redundancy, because the network SNR can be dominated by the SNR of a single detector. A high network SNR does not necessarily imply agreement between detectors.

Our aim in this section is to provide a better understanding of both the power of redundancy and the price that must be paid to obtain it.

We first consider a schematic but instructive example of redundancy in which there are two independent measurements of a common signal consisting of $N$ pieces of data. In the absence of noise, the two measured signals will be identical to one another and to the true signal. Now, simulate noise by assuming that there is a probability, $p$, that any given piece of genuine data, $d_i$, has been replaced by noise $n_i$ (with $n_i \neq d_i$). The probability that both of the measured signals are free of errors and therefore correct is evidently $(1-p)^{2N}$, which vanishes exponentially as the signal becomes more complex (i.e., $N \to \infty$). It is necessary, however, to

consider the possibility of false positives, for which the signals are not correct in spite of being identical. To investigate this question, assume that the probability that two randomly drawn pieces of noise are identical is $q$. (E.g., If the $n_i$ are randomly drawn digits between 0 and 9, $q = 1/9$.) The probability that the two signals will be identical (either genuinely or accidentally) is

$$\sum_{m=0}^{N} (1-p)^{2(N-m)} p^{2m} q^m \frac{N!}{(N-m)!m!} = \left[(1-p)^2 + p^2 q\right]^N \quad . \tag{2}$$

Thus, the probability that identical results of the two measurements will actually be correct is

$$\left[\frac{(1-p)^2}{(1-p)^2 + p^2 q}\right]^N \quad .$$

The extension of this problem to the case where there are $M$ detectors is straightforward. In this case, all $M$ detectors see the same event. The probability that all of the measured signals are free of errors (and therefore measured correctly) is evidently $(1-p)^{MN}$, which clearly decreases exponentially with increasing $M$. The generalization of Eq. 2 describing the probability that these $M$ signals will be identical (but not necessarily correct) then becomes

$$P = \left[(1-p)^M + p^M q^{M-1}\right]^N \quad , \tag{3}$$

and thus the probability that identical results for all $M$ measurements will actually be the correct signal is

$$P = \left[\frac{(1-p)^M}{(1-p)^M + p^M q^{M-1}}\right]^N \quad . \tag{4}$$

To illustrate this result, consider the transmission of an 8-digit telephone number in a noisy environment. For this case, assume $N = 8$, $p = 1/4$, and $q = 1/9$ and consider the cases of $M = 2$, 3, and 4 detectors. The probability that identical (but not necessarily correct) results will be obtained for all $M$ measurements is approximately 0.01, 0.001, and 0.0001, respectively. The probabilities that these identical results will be false are 0.0935, 0.00365, and 0.000135, respectively. The exponential decrease of this error is evident and emphasizes the dramatic improvement in accuracy that results from $M$ identical measurements of the same signal. Unfortunately, it also reminds us that the probability of actually obtaining $M$ identical signals also decreases exponentially with $M$.

The preceding example might seem to indicate that redundant measurement of a given signal will lead to signal detection and extraction with a confidence that grows to 1 exponentially with the redundancy $M$. We now wish to consider a second example to illustrate that this is not necessarily the case. To this end, consider $M$ independent measurements each of which for simplicity consists of a common signal, $s$, and an independent realization of $N$ pieces of random noise.

The data obtained at detector $k$ is thus $d^{(k)} = s + n^{(k)}$.[a] We wish to extract $s$ from this data without making unwarranted assumptions about the noise such as stationarity and/or Gaussianity. Given this strong constraint, the only assumption that can be made is that the measurements in the various detectors are genuinely independent and that there are therefore no correlations in their noise realizations To be concrete, we will imagine that cross-correlations are given as the Pearson cross-correlation to be adopted below.[b]

In these circumstances, it might seem natural to approximate the best common signal as the average record

$$\mathcal{S} = \frac{1}{M}\sum_{k=1}^{M} d^{(k)} = s + \frac{1}{M}\sum_{k=1}^{M} r^{(k)} \ . \tag{5}$$

Given this guess, we can re-express the individual data strings as $d^{(k)} = \mathcal{S} + \rho^{(k)}$ where the residuals are given as

$$\rho^{(k)} = \frac{1}{M}\left[(M-1)r^{(k)} - \sum_{j\neq k} r^{(j)}\right] \ . \tag{6}$$

For sufficiently large $N$, it is reasonable to make the approximation that the cross-correlators $C(s, r^{(k)}) = 0$ for all $k$ and $C(r^{(j)}, r^{(k)}) = 0$ for all $j \neq k$. This leads to the result that

$$C(s,\mathcal{S}) = \frac{1}{\sqrt{1+1/M}} \approx 1 - \frac{1}{2M} \ \text{ and } \ C(\rho^{(j)},\rho^{(k)}) = -\frac{1}{M-1} \ . \tag{7}$$

It is true that $\mathcal{S}$ converges to the exact result $s$ and that the correlations between the residuals, $\rho^{(k)}$, vanish as expected in the limit of large $M$. Unfortunately, these convergence rates, which are an elementary consequence of the central limit theorem, are far too slow to be useful. The fact that all of the $M(M-1)/2$ correlators between the residuals have the same value of $-1/(M-1)$ is also unphysical. Thus, the assumption that the signal can be approximated by Eq. 5 is unjustified. For the case $M = 2$, the cross-correlator $C(s, \mathcal{S})$ has the unsatisfactorily small value of $\sqrt{2/3}$, and there is a perfect anti-correlation between the residuals with $C(\rho_1, \rho_2) = -1$. As noted in our earlier work[4,8], similarly large and unphysical correlations in the residuals determined by LIGO for GW150914[9] suggest the existence of problems with the corresponding GW signal.[c]

[a] Note that this is the model used for Bayesian analysis of the LIGO events.[3]

[b] For two vector records of length $N$, we first shift the records so that each has average value zero and rescale them so that the scalar product of each vector with itself is 1. The Pearson cross-correlation is then the scalar product of these shifted and rescaled vectors and will have a value between $-1$ and $+1$.

[c] The presence of correlations in the Hanford and Livingston residuals determined in original template-based analysis of GW150914 raises questions about this analysis. It is important for others to confirm the existence of these correlations. This can be done using the publicly available data, as described on our webpage:
`http://www.nbi.ku.dk/gravitational-waves/residual_correlations_notebook.html`

The two examples presented in this section can serve as a measure of the extent to which the benefits of redundancy have been realized by a given method of signal extraction. When redundancy is not exploited, we find that the extracted signal converges to the true signal with an error that vanishes slowly (i.e., like $1/\sqrt{M}$) as the degree of redundancy increases. In contrast, a maximal implementation of redundancy leads to an exponentially decreasing error rate as a function of $M$. This test will be applied in practice in the following sections of this paper. It should be noted, however, that this increased confidence level has a relatively high price. As we have seen, the probability that an event will pass the redundancy test also vanishes exponentially with $M$. Thus, if event rates are too low, it may be impossible to realize fully the benefits of redundancy. We stress that the examples here are highly schematic and are intended to illustrate the general fact that the benefit of multiple independent measurements depends sensitively on the way these measurements are analyzed. They do not tell us to how the benefits of redundancy can be maximally realized in the case of GW data. We consider one such approach in the following section.

## 3. Application of the blind estimation method to multiple GW detectors

### 3.1. *Basis of the blind estimation method: cross-correlation and Fisher transformation*

We briefly review our previous work on blind estimation. [1] The strain signal detected by LIGO in the $i$-th detector is assumed to be

$$X_i(t) = a_i \cdot h(t, \Delta\tau_i, \Delta\theta_i) + N_i(t), \tag{8}$$

where $X_i(t)$ is the total strain data, $N_i(t)$ is the noise, and $a_i \cdot h(t, \Delta\tau_i, \Delta\theta_i)$ is the gravitational wave signal with given amplitude $a_i$, time lag $\Delta\tau_i$ and phase shift $\Delta\theta_i$, which contain both contributions from projection and detector acceptance. As mentioned in Ref. 1, we pre-match detector data to roughly remove the contributions of $\Delta\tau_i$ and $\Delta\theta_i$ (this can be done precisely with, e.g., an EM-counterpart), and then the equation becomes

$$X_i(t) = a_i \cdot h(t) + N_i(t). \tag{9}$$

For a blind estimation, we also need to further derive the residual noise, for which we consider two data sets $X_1$ and $X_2$ of length $N$ (e.g. cleaned strain data from two independent detectors) which contain a common signal $A$. The amplitude of $A$ could potentially be different in each detector, either due to projection or detector acceptances. For convenience, we assume that $X_1$, $X_2$, and $A$ have been shifted to have zero average values and normalized to have variance unity. Then the Pearson cross-correlation coefficient of two such vectors, $C_{X_1 X_2}$, is simply the inner product $S_{X_1 X_2}$ given by

$$S_{X_1 X_2} = \frac{1}{N-1} \sum_{k=1}^{N} X_1(k) \cdot X_2(k). \tag{10}$$

The residuals are defined as

$$R_i = X_i - A \cdot \frac{S_{AX_i}}{S_{AA}} = X_i - A \cdot S_{AX_i}. \tag{11}$$

As mentioned above, the amplitude of the term $A$ (i.e. $S_{AX}/S_{AA}$) can be different for two dececctors. By construction, the correlations of both $R_1$ and $R_2$ with $A$ are zero.

The criterion for determining the blind estimate of $A$ is to maximize the $C_{AX_i}$ while simultaneously minimizing the cross-correlation between the residuals $C_{R_1 R_2}$. Note that the residuals $R_1$ and $R_2$ are not automatically normalized.

For familiarity and simplicity, we obtain approximate Gaussianity of the resulting correlations by using the Fisher transformation:[10]

$$Z_{XY} = \frac{1}{2} \log \left( \frac{1 + C_{XY}}{1 - C_{XY}} \right). \tag{12}$$

### 3.2. *Extension of the likelihood approach*

In our previous work,[1] a blind GW-template estimation was done by considering the likelihood that a given initial guess, $A$, is the common signal observed by two detectors ($X_1$ and $X_2$) as

$$\log(L) = Z^2_{AX_1} + Z^2_{AX_2} - k Z^2_{R_1 R_2}, \tag{13}$$

where $Z_{AX_1}$ and $Z_{AX_2}$ represent the similarity between $A$ and the detector data as measured by the Pearson cross correlation, $Z_{R_1 R_2}$ represents the similarity between the residuals from the two detectors, and $k$ is a constant factor determining the relative weight of the two contributions. The likelihood function is designed to be maximized at higher $Z^2_{AX_1}$ and $Z^2_{AX_2}$ and lower $Z^2_{R_1 R_2}$. The initial guess $A$ is then improved by a random walk approach until the likelihood reaches an oscillatory region (see Fig. 2 of Ref. 1). The oscillatory region is used to estimate the range of fluctuation for each pixel as shown in Figs. 4 and 5 of Ref. 1.

The above method was initially designed for the GW150914 event for which there were only two detectors in the network. A natural extension of the method is to apply it to multiple detectors, so the likelihood function becomes:

$$\log(L) = \sum_{i=1}^{M} (Z_{AX_i})^2 - k \sum_{i=1}^{M-1} \sum_{j=i+1}^{M} Z_{R_i R_j}, \tag{14}$$

where $M$ is the number of detectors, $X_i$ is the data from the $i$-th detector, $A$ is the blind estimate of the signal, and $R_i$ is the residual after removing this estimate from the $i$-th detector. With this modified likelihood function, the blind estimation method presented in Ref. 1 can be extended to the case of multiple detectors.

Also note that this kind of likelihood approach is different from a likelihood approach that assumes either a known covariance matrix or a known theoretical model, or even both. Here, neither the covariance matrix nor the theoretical model is assumed, and one starts only from basic ideas about "correlated signals and uncorrelated noise". Thus the likelihood approach here is totally blind, i.e. it makes minimal assumptions. This is unlike template-free methods currently in use by LIGO, such as BayesWave and oLIB, which begin with the assumption of a stationary Gaussian noise model.[11,12] Finally, we note that if there is any reliable additional information, such as a known correlation between two of the detectors, or an especially low SNR in one of the detectors, then such information can also be added to Eq. 14 by changing the weights of the corresponding terms.

### 3.3. *Test and results*

To test the performance of the blind estimation method for the case of multiple detectors, we run a simulation as follows: We select the GW150914 waveform template as the input "real signal", and inject it into genuine strain data taken $2, 3, \ldots, M+1$ seconds after the GW150914 event to simulate the data from multiple detectors. Here, we are mainly interested in the trend of how the error of estimation decreases with increasing number of detectors. Thus, for convenience, we assume identical projections and similar noise levels for all detectors (see also Sec 3.1 of Ref. 1). In practice, when multiple detectors have different projections and signal-to-noise ratios, the overall performance will become worse. For simplicity, we will neglect these concerns here.

For comparison, we adopt a reference estimator of the common signal that is simply the average of the data from the individual detectors and further assume that the detector noise is Gaussian. The estimated error will then scale like $1/\sqrt{M}$. We shall compare the performance of our method with this reference.

As mentioned above, the range of fluctuations is an immediate result from the oscillations of the likelihood function caused by chance correlations. In the simulation here, we select the 10th and 90th percentiles of the fluctuation range and use their difference as a measure of the range of fluctuation for each pixel. This quantity is averaged over the entire time range of the event as the final estimator of the uncertainty of blind estimation:

$$E_M = \langle S_{90}(t) - S_{10}(t) \rangle_M \,. \tag{15}$$

The result of the simulation described above is given in Fig. 1 where it is apparent that the blind estimation (black) performs better than the $1/\sqrt{M}$ reference (red). This result is not surprising because the $1/\sqrt{M}$ reference is obtained by simple averaging without consideration of the residual correlations. In other words, an estimation method that considers both the correlations between signal and data (first term in Eq. 14) and the correlations between residuals (second term in Eq. 14) will certainly give better results than simple averaging.

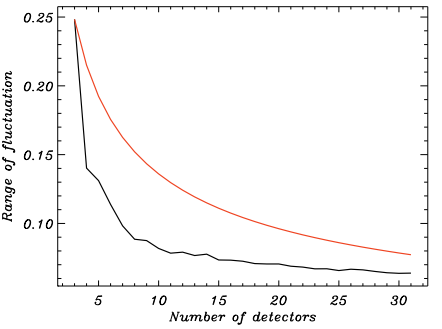

Fig. 1. The range of fluctuation defined by Eq. 15. The horizontal axis shows the number of detectors, and the vertical axis shows the estimator of uncertainty, $E_M$, calculated using the convention that strain data is shifted to have zero mean and normalized to have variance unity. The black line is the performance of the multi-detector blind estimation method, and the red line is the expectation of the central limit theorem that scales as $1/\sqrt{M}$ given by simple averaging, which has been normalized to the black line at $M = 3$.

We also show the input signal and the range of error obtained from blind estimations for the extreme example of 32 detectors in Fig. 2. We include, for test purporses, a slight variation of the above method in which the first term in Eq. 14, $\propto Z^2_{AX_i}$, is dropped. One can see that even without this seemingly essential term, one still gets unbiased estimations of the "real signal". Only the error of estimation is larger.

The error of the estimated common signal can also be evaluated by comparison to the real signal $h(t)$. Three cases are considered: the simple average of multiple detectors, $B_1(t)$; the average of the blind estimations, $B_2(t)$; and the average of blind estimations calculated only using the residual correlation terms in Eq. 14, $B_3(t)$. For each of the three cases, we determine the deviation from the real signal $h(t)$ as

$$\begin{aligned} \delta_1 &= B_1(t) - h(t) \\ \delta_2 &= B_2(t) - h(t) \\ \delta_3 &= B_3(t) - h(t), \end{aligned} \tag{16}$$

and calculate the standard deviations as $\sigma_1$, $\sigma_2$ and $\sigma_3$ respectively. For a given number of detectors, we calculate two ratios

$$\begin{aligned} r_{12} &= \sigma_1/\sigma_2 \\ r_{13} &= \sigma_1/\sigma_3, \end{aligned} \tag{17}$$

which are defined such that larger values correspond to better performance than simply averaging. Our blind estimation method is expected to give smaller uncertainties than simple averaging, thus we should see $r_{12} > 1$. Larger values of $r_{12}$ indicate better results given by the blind estimation. On the other hand, we expect

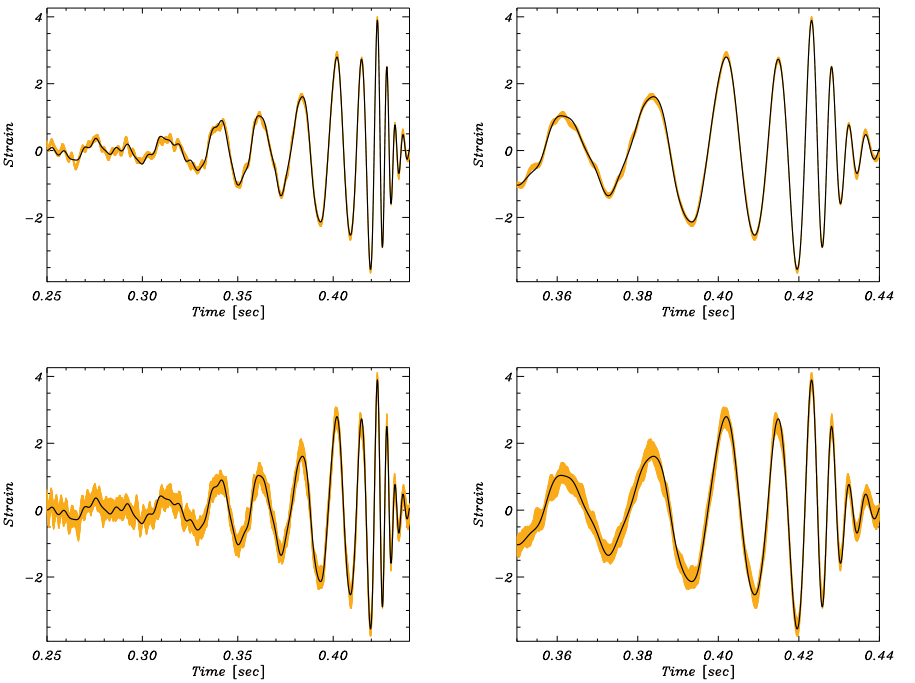

Fig. 2. The real input template (black) and the 10%–90% range of uncertainty (see Eq. 15) given by the blind estimation for the case of 32 detectors. Upper: using the whole likelihood, as in Eq. 14. Lower: same as the upper panels but only the residual terms are used. Left: the full time range. Right: only the second half.

that a blind estimation only using the correlations of the residuals is worse than simple averaging, but it should still be a reasonable estimation, thus $r_{13}$ should be less than 1 but not much lower.

In Fig. 3, we show $r_{12}$ and $r_{13}$ as functions of the number of detectors. The ratio $r_{12}$ lies around 1.2–1.4, indicating that simple averaging gives a 20%–40% larger error than blind estimation. Also, $r_{13}$ is about 0.8–0.9, indicating that, even from only regarding the residual–residual terms of the likelihood, one can still get a reasonably good estimation of the real input signal. Therefore, Figs. 2 and 3 suggest that to only compare template to data and ignore residuals is an inefficient use of experimental resources. We also see from Fig. 3 that, if the number of detectors is less than 10, then the blind estimation method is significantly better than simple averaging. With increasing $M$, however, the improvement of the method slows. This is possibly due to the finite record length. Since in the near future, the number of GW detectors will not exceed 10, a blind estimation method such as this one is especially important.

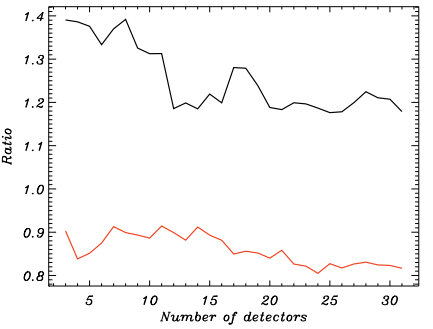

Fig. 3. The ratios $r_{12}$ (black) and $r_{13}$ (red) as functions of the number of detectors. $r_{12} > 1$ means our blind estimation gives lower estimation error than a simple averaging, while $r_{13}$ close to 1 means even without using the template–data term, one can still get a reasonably good estimation of the potential common signal using the same blind estimation method.

## 4. Discussions

The aim of the present paper is two-fold. On the one hand, an exploration of the role of redundancy in the analysis of LIGO data can help better to understand the reliability of events already observed. On the other, it can offer some guidance regarding the most fruitful way to analyze data in the coming multi-detector era of gravitational wave science. It is our firm conviction that template-based analysis alone is in principle circular and thus fundamentally flawed. Clearly, a bank that only contains templates for black hole mergers can never detect anything other than black hole mergers. The best that one can hope for is to claim that an event is *not inconsistent* with black hole merger and then make the best case possible that other possible origins — terrestrial as well as astrophysical — can be excluded. Rather, we are convinced that data analysis should begin with the template-free extraction of a best common signal that can later be compared with specific physical models. This conviction led to the development of the blind signal estimation initially presented in Ref. 1 and extended here. This method enabled us to determine the probability that the best common signal could be described by a gravitational wave template. Unfortunately, this probability is remarkably low. The probability that the common signal is LIGO's original published template was found to be $4\times10^{-6}$. The best GW template was found to have substantially higher masses (38 and 48 solar masses) and high spins (0.96 and $-0.85$, respectively). While better than the published template, the probability that it was the best common signal still had the unacceptably small value of 0.008. It should be noted that GW150914 is by far the strongest event seen. A similar template-free analysis of all other putative gravitational wave events is consistent with a common signal of zero.

Gravitational wave signals are characteristically much smaller than measured data indicating that the noise is much stronger than the signal. Thus, a reliable

blind analysis of GW data requires detailed knowledge of the origin and nature of detector noise. Unfortunately, it is generally acknowledged that this noise is neither Gaussian nor stationary. In order to make a reliable detection of a GW signal, it is essential that there be no correlation between the residuals observed at individual detectors. This obvious requirement lies at the heart of the justification for incurring the expense of performing redundant measurements of a given signal with two or more independent detectors. We have thus provided simple schematic examples to show that the accuracy of detection can be improved exponentially with an increasing degree of redundancy. This stands in sharp contrast to the far slower convergence expected from a simple average of the measured signals. These results are supported by simulations based on a realistic gravitational wave form and real LIGO noise data. These results indicate the important role played by the residual correlations in the data analysis. Indeed, it is possible to obtain a reasonably good estimation of the injected signal by using only these terms. In summary, these results provide a strong reminder of the importance of exploiting redundancy in the analysis of both present and future gravitational wave data and suggest that this can be accomplished by including the suppresion of residual correlations in the construction of a satisfactory likelihood function.

## Acknowledgments

The authors thank the organizers of the MG15 conference. This work has made use of the LIGO software package and data. Our research was funded in part by the Danish National Research Foundation (DNRF) and by Villum Fonden through the Deep Space project. # Status of KAGRA and its science goals

Takaaki Kajita, for the KAGRA collaboration

*Institute for Cosmic Ray Research, The University of Tokyo, Kashia, 277-8582, Japan*
†*E-mail: kajita@icrr.u-tokyo.ac.jp*

KAGRA is an interferometric gravitational-wave detector with 3-km arms constructed at Kamioka, Gifu, Japan. One of the key features of KAGRA is the cryogenic mirrors for the 3 km arm cavities. KAGRA plans to begin the operation before the end of 2019. KAGRA plans to join the network observation of global gravitational wave interferometers.

*Keywords*: Gravitational waves, interferometer, cryogenic, underground.

## 1. Introduction

The gravitational wave astronomy has begun with the detection of gravitational waves (GWs) in the past three years. LIGO Scientific Collaboration and Virgo Collaboration have reported mergers of binary black holes[1,2] and a merger of binary neutron stars[3]. These observations have already proved that the gravitational waves are very important for the understanding of the Universe.

## 2. Overview of KAGRA

KAGRA[4] is a laser interferometer with 3 km arms, constructed in Kamioka, Gifu, Japan, and was in its final installation phase as of August 2018. After the conference, in April 2019, the construction has been completed. KAGRA is located underground for smaller seismic noise. KAGRA will use 4 cryogenic mirrors for the 3 km arm cavities to reduce thermal noise around the detector's most sensitive band at around 100 Hz. The KAGRA collaboration is an international collaboration with more than 200 collaborators.

The optical configuration of KAGRA is similar to LIGO and Virgo, with 3 km arm length and various optical cavities in the arms and recycling systems. Each mirror is suspended by vibration isolation system. Depending on the requirement on the vibration isolation of the mirrors, there are essentially 4 types of vibration isolation systems. For example, the arm cavity mirrors are suspended by a 13.5-meter-long vibration isolation system. Figures 1 and 2 show the interferometer configuration and 4 types of vibration isolation systems.

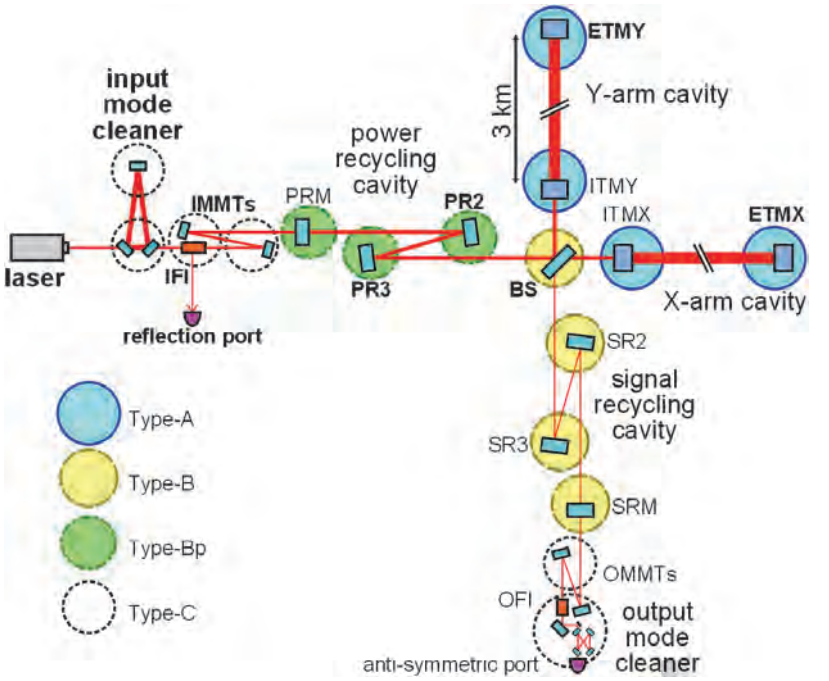

Fig. 1. Schematic of the KAGRA interferometer. All the mirrors shown are suspended inside the vacuum tanks with four types of vibration isolation systems.

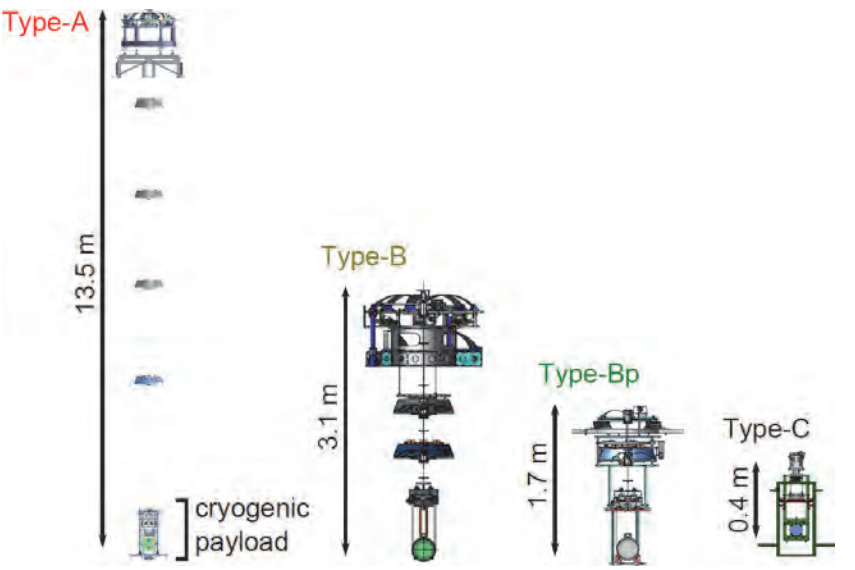

Fig. 2. Vibration isolation system for mirrors. The location of these systems are shown in Fig. 1.

Four cryogenic mirrors are suspended by Type-A system (see Fig. 2). The top part is a room temperature system and the bottom part is cryogenic. Figure 3 shows the details of the cryogenic payload.

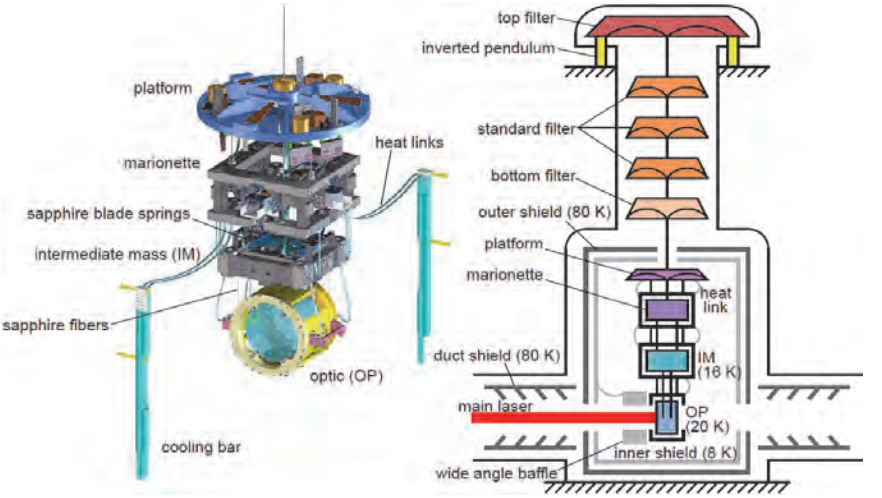

Fig. 3. Left: The drawing of the cryogenic payload under Type-A. Right: The schematic of the cryogenic suspension system of sapphire test masses. Upper part of the suspension system outside of the thermal shield are at room temperature.

## 3. Status of KAGRA

The KAGRA project was approved by the Japanese government in 2010. The excavation of the underground facility including the 3 km × 3 km arm tunnels was finished in March 2014. The installation of vacuum tubes for the 3 km × 3 km arms was completed in February 2015. KAGRA had the initial 3 km interferometer operation in the spring of 2016 with the simplest configuration. Then in the spring of 2018, interferometer operation with one cryogenic mirror was carried out. As of summer, 2018, the construction of the KAGRA interferometer was in the final stage. The construction was finished in April 2019. KAGRA is in the middle of the interferometer commissioning as of May 2019.

## 4. Plan of KAGRA

LIGO and Virgo began the third observation run (O3) in April 2019. O3 is expected to continue until the end of March 2020. Therefore, KAGRA plans to join O3 before the end of 2019. After joining O3, KAGRA would like to fully join the later observation runs (O4, O5 and later).

Figure 4 shows the sensitivity of KAGRA as a function of time[5]. It is estimated that the sensitivity of KAGRA during O3 will be limited (8–25 Mpc) because of the short time for the commissioning and noise hunting before joining O3.

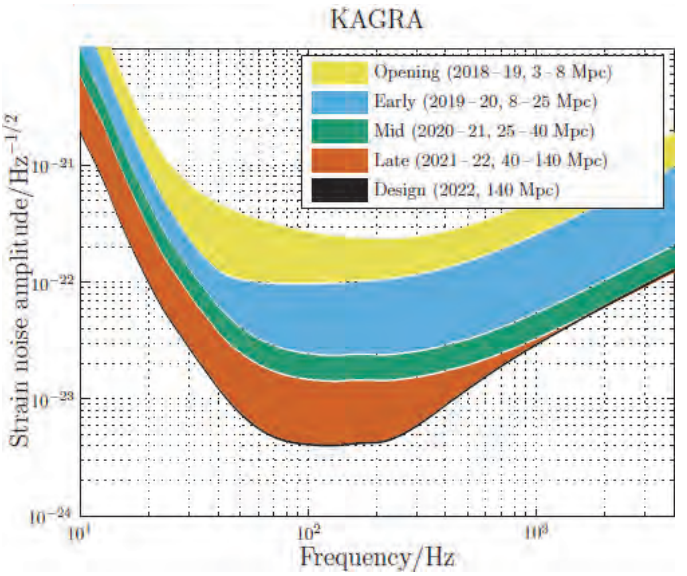

Fig. 4. The expected sensitivity of KAGRA as a function of time[5].

## 5. Scientific merits

It I well known that the scientific merit should be maximized if the operations of the interferometers are coordinated. Therefore, KAGRA plans to join the global network of gravitational wave interferometers, starting in O3.

Let us assume that we need at least 3 interferometers in operation to get scientific results, such as the determination of the source direction. Assuming that each interferometer has the duty cycle of 80%, the probability of the 3-detector coincidence in operation is 51% for 3 interferometer configurations. If there are 4 interferometers including KAGRA, the 3-detector coincidence in operation should be improved to 81%. Clearly adding the 4$^{\text{th}}$ interferometer (namely, adding KAGRA) has a significant impact on the effective observation time of the interferometers.

Initially there were only 2 LIGO interferometers. During that period the accuracy of the source localization was limited. Adding Virgo had a significant impact on the source localization. Since KAGRA is located far from both LIGO and Virgo, KAGRA's operation is expected to make the source localization and waveform reconstruction more precise.

Finally, it should be mentioned that KAGRA is located in the same mountain as Super-Kamiokande. Therefore, if a supernova explodes in our Galaxy, KAGRA and Super-Kamiokande should observe gravitational wave and neutrinos signals, respectively. These data can be analyzed without worrying the relative timing, which is a merit of KAGRA.

## 6. Summary

KAGRA is a unique GW interferometer with the underground site and the cryogenic technology. KAGRA has finished the installation in April 2019, and plans join O3 in late 2019. We would like to contribute to the global network of gravitational wave interferometers and contribute to the science of gravitational wave astronomy.

## Acknowledgments

We would like to thank the Advanced Technology Center (ATC) of NAOJ, the Mechanical Engineering Center of KEK, and the machine shop of the Institute of Solid State Physics (ISSP) of the University of Tokyo for technical support.

Also, we would like to thank LIGO Scientific Collaboration and Virgo Collaboration for various supports.

# The TianQin project

Jun Luo

*TianQin Research Center for Gravitational Physics, Sun Yat-sen University (Zhuhai Campus), 2 Daxue Rd., Zhuhai 519082, P. R. China.*
*MOE Key Laboratory of Fundamental Physical Quantities Measurement & Hubei Key Laboratory of Gravitation and Quantum Physics, PGMF and School of Physics, Huazhong University of Science and Technology, 1037 Luoyu Rd., Wuhan 430074, P. R. China.*
*E-mail: junluo@mail.sysu.edu.cn*

In this talk, I give a brief introduction to the TianQin project, which aims to start space-based gravitational wave detection in the 2030s. My main focus will be on the background, the preliminary concept, the scientific objectives, the development of key technologies, the current progress and the international collaboration of the project.

*Keywords*: TianQin; Gravitational waves; Space-based gravitational wave detection.

## 1. Introduction

Discussions leading to the TianQin project started in 2013 when a team of scientists from the Sternberg Astronomical Institute, Moscow State University, joined our team at the Huazhong University of Science and Technology (HUST) to discuss ideas for future gravitational experiments in space. The focus of the discussion gradually shifted to a feasible gravitational wave mission in space from China. The name "TianQin" was proposed during a meeting in March 2014, followed by the first international workshop on the TianQin science mission in December 2014. A systematic development of the TianQin project was initiated in Sun Yat-sen University (SYSU) in early 2015. The paper summarizing the preliminary mission concept of TianQin was submitted to *Class. Quant. Grav.* on September 1, 2015 [1], 13 days before LIGO detected its first gravitational wave signal.

The name of the planned detector (which will be consisted of three satellites), TianQin, is the phonetic spelling of two Chinese characters that, when put together, mean a harp in space. By choosing this name, the detector is metaphorically seen as a musical instrument in space to be played by nature with gravitational waves.

In this talk, I shall give a brief introduction to the TianQin project, including the background (section 2), the preliminary concept (section 3), the scientific objectives (section 4), the development of key technologies (section 5), the current progress (section 6) and the international collaboration (section 7) of the project.

## 2. Background

For more than 100 years, General Relativity has passed numerous non-trivial experimental tests, including [2]:

- orbital precession of mercury,
- deflection of light by sun,

- gravitational redshift,
- Shapiro delay,
- frame dragging,
- gravitational lensing,

and so on. The first detection of gravitational waves by LIGO in 2015[3] opened a new era when General Relativity can be tested under extreme conditions where even black holes can be radically deformed.

Gravitational waves are extremely weak. In the first event detected by LIGO, GW150914, two black holes with masses $29M_\odot$ and $36M_\odot$ merged at about 1.3 billion light years away[3], producing gravitational waves with strength at the order $10^{-21}$ when reaching Earth. The effect of such gravitational wave is comparable to deforming the distance between the Sun and the Earth by the size of an atom! For this reason, it has taken people a whole century to detect gravitational waves after its prediction by Einstein in 1916.

Gravitational waves provide a new method to study the universe, providing crucial information on the origin and growth of stars, galaxies and the Universe itself, and on the nature of gravity and black holes. New discoveries have already been made with the few gravitational wave events detected since 2015, including:

- Showing that massive stellar mass black holes are more abundant than expected[4];
- Demonstrating the feasibility of multi-messenger astronomy[5,6];
- Showing that binary neutron star mergers are cosmic factories of heavy elements and are central engines of short gamma ray bursts[7].

Close to the frequency band of about 10Hz$\sim 10^4$Hz that has already been opened up with ground based detectors, the millihertz (mHz) frequency band (which typically corresponds to the frequency range $10^{-4}$Hz$\sim$ 1Hz) also has many types of important astronomical and cosmological sources:

- Galactic compact binaries can produce gravitational waves with periods in the order of a few minutes;
- Systems involving massive black holes can produce gravitational waves with periods from minutes to years;
- The birth and the initial expansion of the Universe may leave detectable gravitational waves at all frequencies.

To detect gravitational waves in the mHz frequency band, we need a laser interferometer with arm lengths at the order $10^5$km or greater and to stay away from the seismic noise that has become a limiting factor below about 10Hz for ground based detectors. So the only feasible way is to put the detector in space.

The idea of using a laser interferometer in space to detect gravitational waves can be traced back to the 1970s, and the first such mission concept LAGOS was proposed in the 1980s[9]. By far the most studied mission concept for space-based

gravitational wave detection is LISA, which envisages three spacecraft forming a regular triangle with each side measuring about 2.5 million kilometers[10]. LISA has been selected as the L3 mission in the Cosmic Vision 2015-2025 programme of ESA and is expected to launch in 2034[11].

When TianQin was first proposed in 2014, it was more intended to be an experiment rather than an observatory, with the main goal to verify the prediction of gravitational waves by General Relativity[1]. After the first detection of gravitational waves by LIGO, this primitive goal of TianQin has to be updated. Thanks to the fact that all laser interferometer-based gravitational wave detectors are wide band detectors, TianQin has the natural capability of being a space-based gravitational wave observatory. However, the initial goal of TianQin has allowed it to take some special features that are not shared by any other mission concept proposed. One of our task is to investigate the consequence of such special features when TianQin is to be treated as a gravitational wave observatory.

## 3. The preliminary concept of TianQin

A description of the mission concept of TianQin has been presented in[1]. Here I only summarize some of the key features:

- TianQin will be consisted of three satellites, forming a regular triangle constellation;
- The TianQin satellites will be on nearly identical geocentric orbits with radii at the order $10^5$ kilometers;
- The plane of the TianQin constellation is nearly perpendicular to the ecliptic (the original reason was to let the plane face the ultra-compact binary system RX J0806.3+1527, so as to maximize the response of TianQin to this particular source).

The adoption of geocentric orbits brings some advantages for TianQin: the transfer time for the TianQin satellites to enter the scientific operation orbits is at the order of dozens of days and TianQin foresees little difficulty with communicating with Earth.

However, the same geocentric orbits also bring some extra challenges.

Firstly, TianQin is facing a complicated celestial dynamical environment for being close to Earth and Moon, which directly leads to the question that if TianQin can even find such orbits that are suitable for gravitational wave detection. For TianQin, a candidate orbit need to satisfy the following constraints in order not to interfere with gravitational wave detection:

- The distance between any two satellites need to be very stable, e.g. varying less than 1% throughout the mission lifetime;
- The relative velocity between any two satellites need to be small, e.g. being less than 10m/s during scientific observation time;

- The angle between any pair of arms of the constellation need to be stable, e.g. varying no more than 0.1 degree in the short term (several months) and no more than 0.2 degree in the long term (years).

It has been shown that an orbit satisfying all the above requirement does exist[1].

Recent study has produced more candidate orbits with different orientations, for which all the above constraints are satisfied[12]. Knowledge of the orbit is important for data analysis purpose. An analytical approximation has also been obtained for the orbits of the TianQin satellites, based on which the response of TianQin to gravitational waves have been calculated[13]. The response allows us to expedite the procedure of simulating the stain data output of the detector with decent accuracy and conduct subsequent investigations on the data analysis techniques for various sources.

Secondly, all the orbits known for geocentric gravitational wave mission have their orientation nearly fixed in space. This can be seen in the many examples studied in[14]. As a result, the telescopes used for inter-satellite laser ranging will periodically point toward the Sun. Varying solar radiation on the telescopes can lead to temperature fluctuation and temperature gradient in the satellites, causing problem for the detection of gravitational waves.

With TianQin, a solution to this problem is made possible by a particular feature of the mission: the "standing" orbital plane. The plane of the TianQin constellation is facing J0806, and the location of the latter is about 4.7° below the ecliptic. As a result, the plane of the TianQin constellation is nearly perpendicular to the ecliptic and it will sweep through Sun only twice a year.

When the plane of the TianQin constellation comes too close to the Sun, there will be times that the telescopes point too close to the direction of the Sun, causing problems for the observation. TianQin adopts a "3-month on + 3-month off" detection scheme (to be further optimized) to cope with the problem. The orbit of the Earth can be partitioned into four sections, each has about 3 months:

- From early June to early September and from early December to early March, sunlight is at large angles with respect to the plane of the TianQin constellation. During such times, the telescopes will be well protected from the Sunlight.
- From early March to early June and from early September to early December, sunlight is at small angles with respect to the plane of the TianQin constellation. During such times, there can be direct sunshine on the telescopes and TianQin will suspend observation.

As such, TianQin solves the problem but pays the price of having shortened observation time.

## 4. The scientific objectives of TianQin

The main gravitational wave sources for TianQin include Galactic compact binaries, massive black hole binary coalescence, extreme mass ratio inspirals, stellar mass black hole inspirals, possible first order phase transition in the early Universe, and possibly some unforeseen sources[8]:

- With Galactic compact binaries, TianQin seeks to study the formation and evolution of compact Galactic binaries, to combine GW+EM observation to obtain comprehensive understanding of the Galactic binary systems.
- With massive black hole binary coalescence, TianQin seeks to discover seed black holes in the early universe, to depict massive black hole growth process, to study the surrounding environment of massive black hole merger, to test the Kerr-ness of the post-merger object, and to test deviation from General Relativity.
- With extreme mass ratio inspirals, TianQin seeks to study the dynamic environment around black holes in the nearby universe, to explore the fundamental nature of gravity and black holes, including: the multipolar structure and Kerr-ness of the central massive object, the beyond-general relativity emission channels, the propagation properties of gravitational waves, and the presence of massive fields around massive black holes.
- With stellar mass black hole inspirals, TianQin seeks to facilitate multi-band and multi-messenger observation, and to enhance parameter estimation accuracy, to provide better understanding of the system as well as the nature of gravity.
- With the waveform of a binary system, TianQin seeks to constrain the parameters that characterize the deviation of modified theories of gravity from general relativity.
- TianQin seeks to detect stochastic gravitational waves background originated from stellar mass black hole mergers or even binary neutron star mergers, and to measure or set limit on cosmic origin stochastic background (e.g., first order phase transitions).

We also expect enhanced science output if there is enough overlap in the operation times of TianQin and LISA[15,16].

## 5. The development of key technologies and research teams

TianQin will rely on high precision intersatellite laser interferometry to detect gravitational waves. Two test masses will be placed inside each of the three TianQin satellites. These test masses will be used as the end points for laser interferometry between the satellites. The ideal situation is that the test masses exactly follow the geodesics determined by the ambient gravitational field. In reality, however, there is environmental effect on the test masses due to electromagnetic force, particle collision and so on. So the variation of distance between the test masses and the satellite

is closely monitored and the information is used to control the satellite to follow the motion of the test masses. For this process to work, one will need high precision inertial sensors, micro-Newton thrusters and a dragfree control mechanism.

For the inertial sensor, a preliminary conceptual design for TianQin has been presented in[1]. TianQin requires that the resolution of the inertial sensor is at the order $10^{-15}\mathrm{m/s^2/Hz^{1/2}}$ in the mHz frequency band.

Our team has started working on inertial sensors since 2000. A space electrostatic accelerometer with a resolution of $4\times10^{-8}\mathrm{m/s^2/Hz^{1/2}}$ and a dynamic range of $10^{-2}$ $\mathrm{m/s^2}$ is being tested and functions well in flight from Nov. 2013 up to now[18]. A second space electrostatic accelerometer with a resolution of $3\times10^{-10}$ $\mathrm{m/s^2/Hz^{1/2}}$ and a dynamic range of $10^{-5}\mathrm{m/s^2}$ has been put to use in space from April to Sep. 2017[19].

For intersatellite laser interferometry, TianQin requires that the displacement measurement noise is at the order $10^{-12}\mathrm{m/Hz^{1/2}}$ in the mHz frequency band. In order to achieve this level of accuracy, we need technologies with laser interferometer (including ultra-stable optical bench, laser, telescopes, and clocks and so on), and ultra-stable temperature control of the satellite platform. A preliminary conceptual design for the space laser interferometry for TianQin has been given in[1].

Our team has started working on intersatellite laser interferometry since 2002. We have built a 10-m prototype of intersatellite laser ranging system in 2010 and a resolution of 3.2 nm has been achieved[20]. An ultra-precise phasemeter has been developed in 2012 and a noise level of $1.2\mu\mathrm{rad/Hz^{1/2}}$ at 1Hz has been achieved[21]. Recently, a novel scheme of intersatellite laser beam acquisition has been developed. The averaged acquisition time is 10 s for a scanning radius of 1 mrad with a success rate of 99%[22].

Apart from that for the key payloads, satellite technology is needed to provide ultra-stable and clean environment for the scientific payload and to form and maintain a highly coordinated constellation throughout the scientific observation period. A team responsible for the satellite/system technology has been assembled in SYSU to study the problems in this direction.

A team responsible for theoretical and data analysis has also been assembled in SYSU.

Apart from the teams at HUST and SYSU, there are many other groups in China that have technology background related to space-based gravitational wave detection. There is an effort to engage all these teams in the work of TianQin.

## 6. Recent progress

In order to support the development of key technologies, we are constructing a few dedicated research facilities and have started flight experiments on TianQin key technologies.

### 6.1. *Dedicated research facilities*

As of present we are constructing three dedicated TianQin research facilities:

- The Payload Research Base, which is responsible for all key technology research and development for the project.
- A laser ranging station, which will be used to develop laser ranging capability to TianQin satellites.
- The Ground Simulation Facility, which is responsible for integrated test and research on the TianQin technologies and prototypes.

The Payload Research Base is consisted of the TianQin Research Building and a cave lab. The TianQin Research Building has about 30 thousand square meters in total area and the cave lab has about 10 thousand square meters in total area. The construction of the Payload Research Base and the laser ranging station has started on the SYSU Zhuhai campus in the end of 2017. The TianQin Research Building will be delivered by the end of 2019. The tunnel of the cave lab will be finished by the end of 2020.

The laser ranging station will be equipped with a 1.2 meter telescope, plus an education and outreach facility. The laser ranging station will be ready in the early part of 2019.

The Ground Simulation Facility is a big effort in the TianQin project. The idea is to have a facility that can simulate as close as possible the various aspects of a space-based gravitational wave mission. The facility will have the capability to simulate space environment, inertial reference, inter-satellite laser interferometry, the formation of TianQin constellation and the process of space-based gravitational wave observation. The facility will also aid in signal abstraction and data analysis. The facility will be located on the SYSU Shenzhen Campus.

### 6.2. *Flight experiments*

There are two space experiment projets going on at the moment:

- Laser ranging to the Chang'E 4 (CE4) relay satellite;
- The TQ-1 experimental satellite.

Laser ranging technology will be used to help tracking the TianQin satellites. In order to bring the needed technology to mature, the TianQin project has planned a lunar laser ranging program, which involves (1) creating new generation corner cube retro-reflectors to be deployed on the surface of Moon or to be carried by high Earth orbit satellites, and (2) upgrading/constructing laser ranging stations on the ground. The CE4 relay satellite (QueQiao) has been launched on May 21, 2018 and has successfully entered a Lissajous orbit around the Earth-Moon L2 point. Our team have created a single large aperture hollow corner cube retro-reflector (CCR) and have installed it on the QueQiao satellite. Our next step is to do laser ranging

experiment to the CCR onboard the QueQiao satellite. As part of the project, the Yunnan Observatory (located in Kunmin, China) has successfully carried out the first lunar laser rang experiment in China early 2018. A new laser ranging station is also being constructed on the SYSU Zhuhai campus and is expected to become available in the spring of 2019.

We are also preparing for the first experimental satellite, TQ-1, on TianQin key technologies. The satellite will be equipped with an inertial sensor reaching the resolution level $10^{-12}\mathrm{m/s^2/Hz^{1/2}}$ at 0.1Hz, a laser interferometer reaching the resolution level $0.1\mathrm{nm/Hz^{1/2}}$ at 0.1Hz. The mission has been approved by the China National Space Administration and is scheduled for launch in late 2019.

## 7. International collaboration

International collaboration is an important aspect of the TianQin project. The effort on the TianQin project is expected to span some 15 years. Due to the long duration of the effort, a core team is necessary to make sure that the project evolves as expected. Currently the core team of TianQin is consisted of two teams, located in two universities in China, Huazhong University of Science and Technology (HUST) and Sun Yat-sen University (SYSU). The team at HUST was formed in 1983 and has grown to more than 300 researchers and students by now. SYSU has established in 2016 a new center dedicated to the TianQin project, the TianQin Research Center for Gravitational Physics. The center has grown to more than 100 researchers and students by now.

The TianQin collaboration has been formally established in the end of 2018 during the fifth international workshop on the TianQin science mission.

Analytic approximation methods in general relativity play a very important role when analyzing the gravitational wave signals recently discovered by the LIGO & Virgo detectors. In this contribution, we present the state-of-the-art and some recent developments in the famous post-Newtonian (PN) or slow-motion approximation, which has successfully computed the equations of motion and the early inspiral phase of compact binary systems. We discuss also some interesting interfaces between the PN and the gravitational self-force (GSF) approach based on black-hole perturbation theory, and between PN and the post-Minkowskian (PM) approximation, namely a non-linearity expansion valid for weak field and possibly fast-moving sources.

*Keywords*: gravitational waves, compact binary systems, post-Newtonian approximation, post-Minkowskian approximation, perturbation theory

## 1. Methods to generate gravitational wave templates

The LIGO & Virgo detectors have opened up a fantastic new avenue in Astronomy with the discovery of gravitational waves (GWs) generated by the orbital motion and merger of binary black hole and neutron star systems.[1,2] This also highlights the crucial role played by analytic approximation methods in general relativity (GR), since they permit an accurate description of the two-body problem in GR, which is of direct use in the data analysis of the detectors.[44]

The most important method in this respect is the post-Newtonian (PN) approximation, which is an expansion when the slowness parameter $\epsilon_{\rm PN} = v/c$ of the compact binary system tends to zero, where $v$ is the relative orbital velocity and $c$ the speed of light. For gravitationally bound systems such as compact binaries on quasi-circular orbits, the PN approximation comes along with the post-Minkowskian (PM) one, namely a non-linearity expansion around the Minkowski background, with small expansion parameter $\gamma_{\rm PM} = Gm/(rc^2)$, where $r$ is the size of the orbit and $m$ the total mass of the source. Indeed, in the bounded case we have $\gamma_{\rm PM} \sim \epsilon^2_{\rm PN}$. However, the most important physical application of the PM approximation is for unbound orbits, when $\gamma_{\rm PN}$ and $\epsilon_{\rm PM}$ are unrelated, *i.e.*, the problem of scattering of ultra-relativistic particles ($\epsilon_{\rm PN} \lesssim 1$) and small deviation angle. The PM approximation is sometimes called the weak-field fast-moving approximation.

Black hole perturbation theory constitutes another large body of analytic approximations in GR. In the context of compact binary systems, this approximation is important, first, for analyzing the post-merger waveform of two black holes (BHs) during the so-called ringdown phase, when the newly formed BH emits quasi-normal mode radiation, and, secondly, for describing the dynamics and

GWs of asymmetric compact binaries, *i.e.*, endowed with an extreme mass ratio, $\nu = m_1 m_2/(m_1+m_2)^2 \ll 1$. In the latter case the perturbation method takes the more suggestive name of gravitational self-force (GSF), since it is concerned with the modifications of the background geometry of the larger BH and of the geodesic motion of the particle, due to the self field generated by the particle itself.

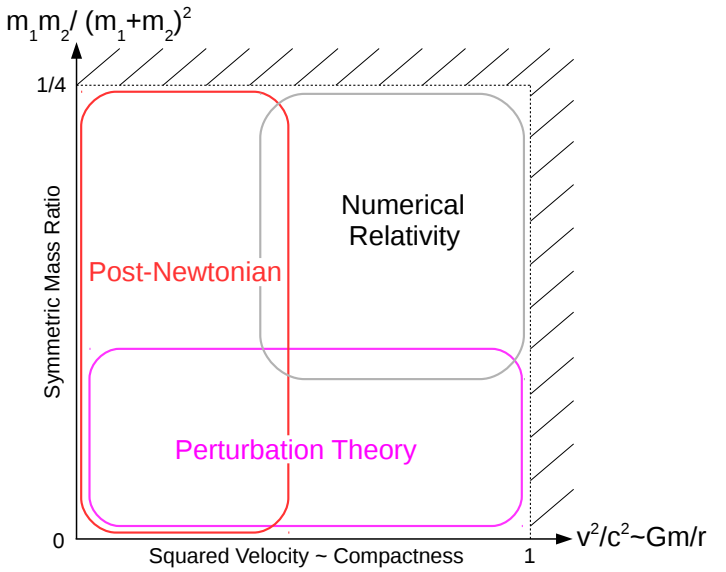

Fig. 1. Analytic approximation and numerical techniques to build GW templates for the compact binary inspiral and merger, depending on the symmetric mass ratio $\nu = m_1 m_2/m^2$ ($m = m_1+m_2$) and the slowness-weak-field parameter $\epsilon_{\rm PN} = v/c \sim \sqrt{Gm/rc^2}$. PN theory and perturbative GSF analysis can be compared in the slow motion weak field regime, $\epsilon_{\rm PN} \ll 1$ thus $r \gg Gm/c^2$, of an extreme mass ratio compact binary, $\nu \ll 1$.

The domains of validity of these approximation methods, together with interesting mutual overlaps, are illustrated in Figs. 1 and 2. Also shown in Fig. 1 is some comparison with numerical relativity (NR), which succeeded at solving the long standing binary black hole challenge.[4,45,93] At first sight it could seem that NR would be able to tackle and solve the complete problem of the inspiral, merger and ringdown for two compact objects. However, in order to monitor the early inspiral of two neutron stars, thousands of orbital cycles have to be computed with high precision. Then the computing times of NR become prohibitively long, and the precision of the NR simulation will never be competitive with that provided by the PN approximation. A fact that is of uttermost importance for building GW templates (and was not *a priori* obvious several years ago[42]), is that the overlap between PN and NR exists and is quite significant. On the other hand, when the

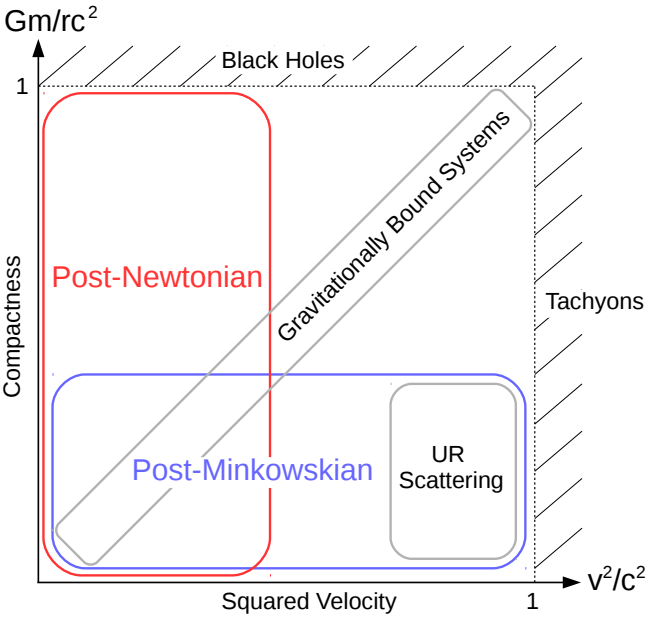

Fig. 2. Comparison between the PN and PM approximations. Gravitationally bound systems such as compact binaries on quasi-circular orbits, stand roughly on the diagonal. For such systems the PM approximation actually reduces to the PN approximation. The PM expansion is a weak-field expansion, defined with no restriction on the slowness parameter $\epsilon_{\rm PN}$, and is mostly relevant in the case of unbound orbits, such as the ultra-relativistic (UR) scattering of two BHs.

mass ratio between the two bodies is extreme, the full NR approach is unfeasible, due to the different length scales corresponding to the very different physical sizes of the compact bodies. We shall discuss in this article the important intersections between PN and GSF as shown in Fig. 1, and between PN and PM, see Fig. 2.

The GW templates are defined as the theoretical prediction from GR, and weighted in the Fourier domain by the detector's spectral density of noise. The templates are cross-correlated with the detector's output, and the correlation builds up when a good match occurs between a particular template and the real signal.[44] This technique is highly sensitive to the phase evolution of the signal, which, in PN templates of compact binary coalescence, is computed from the energy balance between the decay of the binary's energy and (minus) the GW flux.

In principle, as there is a significant overlap between the PN and NR regimes, the templates are obtained by matching together the best PN waveform for the inspiral phase (currently known to order 3.5PN) to a highly accurate numerical waveform for the merger and ringdown phases.[67] For low mass compact binaries, such as double neutron star systems, the detectors are mostly sensitive to the inspiral phase prior to the final coalescence, and the currently known analytical PN templates are accurate

enough for detection, at least when the compact bodies have moderate spins. Thus, the data analysis of neutron star binaries events such as GW170817, is essentially based on the 3.5PN templates.

For larger masses, like BH binary events such as GW150914, the merger occurs at lower frequency, right in the middle of the detector's frequency band. Since only a few orbital cycles before the merger are seen, the match between NR and the PN is not very good and the GW templates are essentially based on the NR results. Nevertheless it is worth pointing out that the mere zeroth-order Newtonian waveform, *i.e.*, based on the Einstein quadrupole formula, gives a reasonably satisfying physical interpretation of the signal even for GW150914!

In practice, for the data analysis of large mass BH binary events, it is important to dispose of analytic rather than numerical templates, since the cross correlations must be performed with many templates associated by many trial parameters (masses and spins). In this case the templates are based on effective analytical methods that interpolate somehow between the initial PN and final NR phases. Two such techniques play a key role in the data analysis of the BH events. One is called the hybrid inspiral-merger-ringdown (IMR or IMR-Phenom) waveform and is constructed by matching together the PN and NR waveforms in an overlapping time interval described phenomenologically.[3] The other technique consists of recasting the real two-body dynamics, as given by PN theory, into a simpler one-body dynamics described in a non perturbative analytic way. The so-called effective-one-body (EOB) waveform obtained in that way extends the domain of validity of the PN approximation (because it is non perturbative) and can therefore be compared and matched to the NR waveform.[43] The IMR and EOB waveforms are extensively used in the LIGO & Virgo data analysis of the recent binary BH events.

## 2. State-of-the-art on equations of motion

The equations of motion (EOM) of a self-gravitating $N$-body system are written in PN like form, up to 4PN order, using one's favorite coordinate system in GR, as

$$\frac{\mathrm{d}\boldsymbol{v}_a}{\mathrm{d}t} = \boldsymbol{A}_a^{\mathrm{N}} + \frac{1}{c^2}\boldsymbol{A}_a^{\mathrm{1PN}} + \frac{1}{c^4}\boldsymbol{A}_a^{\mathrm{2PN}} + \frac{1}{c^5}\boldsymbol{A}_a^{\mathrm{2.5PN}} + \frac{1}{c^6}\boldsymbol{A}_a^{\mathrm{3PN}} + \frac{1}{c^7}\boldsymbol{A}_a^{\mathrm{3.5PN}} + \frac{1}{c^8}\boldsymbol{A}_a^{\mathrm{4PN}} + \mathcal{O}\left(\frac{1}{c^9}\right). \tag{1}$$

The first term is of course, the usual Newtonian acceleration of $N$ "planets",

$$\boldsymbol{A}_a^{\mathrm{N}} = -\sum_{b\neq a}\frac{Gm_b}{r_{ab}^2}\boldsymbol{n}_{ab}\,. \tag{2}$$

The historical works in GR started in the early days of this theory, and solved the problem of the EOM at the 1PN level beyond the Newtonian term.[58,79] This famous Lorentz-Droste-Einstein-Infeld-Hoffmann 1PN correction is fully given as

$$\boldsymbol{A}_a^{\mathrm{1PN}} = -\sum_{b\neq a}\frac{Gm_b}{r_{ab}^2}\boldsymbol{n}_{ab}\Big[v_a^2 + 2v_b^2 - 4(v_a v_b) - \frac{3}{2}(n_{ab}v_b)^2$$

$$- 4\sum_{c\neq a}\frac{Gm_c}{r_{ac}} - \sum_{c\neq b}\frac{Gm_c}{r_{bc}}\left(1-\frac{r_{ab}}{2r_{bc}}(n_{ab}n_{bc})\right)\Big]$$
$$+\sum_{b\neq a}\frac{Gm_b}{r_{ab}^2}\boldsymbol{v}_{ab}\big[4(n_{ab}v_a)-3(n_{ab}v_b)\big] - \frac{7}{2}\sum_{b\neq a}\sum_{c\neq b}\frac{G^2m_bm_c}{r_{ab}r_{bc}^2}\boldsymbol{n}_{bc}\,, \qquad (3)$$

where we denote $\boldsymbol{v}_a = \mathrm{d}\boldsymbol{y}_a/\mathrm{d}t$, $\boldsymbol{v}_{ab} = \boldsymbol{v}_a - \boldsymbol{v}_b$, $r_{ab} = |\boldsymbol{y}_a - \boldsymbol{y}_b|$, $\boldsymbol{n}_{ab} = (\boldsymbol{y}_a - \boldsymbol{y}_b)/r_{ab}$ and the parenthesis indicate the usual Euclidean scalar product, *e.g.* $(n_{ab}v_b) = \boldsymbol{n}_{ab}\cdot\boldsymbol{v}_b$.

Up to the 2PN level the system is *conservative*, *i.e.*, admits the ten invariants associated with the symmetries of the Poincaré group. The first *dissipative* effect appears at the 2.5PN order and features the radiation reaction damping of the system by GW emission. The 2PN and 2.5PN approximations were motivated by the Hulse-Taylor binary pulsar and worked out at the time of its discovery.[33,47,50,72,87,98] Later the motivation for the 3PN EOM came from the development of the LIGO & Virgo detectors and the need of accurate GW templates for inspiralling compact binaries. The 3PN EOM took some time to be fully understood and completed,[23,30,37,51,54,60,69,71,73] together with the relatively easier dissipative 3.5PN term.[70,76,86,88]

Three techniques have been undertaken to obtain the 4PN EOM. One is based on the Arnowitt-Deser-Misner (ADM) Hamiltonian formalism of GR in ADM coordinates,[52,53,74,75] and has led to complete results but for the appearance of one "*ambiguity*" parameter. The second technique is based on the Fokker action of GR in harmonic coordinates,[7–10,83] and has obtained complete results, *i.e.*, free of any ambiguity parameter. The third one is the effective field theory (EFT),[59,61,62,65] which yielded partial results up to now (the terms $\propto G^4$ still being in progress), but is expected to also be free of any ambiguity parameter.[90]

In this section we describe the approach based on the Fokker action in harmonic coordinates. We start with the gravitation-plus-matter action of GR, in which the gravitational piece includes the usual harmonic gauge-fixing term, and the matter term is that of $N$ particles without spins, and with negligible internal structure:

$$S = \frac{c^3}{16\pi G}\int \mathrm{d}^4x\,\sqrt{-g}\Big[R - \frac{1}{2}g_{\mu\nu}\Gamma^\mu\Gamma^\nu\Big] - \sum_{a=1}^{N} m_a c^2\int \mathrm{d}t\,\sqrt{-(g_{\mu\nu})_a\,v_a^\mu v_a^\nu/c^2}\,. \quad (4)$$

Here $\Gamma^\mu = g^{\rho\sigma}\Gamma^\mu_{\rho\sigma}$ and we use, for practical calculations, the Landau-Lifshitz form of the action (*i.e.*, modulo a total divergence).

The Fokker action is obtained when we insert back into (4) an explicit PN solution of the corresponding gauge-fixed Einstein field equations, and given by an explicit functional of the particle's trajectories, *i.e.*,

$$\bar{g}_{\mu\nu}(\mathbf{x},t) = g_{\mu\nu}[\mathbf{x};\boldsymbol{y}_a(t),\boldsymbol{v}_a(t),\cdots]\,. \quad (5)$$

The ellipsis indicate that the metric also depends on accelerations $\boldsymbol{a}_a = \mathrm{d}\boldsymbol{v}_a/\mathrm{d}t$, derivatives of accelerations $\boldsymbol{b}_a = \mathrm{d}\boldsymbol{a}_a/\mathrm{d}t$, *etc.*, since we do not perform any replacements of accelerations when iterating the Einstein field equations, the EOM being

considered off-shell at this stage. Substituting $\bar{g}_{\mu\nu}$ into Eq. (4) defines the Fokker action $S_{\rm F}[\boldsymbol{y}_a, \boldsymbol{v}_a, \cdots]$, and the EOM of the self-gravitating system of particles are obtained as the (generalized Euler-Lagrange) equations

$$\frac{\delta S_{\rm F}}{\delta \boldsymbol{y}_a} = 0\,. \tag{6}$$

Once they have been constructed, the EOM can be order reduced by replacing all the higher-order accelerations by their expressions coming from the lowest-order PN equations. The Fokker action describes only the conservative dynamics, and the dissipative effects have to be added separately in the EOM. Note that the Fokker action is equivalent to the EFT action in the "tree-level" approximation, in which we neglect quantum loops.

An interesting feature of the local (near zone) 4PN dynamics is that there is an imprint of GW tails propagating at infinity. The tails are secondary non-linear waves caused by backscattering of linear waves onto the space-time curvature generated by the total mass $M$ of the source. Part of the effect can be seen as a tail-induced modification of the leading 2.5PN radiation reaction force at the relative 1.5PN order.[16,18,21] However, associated with this dissipative piece, there exists also a conservative effect which thus enters into the 4PN conservative dynamics. Its contribution to the Fokker action reads as[7,52,62,65]

$$S_{\rm F}^{\rm tail} = \frac{G^2 M}{5c^8} \int_{-\infty}^{+\infty} {\rm d}t\, I_{ij}^{(3)}(t) \int_0^{+\infty} {\rm d}\tau \ln\left(\frac{\tau}{\tau_0}\right) \left[I_{ij}^{(4)}(t-\tau) - I_{ij}^{(4)}(t+\tau)\right]. \tag{7}$$

Here $I_{ij} = \sum_a m_a y_a^{\langle i} y_a^{j\rangle}$ is the Newtonian quadrupole moment of the system (the angular brackets refer to the symmetric-trace-free projection), the superscript $(n)$ denotes multiple time derivatives, and $\tau_0$ is an arbitrary constant. To leading order the total mass $M$ reduces to $\sum_a m_a$, but at higher order it should involve the contribution of the gravitational binding energy of the particles. An elegant rewriting of Eq. (7) is with the Hadamard "*Partie finie*" (Pf) integral,

$$S_{\rm F}^{\rm tail} = \frac{G^2 M}{5c^8} \operatorname*{Pf}_{\tau_0} \iint \frac{{\rm d}t\, {\rm d}t'}{|t-t'|} I_{ij}^{(3)}(t)\, I_{ij}^{(3)}(t')\,. \tag{8}$$

Due to this conservative tail contribution, the 4PN dynamics is non-local in time, and this entails subtleties in the derivation of the invariants of motion, which have been recently fully elucidated.[9,41,52,53]

The calculation crucially relies on the systematic use of dimensional regularization (DR), to cure both ultra-violet (UV) divergences due to the model of point particles adopted to describe the compact objects, and infra-red (IR) divergences that start appearing precisely at the 4PN order and are associated with GW tails. We are here borrowing DR from EFT and quantum field theory, and we use it in the classical $N$-body problem as a mean to preserve the diffeomorphism invariance of GR. For this reason we conjecture that DR is the only known regularization technique able to successfully solve the problem of EOM in high PN approximations.

In an initial calculation (valid for two particles, $N = 2$), we used DR for UV divergences but a variant of the Hadamard regularization (HR) for IR divergences.[7,9] Based on some trial calculations, using various types of regularizations, we conjectured that the results of different IR regularizations will physically differ by at most two parameters called ambiguities and denoted $\delta_1$ and $\delta_2$.[9] This finding was in agreement with an earlier suggestion.[53] Modulo unphysical shifts of the trajectories, the two offending ambiguity terms in the Fokker Lagrangian ($S_{\rm F} = \int {\rm d}t L_{\rm F}$) turn out to appear at the difficult $G^4$ level and be of the form

$$\delta L_{\rm F} = \frac{G^4(m_1+m_2)\,m_1^2 m_2^2}{c^8 r_{12}^4}\Big(\delta_1 (n_{12}v_{12})^2 + \delta_2 v_{12}^2\Big)\,. \tag{9}$$

To determine what the values of these ambiguities are we embarked on the DR treatment of the IR divergences. Consider a typical term in the Fokker Lagrangian with non-compact support and generic function $F$, which diverges at infinity. With HR such term is treated as

$$L_{\rm F}^{\rm HR} = \underset{B=0}{\rm FP}\int_{r>\mathcal{R}} {\rm d}^3\mathbf{x}\left(\frac{r}{r_0}\right)^B F(\mathbf{x})\,. \tag{10}$$

Since we focus on IR divergences we consider only the far zone contribution $r > \mathcal{R}$, where $\mathcal{R}$ denotes an arbitrary large radius, typically the inner radius of the wave zone. The Finite Part (FP) operation is closely related to the Hadamard partie finie Pf, and consists of applying analytical continuation in $B \in \mathbb{C}$, expanding the integral when $B$ tends to zero, and keeping only the coefficient of the zero-th power of $B$ in that expansion (discarding any strictly positive or negative power of $B$). On the other hand, with DR the same term is treated as

$$L_{\rm F}^{\rm DR} = \int_{r>\mathcal{R}} \frac{{\rm d}^d\mathbf{x}}{\ell_0^{d-3}}\,F^{(d)}(\mathbf{x})\,, \tag{11}$$

where $F^{(d)}$ is the $d$-dimensional analogue of the generic function $F$ in (10), and where $\ell_0$ is the characteristic length scale associated with DR. We find that the difference between the two prescriptions is given by[8]

$$L_{\rm F}^{\rm DR} - L_{\rm F}^{\rm HR} = \sum_q \left[\frac{1}{(q-1)\varepsilon} - \ln\left(\frac{r_0}{\ell_0}\right)\right]\int {\rm d}\Omega_{2+\varepsilon}\,\varphi_{3,q}^{(\varepsilon)}(\mathbf{n}) + \mathcal{O}(\varepsilon)\,. \tag{12}$$

The functions $\varphi_{p,q}^{(\varepsilon)}$ represent the coefficients of $r^{-p-q\varepsilon}$ (with $p, q \in \mathbb{Z}$) in the expansion of $F^{(d)}$ when $r \to +\infty$ along the direction $\mathbf{n}$. We pose $\varepsilon = d - 3$ and neglect the terms dying with $\varepsilon \to 0$. The angular integration in (12) is over the sphere in $d - 1 = 2 + \varepsilon$ dimensions. Notice that the result (12) depends only on the singular coefficients $\varphi_{3,q}^{(\varepsilon)}$ of the expansion of $F^{(d)}$ at infinity, and that the arbitrary scale $\mathcal{R}$ has disappeared from it.

The formula (12) contains an IR pole $\propto 1/\varepsilon$. In the language of the EFT, this pole comes from the "potential mode" contribution. However, we have also to take into account the 4PN tail effect given by Eq. (8) but in $d$ dimensions. In the EFT language this will correspond to the "radiation" contribution and should

also contain a pole $\propto 1/\varepsilon$, but this time of UV type. Our explicit calculation has shown that the two IR and UV poles exactly cancel out (modulo unphysical shifts of the trajectories),[8,83] in complete agreement with general arguments within the EFT.[90] The 4PN tail term in $d$ dimensions takes the same form as (8) but with the arbitrary scale $\tau_0$ determined by the DR scale $\ell_0$ as

$$\tau_0^{\rm DR} = \frac{2\ell_0}{c\sqrt{4\pi}} \exp\Big[\frac{1}{2\varepsilon} - \frac{1}{2}\gamma_{\rm E} - \frac{41}{60}\Big]\,, \tag{13}$$

with $\gamma_{\rm E}$ denoting the Euler constant, and the UV pole $\propto 1/\varepsilon$ cancelling the IR one in (12). The result (13) has been obtained thanks to a "matching" equation relating the near zone which is the domain of validity of the PN approximation, to the far zone where GW tails propagate. Finally we find that the rational fraction $-\frac{41}{60}$ in (13), is just the one necessary and sufficient to determine the values of the two ambiguity parameters in (9) as

$$\delta_1 = -\frac{2179}{315}\,, \qquad \delta_2 = \frac{192}{35}\,, \tag{14}$$

therefore resolving the problem of ambiguities. The values (14) are consistent with numerical and analytical GSF calculations of the energy and periastron advance for circular orbits in the small mass ratio limit.[8,52,53] Remarkably, the result (13) agrees with that of Galley *et al.*,[65] obtained by means of a diagrammatic evaluation of the tail term in $d$ dimensions with EFT methods. On the other hand, the lack of a consistent matching between the near and far zones in the ADM Hamiltonian formalism,[52,53,74,75] and therefore a complete control of the tail term (8) including the final determination of Eq. (13), forces this formalism to be still plagued by one ambiguity parameter, denoted $C$ in[52].

## 3. State-of-the-art on GW generation

The two basic ingredients in the theoretical PN analysis correspond to the two sides of the energy balance equation obeyed by the binary's orbital frequency and phase. Since the orbit will have circularized by radiation reaction at the time when the signal enters the detectors' bandwidth there is no need to invoke the balance equation for the orbital angular momentum. Thus we just impose

$$\frac{{\rm d}E}{{\rm d}t} = -\mathcal{F}\,. \tag{15}$$

The energy $E$ is nothing but the Noetherian conserved energy $E$ associated with the Fokker Lagrangian computed in the previous section. On the other hand, the GW energy flux $\mathcal{F}$ on the right-hand side is obtained from a GW generation formalism. From Eq. (15) one deduces the time evolution of the binary's orbital frequency $\omega$ and orbital phase $\phi$ by solving

$$\phi = \int \omega\,{\rm d}t = -\int \frac{\omega}{\mathcal{F}}\frac{{\rm d}E}{{\rm d}\omega}\,{\rm d}\omega\,. \tag{16}$$

At the 4.5PN order, for circular orbits, the conserved energy function is given by

$$E = -\frac{m\,\nu c^2 x}{2}\left\{1 + \left(-\frac{3}{4} - \frac{\nu}{12}\right)x + \left(-\frac{27}{8} + \frac{19}{8}\nu - \frac{\nu^2}{24}\right)x^2 \right.$$
$$+ \left(-\frac{675}{64} + \left[\frac{34445}{576} - \frac{205}{96}\pi^2\right]\nu - \frac{155}{96}\nu^2 - \frac{35}{5184}\nu^3\right)x^3$$
$$+ \left(-\frac{3969}{128} + \left[-\frac{123671}{5760} + \frac{9037}{1536}\pi^2 + \frac{896}{15}\gamma_{\rm E} + \frac{448}{15}\ln(16x)\right]\nu\right.$$
$$\left.\left. + \left[-\frac{498449}{3456} + \frac{3157}{576}\pi^2\right]\nu^2 + \frac{301}{1728}\nu^3 + \frac{77}{31104}\nu^4\right)x^4\right\}, \tag{17}$$

where $m = m_1 + m_2$ is the total mass, $\nu = m_1 m_2/m^2$ is the symmetric mass ratio, $\gamma_{\rm E}$ is Euler's constant, and we employ for convenience the PN ordering parameter $x = (\frac{Gm\omega}{c^3})^{2/3}$ defined from the orbital frequency $\omega$ of the circular orbit, and which constitutes an invariant in a large class of coordinate systems. Notice that Eq. (17) is valid up to the 4.5PN order *included*, as there is no term at the 4.5PN order in the conserved energy for circular orbits.

The most complete formula for the GW flux is valid at the 3.5PN order beyond the Einstein quadrupole formula. However, the 4.5PN coefficient is also known,[84] while the 4PN coefficient is in progress. This formula has been obtained by application of a GW generation formalism based on a Multipolar-Post-Minkowskian (MPM) expansion for the external field of an isolated source,[15,20–22] and followed by a matching to the inner (near zone) PN field of that source.[17,19,32,91] The first important step in this computation is the obtention of the multipole moments of the source, $I_{i_1\cdots i_\ell}$ (mass type) and $J_{i_1\cdots i_\ell}$ (current type). The most difficult of these moments (because it necessitates the highest PN precision) is the mass quadrupole moment $I_{i_1 i_2}$, given at 3.5PN order for quasi-circular orbits as

$$I_{i_1 i_2} = m\nu\left(A\,x_{\langle i_1 i_2\rangle} + B\,\frac{r^2}{c^2}v_{\langle i_1 i_2\rangle} + \frac{G^2m^2\nu}{c^5 r}\,C\,x_{\langle i_1}v_{i_2\rangle}\right), \tag{18}$$

where the terms are explicitly given by[38,39]

$$A = 1 + \gamma\left(-\frac{1}{42} - \frac{13}{14}\nu\right) + \gamma^2\left(-\frac{461}{1512} - \frac{18395}{1512}\nu - \frac{241}{1512}\nu^2\right)$$
$$+ \gamma^3\left(\frac{395899}{13200} - \frac{428}{105}\ln\left(\frac{r}{r_0}\right) + \left[\frac{3304319}{166320} - \frac{44}{3}\ln\left(\frac{r}{r'_0}\right)\right]\nu\right.$$
$$\left. + \frac{162539}{16632}\nu^2 + \frac{2351}{33264}\nu^3\right), \tag{19a}$$

$$B = \frac{11}{21} - \frac{11}{7}\nu + \gamma\left(\frac{1607}{378} - \frac{1681}{378}\nu + \frac{229}{378}\nu^2\right)$$
$$+ \gamma^2\left(-\frac{357761}{19800} + \frac{428}{105}\ln\left(\frac{r}{r_0}\right) - \frac{92339}{5544}\nu + \frac{35759}{924}\nu^2 + \frac{457}{5544}\nu^3\right), \tag{19b}$$

$$C = \frac{48}{7} + \gamma\left(-\frac{4096}{315} - \frac{24512}{945}\nu\right). \tag{19c}$$

Here the PN ordering parameter is $\gamma = \frac{Gm}{rc^2}$ where $r$ is the separation distance in harmonic coordinates. Note the two constant scales entering the logarithmic terms at the 3PN order, one being the length scale $r_0$ coming from the MPM algorithm,[20] while the other one $r'_0$ comes from the 3PN EOM in harmonic coordinates.[30]

The second step is the relationship between the multipole moments of the source, and the so-called "radiative" multipole moments parametrizing the observable GW at future null infinity. Such relationship involves in particular the well-known tail effects and their iterations. At the 4.5PN order the radiative mass quadrupole moment $U_{i_1 i_2}$ is related to the mass quadrupole moment of the source $I_{i_1 i_2}$ by

$$\begin{aligned} U_{i_1 i_1}(t) = I^{(2)}_{i_1 i_2}(t) &+ \frac{GM}{c^3}\int_0^{+\infty} \mathrm{d}\tau\, I^{(4)}_{i_1 i_2}(t-\tau)\left[2\ln\left(\frac{c\tau}{2b_0}\right) + \frac{11}{6}\right] \\ &+ \frac{G^2M^2}{c^6}\int_0^{+\infty} \mathrm{d}\tau\, I^{(5)}_{i_1 i_2}(t-\tau)\left[2\ln^2\left(\frac{c\tau}{2b_0}\right) + \frac{11}{3}\ln\left(\frac{c\tau}{2b_0}\right)\right. \\ &\qquad \left. - \frac{214}{105}\ln\left(\frac{c\tau}{2r_0}\right) + \frac{124627}{22050}\right] \\ &+ \frac{G^3M^3}{c^9}\int_0^{+\infty} \mathrm{d}\tau\, I^{(6)}_{i_1 i_2}(t-\tau)\left[\frac{4}{3}\ln^3\left(\frac{c\tau}{2b_0}\right) + \frac{11}{3}\ln^2\left(\frac{c\tau}{2b_0}\right)\right. \\ &\qquad + \frac{124627}{11025}\ln\left(\frac{c\tau}{2b_0}\right) - \frac{428}{105}\ln\left(\frac{c\tau}{2b_0}\right)\ln\left(\frac{c\tau}{2r_0}\right) \\ &\qquad \left. - \frac{1177}{315}\ln\left(\frac{c\tau}{2r_0}\right) + \frac{129268}{33075} + \frac{428}{315}\pi^2\right]. \end{aligned} \tag{20}$$

For simplicity, we have not included here the non-linear memory effect which arises at 2.5PN order,[22,46,102,106] as well as many instantaneous (non-tails) terms, that are relatively easy to compute. The terms at 1.5PN, 3PN and 4.5PN orders shown in (20) correspond to what can rightly be called the "tail", the "tail-of-tail", and the "tail-of-tail-of-tail", respectively.[84] The expression (20) contains still another arbitrary scale $b_0$, parametrizing the coordinate transformation between harmonic coordinates and radiative coordinates. We find that the scale $b_0$ as well as the two previous scales $r_0$ and $r'_0$ in Eq. (18) cleanly cancel out in the GW flux, expressed in terms of the invariant PN parameter $x$, which is finally given by[24–27,31,38–40]

$$\begin{aligned} \mathcal{F} = \frac{32c^5}{5G}\nu^2 x^5 \Bigg\{ &1 + \left(-\frac{1247}{336} - \frac{35}{12}\nu\right)x + 4\pi x^{3/2} \\ &+ \left(-\frac{44711}{9072} + \frac{9271}{504}\nu + \frac{65}{18}\nu^2\right)x^2 + \left(-\frac{8191}{672} - \frac{583}{24}\nu\right)\pi x^{5/2} \\ &+ \left(\frac{6643739519}{69854400} + \frac{16}{3}\pi^2 - \frac{1712}{105}\gamma_{\mathrm{E}} - \frac{856}{105}\ln(16\,x)\right. \\ &\qquad \left. + \left[-\frac{134543}{7776} + \frac{41}{48}\pi^2\right]\nu - \frac{94403}{3024}\nu^2 - \frac{775}{324}\nu^3\right)x^3 \\ &+ \left(-\frac{16285}{504} + \frac{214745}{1728}\nu + \frac{193385}{3024}\nu^2\right)\pi x^{7/2} + F_{4\mathrm{PN}}\,x^4 \end{aligned}$$

$$+\left(\frac{265978667519}{745113600}-\frac{6848}{105}\gamma_{\rm E}-\frac{3424}{105}\ln(16x)+\left[\frac{2062241}{22176}+\frac{41}{12}\pi^2\right]\nu\right.$$
$$\left.-\frac{133112905}{290304}\nu^2-\frac{3719141}{38016}\nu^3\right)\pi x^{9/2}\Bigg\}. \tag{21}$$

This is valid up to 4.5PN order, with the notable exception that the 4PN coefficient, denoted $F_{\rm 4PN}$ in (21), is not yet known. However, from BH perturbation theory we know already the test mass limit of this coefficient, *i.e.*, in the small mass ratio limit $\nu \to 0$:[63,64,96,100,101]

$$F_{\rm 4PN} = -\frac{323105549467}{3178375200}+\frac{232597}{4410}\gamma_{\rm E}-\frac{1369}{126}\pi^2$$
$$+\frac{39931}{294}\ln 2-\frac{47385}{1568}\ln 3+\frac{232597}{8820}\ln x+\mathcal{O}(\nu)\,. \tag{22}$$

Of course, this nice result from BH perturbation theory will have to be confirmed by PN theory, which will also be able to provide the mass ratio corrections $\mathcal{O}(\nu)$.

## 4. PN theory versus GSF theory

The conservative dynamics and GWs of compact binary systems in the extreme mass ratio limit, is the realm of the perturbative gravitational self force (GSF) theory.[55,57,66,85,92,94] For the conservative dynamics, a comparison between GSF computations and traditional PN calculations was initiated some years ago,[56] applying to systems that are at once slowy moving and with extreme mass ratio, see the overlap region between PN and perturbation theory in Fig. 1. In recent years the possibility for this comparison has been dramatically extended. Such progress is due in large part due to high precision numerical and analytical computations from a self force perspective,[12–14,80–82,95,99] and to extensive analytical computations within the PN approximation.[28,29,34,35,77]

For a particle moving on an exact circular orbit around a Schwarzschild BH (neglecting radiation reaction), one disposes of a very interesting quantity, which is the invariant associated with the helical Killing symmetry, appropriate for exact circular orbits.[56] This invariant, denoted $u_1^t$, is defined by

$$u_1^\mu = u_1^t\, K_1^\mu\,, \tag{23}$$

where $u_1^\mu$ is the normalized four-velocity of the particle 1 (with mass $m_1 \ll m_2$), $K^\mu$ is the helical Killing vector (HKV) and $K_1^\mu$ the HKV at the location of the particle. Adopting a coordinate system in which the HKV reads $K^\mu\partial_\mu = \partial_t + \omega\,\partial_\varphi$, where $\omega$ is the orbital frequency of the circular orbit, the invariant reduces to the time component of the four-velocity hence its name $u_1^t$, and we have

$$u_1^t = \frac{1}{z_1} = \left[-(g_{\mu\nu})_1\frac{v_1^\mu v_1^\nu}{c^2}\right]^{-1/2}, \tag{24}$$

where $(g_{\mu\nu})_1$ is the metric evaluated at the particle's location, following a certain regularization (here $v_1^\mu = {\rm d}y_1^\mu/{\rm d}t$ denotes the coordinate velocity, *i.e.*, $y_1^0 = ct$ and

$v_1^0 = c$). The inverse of $u_1^t$ appears to be a redshift $z_1$, and sometimes $u_1^t$ itself is called the redshift. [For a generalization of the notion of redshift to eccentric orbits, see[5].] In the exact test mass limit $\nu = 0$, the invariant reduces to the one appropriate to a Schwarzschild BH,

$$u^t_{\rm Schw} = \frac{1}{\sqrt{1-3y}}\,, \tag{25}$$

where $y = (\frac{Gm_2\omega}{c^3})^{2/3}$ is the frequency-related PN parameter associated with the larger BH mass $m_2$. The GSF part is then defined as the coefficient of the mass ratio correction beyond Eq. (25),

$$u^t_1 = u^t_{\rm Schw} + \nu\, u^t_{\rm GSF} + \mathcal{O}(\nu^2)\,. \tag{26}$$

It is clear that with this approximation the symmetric mass ratio $\nu = \frac{m_1 m_2}{m^2}$ can be replaced by the ordinary mass ratio $q = \frac{m_1}{m_2}$. In the PN approximation, the GSF part of the redshift factor appears to be an infinite PN series of the type

$$u^t_{\rm GSF} = \sum_{j=0}^{+\infty} \big(\alpha_j + \beta_j \ln y\big)\, y^{j+1}\,. \tag{27}$$

We have included terms linear in the logarithm of $y$, but we neglect (just for this discussion) the higher powers of $\ln y$, that occur at large PN orders. Recall that the most general structure of the PN expansion involves any (integer) powers of the logarithm, $\sim (\ln y)^k y^{j+1}$.[20]

Here we report the results that have been obtained so far using the "traditional" PN approach. Recall that the PN method heavily relies on dimensional regularization (DR) to treat both UV and IR divergences, see Sec. 2. Another feature of the PN calculation is that it requires a machinery of tails and related non-linear effects, see Eq. 20. In the PN approach one computes $u_1^t$ as a redshift in harmonic coordinates using Eq. (24), and evaluates the metric at the particle's location with DR. In that way the GSF redshift has been obtained up to 4PN order as[12,28,29,77]

$$\begin{aligned} u^t_{\rm GSF} =& -y - 2y^2 - 5y^3 + \left(-\frac{121}{3} + \frac{41}{32}\pi^2\right) y^4 \\ &+ \left(-\frac{1157}{15} + \frac{677}{512}\pi^2 - \frac{128}{5}\gamma_{\rm E} - \frac{64}{5}\ln(16y)\right) y^5 + \mathcal{O}(y^6)\,. \end{aligned} \tag{28}$$

In addition, PN theory has been able to fix the logarithmic term at the 5PN order, which is due to a subdominant tail effect, namely

$$\beta_5 = \frac{956}{105}\,, \tag{29}$$

while the coefficient $\alpha_5$ is known only from GSF methods but has not yet been checked with PN theory. The results (28)–(29) are in full agreement with direct GSF computations. This constitutes a strong confirmation of the adequation of DR for traditional PN calculations, as well as of the procedure of subtraction of the singular field which is employed by GSF theory.

A feature of the PN expansion of the redshift factor at high orders is the appearance of half-integral PN approximations, say $\frac{n}{2}$PN. At first sight these terms sound surprising because the dynamics is purely conservative (exactly circular orbits with a HKV), and we are used to the fact that half-integral PN approximations like 2.5PN are associated with dissipative radiation reaction. The existence of such terms in the conservative redshift factor, starting at 5.5PN order, has been pointed out with numerical GSF methods,[99] and later it was proved that these terms originate from iterated non-linear tail effects, called "tails-of-tails".[34,35] The leading 5.5PN, next-to-leading 6.5PN and next-to-next-to-leading 7.5PN coefficients in this category have been found to be

$$\alpha_{\frac{11}{2}} = -\frac{13696}{525}\pi\,, \qquad \alpha_{\frac{13}{2}} = \frac{81077}{3675}\pi\,, \qquad \alpha_{\frac{15}{2}} = \frac{82561159}{467775}\pi\,, \tag{30}$$

while the corresponding $\beta_j$'s are zero. Notice that 7.5PN is arguably the highest order ever reached by traditional PN methods. Again the PN results (30) are in full agreement with numerical and analytical results derived by GSF methods.

## 5. PN versus PM

The post-Minkowskian approximation has been developed in many pionneering works.[6,11,68,89,104,105] Notably the gravitational scattering angle of two relativistic particles has been obtained up to 2PM order (quadratic in $G$).[103] Recently there has been a renewal of interest in the PM approximation. Ledvinka, Schäfer and Bičák[78] obtained a closed-form expression for the Hamiltonian of $N$ particles in the 1PM approximation, and new works appeared on the gravitational scattering angle and the link between the PM expansion and the EOB formalism.[48,49] Here we outline our own contribution,[36] which concerns the comparison between 1PM and the recent 4PN calculation of the EOM of compact binaries. The Fig. 2 showed the domain of validity of the PM approximation *versus* that of the PN expansion.

At the 1PM approximation the field equations for a system of $N$ particles in harmonic coordinates, deduced from the gauge-fixed action (4), read

$$\Box h^{\mu\nu} = \frac{16\pi G}{c^2}\sum_{a=1}^{N} m_a \int_{-\infty}^{+\infty} \mathrm{d}\tau_a\, u_a^\mu u_a^\nu \delta^{(4)}(x - y_a)\,, \tag{31}$$

where $\Box$ denotes the flat space-time d'Alembertian operator, $\delta^{(4)}$ is the four-dimensional Dirac function, $y_a^\mu$ are the particle's worldlines and $u_a^\mu = \mathrm{d}y_a^\mu/(c\mathrm{d}\tau_a)$ their normalized four-velocities, with the special-relativistic proper time $\mathrm{d}\tau_a = \sqrt{-\eta_{\mu\nu}\mathrm{d}y_a^\mu \mathrm{d}y_a^\nu/c^2}$. We solve Eqs. (31) by means of the standard Lienard-Wiechert procedure. Adopting a parametrization by the coordinate time $t$, *i.e.*, such that $y_a^\mu = (ct, \boldsymbol{y}_a)$, the retarded time $t_a^{\mathrm{ret}}$ on the trajectory $a$ associated with the propagation from $a$ to the field point $x^\mu = (ct, \mathbf{x})$, is given by the implicit retardation equation $t_a^{\mathrm{ret}} = t - r_a^{\mathrm{ret}}/c$ with $r_a^{\mathrm{ret}} = |\mathbf{x} - \boldsymbol{y}_a(t_a^{\mathrm{ret}})|$. The solution of (31) is then

$$h^{\mu\nu}(x) = -\frac{4G}{c^2}\sum_a \frac{m_a\, u_a^\mu u_a^\nu}{r_a^{\mathrm{ret}}\,(ku)_a^{\mathrm{ret}}}\,, \tag{32}$$

where $k_a^\mu = [x^\mu - y_a^\mu(t_a^{\rm ret})]/r_a^{\rm ret} = (1, \boldsymbol{n}_a^{\rm ret})$ is the Minkowski null vector between $a$ and the field point, $(ku)_a^{\rm ret} = k_\mu^a u_a^\mu = \gamma_a(-1 + \boldsymbol{n}_a^{\rm ret}\cdot\boldsymbol{v}_a/c)$ is the usual redshift factor, with $\gamma_a = u_a^0$ the Lorentz factor and $v_a^\mu = cu_a^\mu/\gamma_a = (c, \boldsymbol{v}_a)$, the velocities being computed at the retarded time $t_a^{\rm ret}$.

However, we repeatedly use the fact that the accelerations are of order $G$ and therefore their contributions in (32) will be of order $G^2$, hence negligible with the 1PM approximation. Thus, we are allowed to assume that the four velocities $u_a^\mu$ and Lorentz factors $\gamma_a$ are constant. Furthermore, neglecting terms of order $G^2$, we can solve the retardation equation to get the retarded time $t_a^{\rm ret}$, the distance $r_a^{\rm ret}$, and the direction $\boldsymbol{n}_a^{\rm ret}$, in terms of their current values at time $t$, *i.e.*, the "instantaneous" distance $r_a = |\mathbf{x} - \boldsymbol{y}_a(t)|$ and direction $\boldsymbol{n}_a = [\mathbf{x} - \boldsymbol{y}_a(t)]/r_a$. In this way, Eq. (32) becomes equivalent to

$$h^{\mu\nu} = -\frac{4G}{c^2}\sum_a \frac{m_a\, u_a^\mu u_a^\nu}{r_a\sqrt{1+(n_a u_a)^2}}\,, \tag{33}$$

which is valid at any field point except at the singular locations of the particles. Nevertheless, we can easily extend its validity to the particles by using a self-field regularization. For this purpose, it is sufficient to discard the self-field contribution from the sum of particles. An explicit self-field regularization process yielding the same result was implemented in [6]. Therefore, at the location of particle $a$, we have

$$(h^{\mu\nu})_a = -\frac{4G}{c^2}\sum_{b\neq a} \frac{m_b\, u_b^\mu u_b^\nu}{r_{ab}^2\big[1+(n_{ab}u_b)^2\big]^{1/2}}\,, \tag{34}$$

where the sum runs over all particles except $a$, we pose $r_{ab} = |\boldsymbol{y}_a - \boldsymbol{y}_b|$, and denote $n_{ab}^0 = 0$ and $n_{ab}^i = [\boldsymbol{y}_a - \boldsymbol{y}_b]/r_{ab}$.

The EOM of the particles is just the geodesic equation, computed at the linearized order consistent with our approximation, and we obtain

$$\begin{aligned}\frac{{\rm d}u_a^\mu}{{\rm d}\tau_a} = -\frac{1}{c}\sum_{b\neq a}\frac{Gm_b}{r_{ab}^2\big[1+(n_{ab}u_b)^2\big]^{3/2}}\bigg[&(2\epsilon_{ab}^2-1)n_{ab}^\mu \\ &+(2\epsilon_{ab}^2+1)\Big(-(n_{ab}u_a)+\epsilon_{ab}(n_{ab}u_b)\Big)u_a^\mu + \Big(4\epsilon_{ab}(n_{ab}u_a)-(2\epsilon_{ab}^2+1)(n_{ab}u_b)\Big)u_b^\mu\bigg]\,.\end{aligned} \tag{35}$$

We use $\epsilon_{ab} = -(u_a u_b)$ as a shorthand notation. Equivalently we have also the non-covariant form of the EOM (*i.e.*, PN like form), in which we introduce the ordinary velocities and accelerations and the relevant Lorentz factors (with $\boldsymbol{v}_{ab} = \boldsymbol{v}_a - \boldsymbol{v}_b$),

$$\begin{aligned}\frac{{\rm d}\boldsymbol{v}_a}{{\rm d}t} = -\gamma_a^{-2}\sum_{b\neq a}\frac{Gm_b}{r_{ab}^2\big[1+\gamma_b^2(n_{ab}v_b)^2/c^2\big]^{3/2}}\bigg[&(2\epsilon_{ab}^2-1)\boldsymbol{n}_{ab} \\ &+\gamma_b\Big(-4\epsilon_{ab}\gamma_a(n_{ab}v_a)+(2\epsilon_{ab}^2+1)\gamma_b(n_{ab}v_b)\Big)\frac{\boldsymbol{v}_{ab}}{c^2}\bigg]\,.\end{aligned} \tag{36}$$

At the 1PM order the EOM are conservative, thus admit conserved integrals of energy, angular momentum and linear momentum. Indeed, the radiation reaction

dissipative effects are at least 2PM, *i.e.*, second order in $G$. The closed-form expression of the energy through 1PM reads $E = \sum_a m_a c^2 \gamma_a + V$, with the first term being the usual special-relativistic expression and

$$V = G \sum_a \sum_{b \neq a} \frac{m_a m_b}{r_{ab} \left[1 + \gamma_b^2 (n_{ab} v_b)^2 / c^2\right]^{1/2}} \left\{ \gamma_a \left( 2\epsilon_{ab}^2 + 1 - 4 \frac{\gamma_b}{\gamma_a} \epsilon_{ab} \right) \right. \tag{37}$$
$$\left. + \frac{\gamma_b^2}{\gamma_a} \left(2\epsilon_{ab}^2 - 1\right) \frac{\dot{r}_{ab}(n_{ab} v_b) - (v_{ab} v_b)}{\left(v_{ab}^2 - \dot{r}_{ab}^2\right) \left[1 + \gamma_b^2 (n_{ab} v_b)^2 / c^2\right] + \frac{\gamma_b^2}{c^2} \left(\dot{r}_{ab}(n_{ab} v_b) - (v_{ab} v_b)\right)^2} \right\}.$$

We have verified[36] that Eqs. (36) and (37) perfectly reproduce the PN results in harmonic coordinates, in the case of two particles ($N = 2$) at the linear order in $G$ and up to the 4PN order.[8,10]

Next we consider the Lagrangian associated with the EOM (35)–(36), for any $N$, in harmonic coordinates. The Lagrangian will be given by the special-relativistic expression plus terms of order $G$, and again, we neglect higher-order terms in $G$. In PN theory, it is known that the Lagrangian in harmonic coordinates is a *generalized* one, depending not only on positions and velocities $\boldsymbol{y}_a, \boldsymbol{v}_a$ but also on accelerations $\boldsymbol{a}_a = \mathrm{d}\boldsymbol{v}_a/\mathrm{d}t$.[50] Such accelerations are contained in terms at least linear in $G$, so that, replacing the accelerations by the EOM would yield negligible terms of order $G^2$ at least. However, it is not allowed to replace accelerations in a Lagrangian while remaining in the same coordinate system. Such replacement is equivalent to a shift in the particles' trajectories (or so-called "contact" transformation), *i.e.*, the new Lagrangian is physically equivalent to the original one but written in a different coordinate system.[97] Furthermore, by employing the technique of double-zero (or multiple-zero) terms, it is sufficient to consider a Lagrangian that is linear in accelerations (since the procedure can work for any PN order, and is thus formally valid at the 1PM order). Therefore, we look for a Lagrangian of the form

$$L\big[y, v, a\big] = -\sum_a \frac{m_a c^2}{\gamma_a} + \lambda + \sum_a q_a^i a_a^i \,. \tag{38}$$

We symbolize the functional dependence by $L[y, v, a] \equiv L[\{\boldsymbol{y}_a, \boldsymbol{v}_a, \boldsymbol{a}_a\}]$. The terms $\lambda$ and $q_a^i$ are of order $G$ and depend only on positions and velocities, *i.e.*, $\lambda[y, v]$ and $q_a^i[y, v]$. Denoting by $p_a^i$ and $q_a^i$ the conjugate momenta associated with the positions $y_a^i$ and velocities $v_a^i$, *i.e.*,

$$p_a^i = \frac{\delta L}{\delta v_a^i} = \frac{\partial L}{\partial v_a^i} - \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial a_a^i}\right), \tag{39a}$$

$$q_a^i = \frac{\delta L}{\delta a_a^i} = \frac{\partial L}{\partial a_a^i}, \tag{39b}$$

the EOM take the ordinary Euler-Lagrange form

$$\frac{\mathrm{d}p_a^i}{\mathrm{d}t} = \frac{\partial L}{\partial y_a^i}, \tag{40}$$

while the conserved energy $E$ is given by the generalized Legendre transformation

$$E = \sum_a \Big( p_a^i v_a^i + q_a^i a_a^i \Big) - L \,. \tag{41}$$

In both (40) and (41) we are allowed to replace the accelerations by the EOM. For instance, the term $q_a^i a_a^i$ in $E$ will be second-order in $G$ and can be neglected at 1PM order. With (38) we obtain the EOM

$$f_a^i = \frac{\delta \lambda}{\delta y_a^i} + \ddot{q}_a^i \,, \tag{42}$$

where $f_a^i = m_a \frac{\mathrm{d}}{\mathrm{d}t}(\gamma_a v_a^i)$ and $\frac{\delta \lambda}{\delta y_a^i} = \frac{\partial \lambda}{\partial y_a^i} - \frac{\mathrm{d}}{\mathrm{d}t}(\frac{\partial \lambda}{\partial v_a^i})$, and the dots refer to time derivatives. The potential $V$ (such that $E = \sum_a m_a c^2 \gamma_a + V$) reads

$$V = \sum_a v_a^i \frac{\partial \lambda}{\partial v_a^i} - \lambda - \sum_a v_a^i \dot{q}_a^i \,. \tag{43}$$

The left-hand sides of (42) and (43) are known from Eqs. (35)–(36) and (37). However, the two equations are not independent, since $f_a^i$ and $V$ satisfy the constraint

$$\frac{\mathrm{d}V}{\mathrm{d}t} + \sum_a v_a^i f_a^i = 0 \,. \tag{44}$$

In order to find $L$, our strategy is to determine first a particular Lagrangian $\hat{L}$, characterized by $(\hat{\lambda}, \hat{q}_a^i)$, such that the conjugate momenta $\hat{q}_a^i$ obey

$$\sum_a v_a^i \hat{q}_a^i = 0 \,. \tag{45}$$

To order $G$, the same equation is also satisfied by the time derivative $\dot{\hat{q}}_a^i$. Therefore, for the particular solution $(\hat{\lambda}, \hat{q}_a^i)$, the equation (43) reduces to an ordinary Legendre transformation,

$$V = \sum_a v_a^i \frac{\partial \hat{\lambda}}{\partial v_a^i} - \hat{\lambda} \,. \tag{46}$$

To determine $\hat{\lambda}$, we note that the potential $V$ given by (41) reduces in the limit $c \to +\infty$ to the Newtonian approximation, namely $V = U + \mathcal{O}(1/c^2)$ where

$$U = -\sum_{a<b} \frac{G m_a m_b}{r_{ab}} \,. \tag{47}$$

If we subtract its Newtonian limit $U$ to $V$, we get a quantity which tends to zero when $c \to +\infty$ like $\mathcal{O}(1/c^2)$. Then, it is straightforward to show that a well-behaved solution of Eq. (46) is

$$\hat{\lambda} = -U + \frac{1}{c} \int_c^{+\infty} \mathrm{d}s \left[ V\Big( \boldsymbol{y}_a, \frac{\boldsymbol{v}_a}{s} \Big) - U(\boldsymbol{y}_a) \right] . \tag{48}$$

Namely, we have to insert into Eq. (37) all the relevant factors $c$ and make the replacement of $c$ by $s$, then integrate over the "speed of light" $s$ from the physical value $c$ up to infinity. The bound $s \to +\infty$ of the integral corresponds to the

Newtonian limit and we see from the definition of the Newtonian potential (47) that the integral is convergent. The first term in Eq. (48) represents the Newtonian approximation with the correct minus sign for a Lagrangian, and the integral represents formally the complete series of PN corrections, but resummed in the PM approximation. The result (48) can be rewritten in a simpler way as the Hadamard "partie finie" (Pf) of the integral, in the same sense as was used in Eq. (8), for taking care of the divergence at infinity:

$$\hat{\lambda} = \mathrm{Pf}\,\frac{1}{c}\int_{c}^{+\infty} \mathrm{d}s\, V\Big(\boldsymbol{y}_a, \frac{\boldsymbol{v}_a}{s}\Big)\,. \tag{49}$$

For this very simple type of divergence $\sim s^0 + \mathcal{O}(s^{-2})$ the Pf does not depend on an arbitrary constant, unlike in (8). The expressions (48)–(49) give a particular solution of the equation (43) but we still have to adjust $\hat{q}_a^i$ in order to satisfy the EOM, see (42). Thus, we look for $\hat{q}_a^i$ satisfying

$$\ddot{\hat{q}}_a^i = f_a^i - \frac{\delta\hat{\lambda}}{\delta y_a^i}\,, \tag{50}$$

where the right-hand side is known. To order $G$ we have been able to integrate twice this relation to determine $\hat{q}_a^i$, and that solution automatically satisfies the constraint (45) by virtue of (44).

Finally we have found a particular Lagrangian $(\hat{\lambda}, \hat{q}_a^i)$. Now the general solution $(\lambda, q_a^i)$ can be obtained by adding an arbitrary total time-derivative $\mathrm{d}F/\mathrm{d}t$, where $F$ is a function of the positions $y_a^i$ and velocities $v_a^i$. Hence the general solution (for the class of harmonic-coordinate Lagrangians that are linear in accelerations) reads

$$\lambda = \hat{\lambda} + \sum_a v_a^i \frac{\partial F}{\partial y_a^i}\,, \tag{51a}$$

$$q_a^i = \hat{q}_a^i + \frac{\partial F}{\partial v_a^i}\,. \tag{51b}$$

At 1PM order the Lagrangian in harmonic coordinates irreducibly depends on accelerations, *i.e.*, it is impossible to determine $F$ such that $q_a^i = 0$. However, we know that the accelerations in a Lagrangian can be eliminated by appropriate shifts of the trajectories. In fact, it can be shown that the particular solution $\hat{\lambda}$ found in (48)–(49) represents an ordinary Lagrangian which is physically equivalent but expressed in some shifted (non harmonic) variables.[36]

Given the complicated structure of $V$ in Eq. (37), we could not find a closed form expression for the 1PM harmonic coordinate Lagrangian in the general case. However, we could easily work out the integral (48) in the PN approximation $c \to +\infty$ to any order. We start from the known 4PN expansion of the potential $V$ following from (37), and explicitly perform the integration (48) term by term, to obtain the corresponding 4PN expansion of $\hat{\lambda}$. Then, we derive the coefficient of accelerations $\hat{q}_a^i$ at 4PN order, see[36] for details. Finally, we find a unique total

time-derivative, with some function $F_{\rm PN}$ given in the form of a PN expansion, so that the Lagrangian satisfyingly agrees up to order $G$ with the published 4PN Lagrangian.[8,10] Furthermore, we have pushed the analysis to the next order and obtained all the terms of order $G$ in the harmonic coordinates Lagrangian up to the 5PN order.[36]

In another application, we worked out the case of equal masses for which it is possible to find a closed form expression for the Lagrangian, and we have verified that the associated Hamiltonian differs from the one obtained by Ledvinka, Schäfer and Bičák[78] in the ADM Hamiltonian by a mere canonical transformation.

# DAMPE and its latest results

Fabio Gargano on behalf of the DAMPE Collaboration

*Istituto Nazionale di Fisica Nucleare (INFN) Sezione di Bari, I-70125 Bari, Italy*
*E-mail: fabio.gargano@ba.infn.it*

Dark Matter Particle Explorer (DAMPE), the first Chinese astronomical satellite, was launched into a Sun-synchronous orbit at an altitude of about 500 km on 17 December 2015. DAMPE is a high-energy particle detector optimized for observations of cosmic ray electrons and gamma-rays up to about 10 TeV. The on-orbit performance of the detector, the calibration, and the latest results on cosmic rays and gamma-rays of DAMPE will be presented.

*Keywords*: Astro-particle; Cosmic-rays; Space Mission; Gamma-ray astronomy

## 1. Introduction

The DArk Matter Particle Explorer (DAMPE)[1] is a particle detector launched on 17 December 2015 in a Sun-synchronous orbit at a 500 km altitude. Its main scientific goals are the study of cosmic-rays, namely electrons, photons, protons and nuclei; the observation of gamma-rays from astrophysical sources; the search for dark matter signatures, for electromagnetic counterparts of gravitational waves or neutrinos and for exotic particles. DAMPE has been designed to detect particles with energy from some GeV up to tens of TeV with an energy resolution $\leq 1.5\%$ at 100 GeV for electromagnetic showers, an accurate angular resolution $\leq 0.1^\circ$ at 100 GeV for gamma-rays and a field of view of 1 sr.

## 2. The DAMPE instrument

DAMPE is composed by four sub-detectors (Figure 1): a Plastic Scintillator Detector (PSD), a Silicon-Tungsten Tracker (STK), a BGO Calorimeter (CALO) and a Neutron Detector (NUD). The PSD has two tasks: to work as a veto for charged particles and to measure the charge number $Z$ of incident high-energy particles. It is made by two layers of staggered scintillator bars in orthogonal arrangements, providing information on the $x$ and $y$ coordinates. The STK is devoted to reconstruct the particle tracks and to convert photons. It consists of 12 position-sensitive silicon detector planes (6 for the $x$-, 6 for the $y$-coordinate); 3 layers of tungsten, each 1 mm thick, are between the silicon planes 2, 3, 4 and 5 to enhance the conversion probability of gamma rays into electron-positron pairs. The BGO calorimeter is used to measure the energy deposition of incident particles and to reconstruct the electromagnetic shower profile. It is composed of 308 BGO crystal bars optically isolated from each other and arranged in 14 layers of 22 bars each; the bars of a layer are orthogonal to those of the adjacent one, to reconstruct the shower in the $xz$ and $yz$ views. The total depth of the calorimeter is 32 radiation lengths and 1.6 nuclear interaction lengths. The last sub-detector is the NUD, made of four

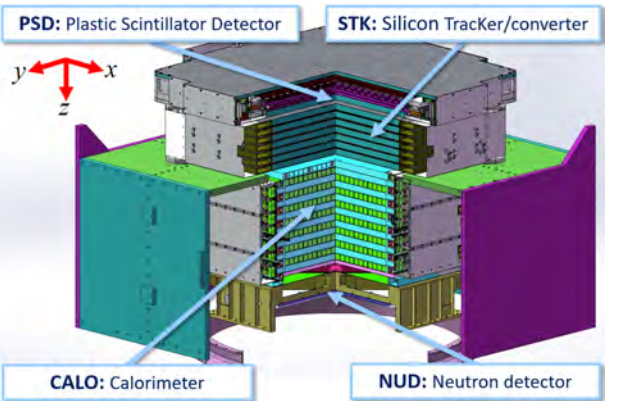

Fig. 1. The DAMPE instrument.

boron-loaded plastic scintillators. It is used to improve overall hadron identification efficiency.

### 2.1. *The Plastic Scintillation array Detector (PSD)*

The main purpose of the PSD is to provide charged-particle background rejection for the gamma-ray detection and to measure the absolute value of the charge (hereafter Z) of incident high-energy particles in a wide range (i.e., $Z \leq 26$). Therefore high detection efficiency, large dynamic range, and good charge resolution are required for charged particle detection of PSD.

The PSD has an active area of $82.5 \times 82.5\text{cm}^2$, which is larger than the on-axis cross-section of other subdetectors of DAMPE. The PSD consists of 82 plastic scintillators bars (EJ-200 produced by Eljen) arranged in two planes, each with a double layer configuration. Each bar is 88.4cm long with a $2.81.0\text{cm}^2$ cross-section; the signals are read out by two Hamamatsu R4443 Photomultiplier Tubes (PMTs) coupled to the ends of each scintillator bar.

The bars in the top plane are perpendicular to those in the bottom plane. The bars of the two layers of a plane are staggered by 0.8cm, allowing full coverage of the detector with the active area of scintillators without any gap. As the efficiency of a single layer is $\geq 0.95$, the PSD provides an overall efficiency $\geq 0.9975$ for charged particles. The segmented structure of the PSD allows suppressing the spurious veto signals due to the "backsplash effect", which can lead to a misidentification of gamma rays as charged particles.

Since the PSD is used to identify cosmic-ray nuclei from helium to iron ($Z = 26$), a wide dynamic range extending up to $\sim 1400$ times the energy deposition of a minimum ionizing particle (MIP) is required. To cover such a broad range with good energy resolution, a double dynode readout scheme for each PMT has been

implemented. Signals from the dynode with high gain cover the range from 0.1 MIPs to 40 MIPs, while those from the dynode with low gain cover the range from 4 MIPs to 1600 MIPs; the overlap region can be used for cross-calibration. The dynode signals are coupled to the VA160 ASIC chip developed by IDEAS. This chip integrates the charge sensitive preamplifier, the shaper and the holding circuit. The performance of the PSD has been tested with the relativistic heavy ion beams at CERN. In this test, the primary Argon beam of 40 GeV/n was sent onto a 40 mm polyethylene target, and the secondary fragments with A/Z = 2 were selected by beam magnets, thus allowing to study the PSD response to all the stable nuclei with Z = 2/18. Fig. 2 shows the reconstructed charge spectra for different ions ($Z \geq 2$) from one PSD module within the beam spot. In this figure, the Helium contribution has been removed for clarity (the He fraction is much higher than that of other ion species). The signals from both sides of each module are used (geometric mean) and the quenching effect has been corrected based on the ion response from the same test.

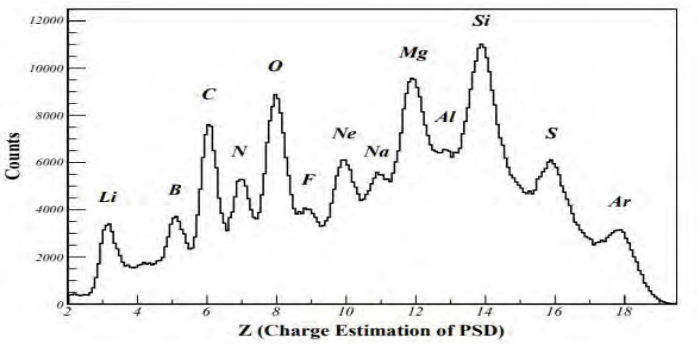

Fig. 2. Reconstructed charge spectra of PSD for nuclei with A/Z = 2, generated by a 40 GeV/n 40Ar beam. The helium peak has been removed for clarity.

### 2.2. *The Silicon-Tungsten tracKer-converter (STK)*

The DAMPE STK is designed to accomplish the following tasks: precise particle track reconstruction with a resolution better than 80 $\mu$m for most of the incident angles, measurement of the electrical charge of incoming cosmic rays, and photon conversion to electron-positron pairs.

It is composed of six position-sensitive double (X and Y) planes of silicon detectors with a total area of about $7m^2$. Multiple thin tungsten layers have been inserted in the tracker structure in order to enhance the photon conversion rate while keeping negligible multiple scattering of electron/positron pairs (above $\sim$ 5 GeV). The total thickness of STK corresponds to about one radiation length, mainly due to

the tungsten layers. The STK detector is equipped with a total of 768 single-sided AC-coupled silicon microstrip detectors (SSD). Four SSDs are assembled together with a wire bonded strip-to-strip connection to form a silicon detector ladder. The total strip length along a ladder is about 37cm. The ladders are glued on the seven support trays to form the 12 STK silicon layers. Each silicon layer consists of 16 ladders. The silicon ladders on the bottom surface of each tray are placed orthogonally with respect to the ones of the top surface of the lower tray, in order to measure the X-Y coordinates of the incident particles. The silicon microstrip sensors produced by Hamamatsu Photonics have a size of $95 \times 95 \times 0.32$ mm$^3$ and each SSD is segmented in 768 strips. The strips are 48 $\mu$m wide and 93.196 mm long with a pitch of 121 $\mu$m.

The signal shaping and amplification is performed by six VA140 ASIC chips (produced by IDEAS)

The ions charge identification power of STK was evaluated with a dedicated test conducted on single ladder unit at CERN with a lead beam. The particle charge can be identified by looking at the mean value of the signal associated with the track. Due to the non-linearity of the VAs above a signal of 200 fC, the identification of ions above Oxygen with the STK becomes non-trivial and on-going work is under preparation to improve the charge identification power (see Fig. 3).

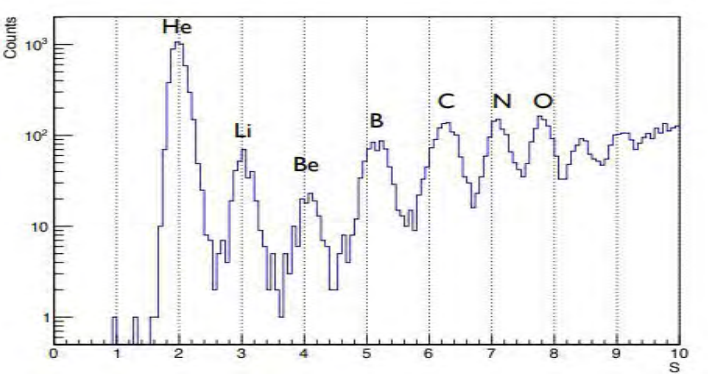

Fig. 3. STK signal mean distribution for nuclei produced by a lead beam on target, after removing Z=1 particles. The signal mean, with current reconstruction procedures, allows for the identification of ions until Oxygen.

### 2.3. *The BGO calorimeter (BGO)*

The BGO calorimeter onboard DAMPE has three primary purposes: (1) measuring the energy deposition of incident particles; (2) imaging the 3D profile (both longitudinal and transverse) of the shower development, and provide electron/hadron discrimination; (3) providing the level 0 trigger for the DAMPE data acquisition

system. Each crystal is readout by two Hamamatsu R5610A-01 PMTs mounted on both ends (named S0 and S1, respectively): the left/right light asymmetry provides a measurement of the position of the energy deposit along the bar. The signals are read out from three different dynodes (dy2, dy5, dy8), thus allowing to cover a very large dynamic range of energy deposition, The PMTs are coupled to the crystals with optical filters, which attenuate the scintillation light produced in the BGO. The filter on S1 has a 5× attenuation factor with respect to the one on S0. The signals are sent to VA160 chip which is composed of a charge sensitive pre-amplifier, a CR-RC shaping amplifier and a sample-hold circuit. The ground calibration of BGO has been performed using both the data collected in a beam test campaign at CERN and cosmic ray data collected from ground. The calibration procedure includes the measurement of the pedestals, the evaluation of the calibration constants from the MIP peaks, the evaluation of the dynode ratios, and the measurement of the bar attenuation lengths.

The data shown in the figure was obtained during the beam test campaigns performed at CERN. The linearity of reconstructed energy is better than 1%, and the energy resolution is better than 1.2% at the energies above 100 GeV (see Fig. 4).

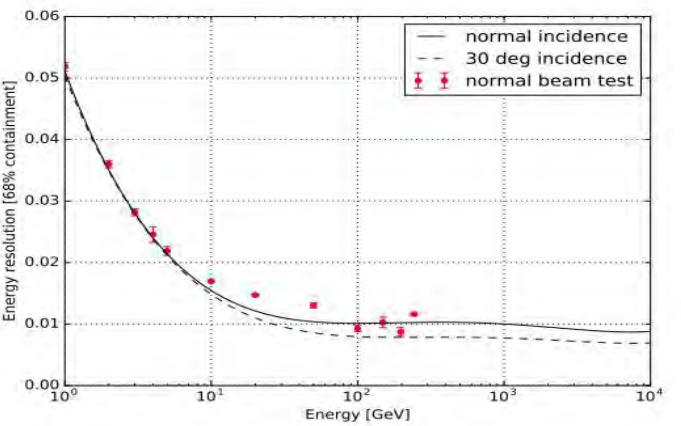

Fig. 4. Energy resolution for gamma rays and electrons/positrons at normal incidence (solid line) and at 30° off-axis angle (dashed line). DAMPE beam test results (with electrons) are over-plotted

### 2.4. *The NeUtron Detector (NUD)*

The main purpose of the NUD is to perform electron/hadron identification using the neutrons produced in hadronic showers initiated in the BGO calorimeter. In fact, for given initial particle energy, the neutron content of a hadronic shower is expected to be one order of magnitude larger than that of an electromagnetic shower. Once

the neutrons are created, they are quickly thermalized in the BGO calorimeter, and the total neutron activity over a few microseconds is measured by NUD.

It consists of four $30 \times 30 \times 1.0\text{cm}^3$ blocks of boron-loaded plastic scintillator (Eljen Technologies EJ-254), with 5% boron concentration by weight which has the natural $^{10}B$ abundance of 20%. Each scintillator is wrapped with a layer of aluminum film for photon reflection, anchored in aluminum alloy framework by silicone rubber.

The scintillators are embedded with wavelength shift fibers for optical transmission in order to reduce the fluorescence attenuation and increase photon collection efficiency, and then the signals are read out by corner-on Hamamatsu R5610A-01 PMTs.

Preliminary estimates, based on on-orbit calibration data, show that a rejection power is $\sim 12.5$ for incoming particles with BGO energy deposit above 800 GeV.

## 3. On-orbit performance

### 3.1. *Trigger rate*

The on-orbit trigger rate depends on the flux of the cosmic rays. It is lower in the equatorial regions but higher in the polar ones due to the Earth's magnetic field bending effect.

Four different triggers have been implemented: Unbiased trigger, MIP trigger, High Energy trigger and Low Energy trigger. They are "OR-ed" to generate the global trigger signal for the detector.

The Unbiased trigger requires signals in the two top BGO layers exceeding a low threshold of ∼0.4MIPs in each hit BGO bar. The MIP trigger aims to select particles crossing all the BGO layers. The High Energy trigger selects events with energy depositions in the top four BGO layers exceeding a high threshold of ∼10MIPs in each hit BGO Bar. The Low Energy trigger is similar to the High Energy one, but with a lower threshold of ∼2MIPs. A periodic signal of 100 Hz is also implemented in the trigger board for pedestal calibration.

The Unbiased, MIP and Low Energy triggers are pre-scaled with the ratios of 512 : 1, 4 : 1, 8 : 1, respectively, when the satellite is in the low latitude region ($\pm 20°$). At high latitudes, the MIP trigger is disabled and the pre-scaler ratios of Unbiased and Low Energy triggers are set to 2048 : 1 and 64 : 1, respectively.

The expected average rate of global triggers is about 70 Hz in flight (the rate of High Energy triggers is 50 Hz, the rate of Unbiased triggers is about 2.5 Hz) (see Fig. 5 and 6)

The DAQ systems work in an "event by event" mode, and a 3 ms time interval is set to acquire each event so that the dead time is fixed to 3 ms as a consequence.

About 15 GB of raw and control data are transmitted to ground each day and, after off-line processing, 85 GB of reconstructed data is produced. The yearly data production is 35 TB.

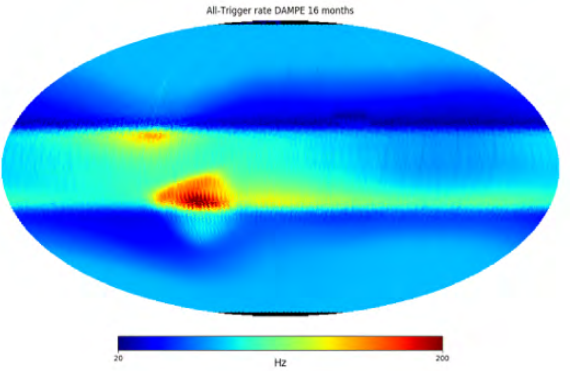

Fig. 5. All trigger rate. It is evident the effect of the pre-scaling at $\pm 20^{\circ}$ and the South Atlantic Anomaly.

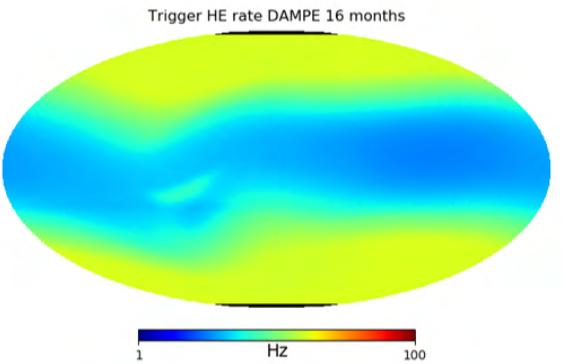

Fig. 6. High Energy trigger rate

### 3.2. *STK Alignment*

The position resolution of the STK silicon sensors is better than 70 $\mu$m. At the same time, the construction precision of the mechanical assembly of STK is about 100 $\mu$m. To maximally profit from the position resolution capabilities of the silicon detectors, alignment parameters are introduced to correct for shifts and rotations of each silicon sensor with respect to its position in the nominal instrument design. Alignment corrections are calculated based on the data and then used in the reconstruction procedure to correct the coordinates of particle hits.

Given the mechanical stability of the tracker structure and the limited temperature variation of the detector, the alignment parameters are updated every two weeks to ensure optimal tracking performance. We estimate the effective position resolution for protons in the x and y internal tracker planes, after the alignment procedure is applied, to be $47\pm2$ $\mu$m for events arriving at normal incidence ($\leq 10^{\circ}$), $41\pm2$ $\mu$m for intermediate inclinations and $45\pm3$ $\mu$m at high incidence angles ($\geq 45^{\circ}$) (see Fig. 7).

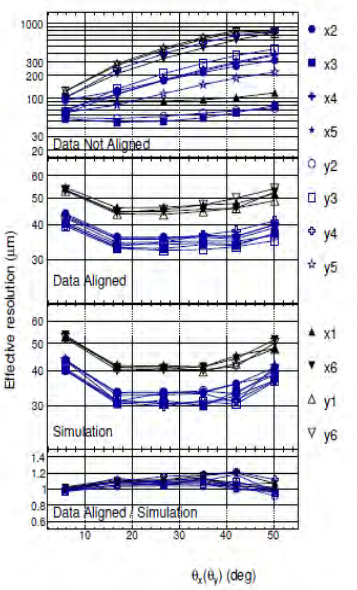

Fig. 7. Alignment results for different STK planes and comparison with simulation.

### 3.3. *Absolute energy calibration*

A method to determine the absolute energy scale of DAMPE has been developed within the Collaboration[2]. In fact, cosmic-ray electrons and positrons below a certain rigidity are bent back to space by the Earth's magnetic field and this causes a clear cutoff in their spectrum. This cutoff was calculated using the geomagnetic field model IGRF-12[3] and back-tracking the particle trajectories in the magnetic field, yielding a value of about 13 GeV, which was compared with the measured cutoff in the interval of McIlwain $L$ parameter between 1.0 and 1.14. A correction factor of 1.2% to be applied to DAMPE data was obtained (Fig. 8).

For a complete review of the on-orbit calibration of all the sub detectors please refer to[12].

## 4. Measurement of the all-electron spectrum

The behavior of the spectrum of the cosmic electrons and positrons (CREs) at very high energies is related to some of the most relevant questions of physics and astrophysics[4,5], and its study is one of the main goals of DAMPE, that can extend its measurements up to about 10 TeV with an acceptance of 0.3 $m^2$sr and an energy resolution of $\sim$1% for energies above 100 GeV.

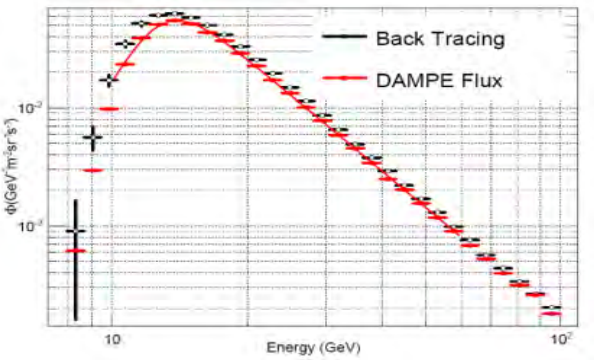

Fig. 8. Energy calibration: the geomagnetic cutoff (left) and its stability over time (right).

To study CREs, the particle identification (PID) and the separation from protons are crucial and can be carried out in several ways, based on the sub-detectors response and on the event topology. In our main analysis, a dedicated parameter, called $\zeta$, was computed from the lateral shower development size and the energy deposition in the last layer of the BGO. Its capability to discriminate electrons from protons was validated with beam tests at CERN: for 90% electron efficiency, the hadron background is ∼2% at 1 TeV and ∼10% at 5 TeV. Other PID strategies have been investigated within the Collaboration: for example, machine learning algorithms and neural networks showed to be very effective and are currently used in new analyses.

The CRE spectrum (Fig. 9) has been measured by DAMPE from about 20 GeV up to about 5 TeV[6]. The main feature is a spectral break at ∼1 TeV, so a smoothly broken power law, with $\gamma$ varying from 3.1 to 3.9, fits DAMPE data. The next step is to improve the statistics and search for spectral structures that may be related to possible sources such as nearby pulsars, or dark matter.

## 5. Measurement of cosmic protons and nuclei spectra

Among DAMPE's tasks, the measurement of the charge of the incident cosmic rays plays a relevant role. The scientific goal is to improve the direct measurement of the cosmic rays spectrum from a few GeV up to 100 TeV — a region that is poorly investigated — thanks to the very good calorimetric and geometric characteristics of the instrument. The capabilities of the PSD and the STK to measure the charge of ions nuclei have been evaluated and tuned with a beam test campaign at the CERN SPS, in which many tests have been performed with Lead and Argon beams that produced ion fragments with a wide range of charge number $Z$. Once in orbit, the PSD has measured the charge from protons to Iron ions with a resolution ranging from 0.2 to 0.4, while the STK has measured the charge from protons to Oxygen ions. Fig. 10 shows the cosmic rays charge spectrum after two years of on-orbit data taking[13].

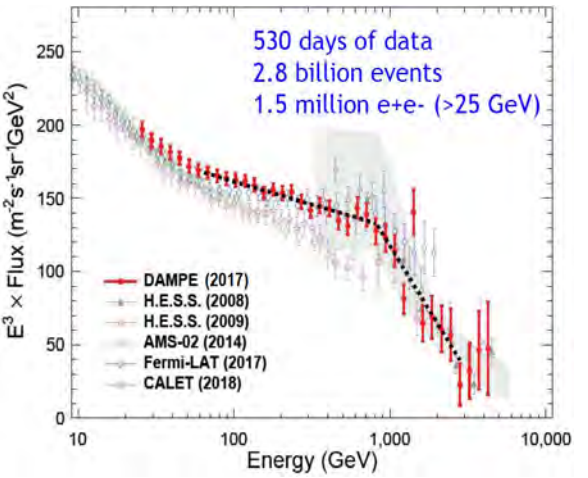

Fig. 9. The all-electron spectrum measured by DAMPE, compared with results by HESS[7,8], AMS-02[9], Fermi[10] and CALET[11].

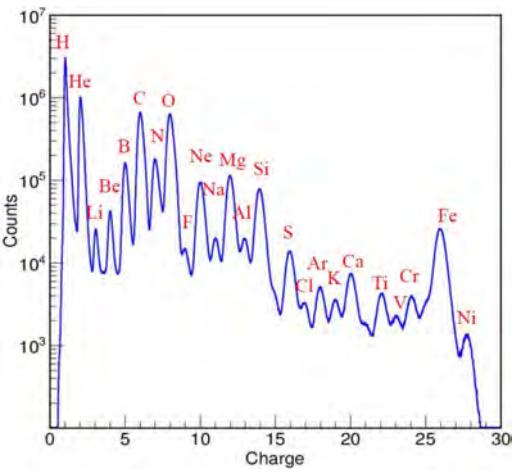

Fig. 10. The cosmic rays charge spectrum measured by DAMPE after two years of data taking.

Also, the fluxes of protons and Helium ions (Fig. 11) as a function of the kinetic energy are being measured. The preliminary results show good agreement with the PAMELA[14] and AMS-02[15] data for $E - k < 200$ GeV. With the accumulation of data, the region from 1 TeV up to 100 TeV is being analyzed by DAMPE with high precision and new results are expected soon.

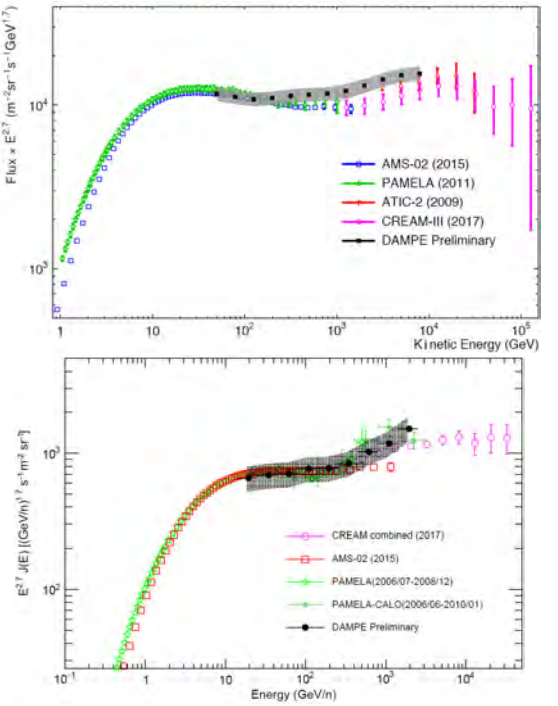

Fig. 11. The preliminary fluxes of CR protons (left) and Helium (right) measured by DAMPE, compared with previous results by PAMELA [14], AMS-02 [15], ATIC-2 [16] and CREAM [17]. The error bars represent statistical errors and the grey bands show the systematic errors.

## 6. Photons

DAMPE is also able to detect high-energy cosmic gamma rays. The photon selection is a challenging task since the background of charged particles has fluxes much higher than the galactic gamma-ray emission: the minimum rejection power required at 100 GeV is $10^5$ for protons and $10^3$ for electrons. The rejection techniques are based on the event topology. Protons are mainly suppressed using the PSD response and the shower profile in the BGO calorimeter, with a contribution from the NUD, while electrons are mainly rejected using the PSD response and the first plane of the STK. Also, innovative procedures, like neural networks and "random forest" classifiers [19], are under test and show excellent particle identification performance. An average number of 150 photons is identified daily by DAMPE. The major sources are resolved with a good angular resolution and their positions agree with those measured by the Fermi-LAT.

DAMPE can also observe the time behavior of variable sources. For instance, Fig. 12 shows the phase profile of the Geminga pulsar while Fig. 13 shows the short-term variability of the CTA 102 blazar.

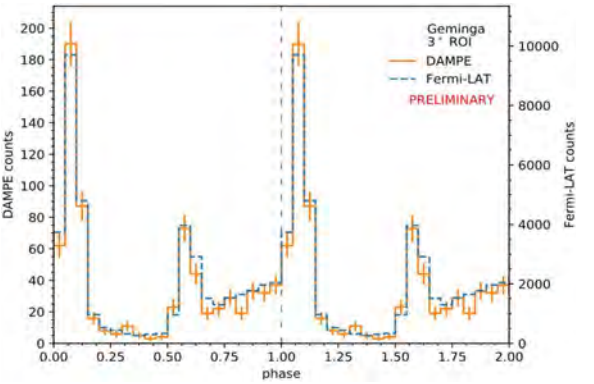

Fig. 12. Phase profile of the Geminga pulsar, compared with Fermi[18].

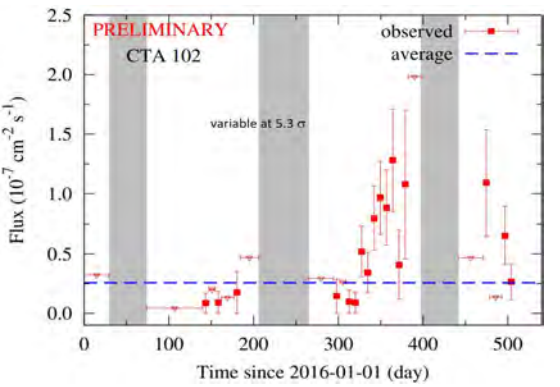

Fig. 13. Short-term variations in the gamma-ray emission of the CTA 102 blazar[20].

Finally, DAMPE participates to the multi-messenger observation of high-energy cosmic phenomena: for example, it has observed the extragalactic source TXS 0506+056 which is the possible origin of the 290 TeV muon neutrino detected by IceCube in September 2017[21].

## 7. Summary

DAMPE is working extremely well since December 2015. Its geometric factor is about 0.3 $m^2$sr for electrons, its Si-W tracker reaches a 40 $\mu$m spatial resolution and a 0.15° angular resolution and its 32 $X-0$ deep BGO calorimeter provides, at energies above 100 GeV, ∼1% energy resolution for cosmic gamma rays and ∼40% for hadrons. Absolute energy calibration is performed using the geomagnetic cutoff.

The all-electron spectrum has been precisely measured up to TeV energies and a spectral break has been directly measured at ∼1 TeV; improved precision of

this spectrum may shed light on nearby sources, anisotropies, dark matter. Proton, Helium and nuclei measurements are ongoing with good preliminary results. Photon detection capability has been assessed; more statistics are being collected to profit the excellent energy resolution at high energy.

## Acknowledgments

The DAMPE mission is founded by the strategic priority science and technology projects in space science of the Chinese Academy of Sciences XDA04040000 and XDA04040400. In China it is supported by the National Key R&D Program 2016YFA0400200, the National Basic Research Program 2013CB837000, the NSFC grants 11525313, 11622327, XDB23040000, 11273070, 11303096, 11303105, 11303106, 11303107, 11673075, U1531126, U1631111 and the 100 Talents Program of Chinese Academy of Sciences. In Europe, the activities are supported by the Italian National Institute for Nuclear Physics (INFN), the Italian University and Research Ministry (MIUR), the Swiss National Science Foundation (SNSF) and the University of Geneva.

Binary driven hypernova (BdHN) models long gamma-ray burst (GRBs) as occurring in the binary systems involving a carbon-oxygen core ($CO_{core}$) and a companion neutron star (NS) or a black hole (BH). This model, first proposed in 2012, succeeds and improves upon the fireshell model and the induced gravitational collapse (IGC) paradigm. After nearly a decade of development, the BdHN model has reached a nearly complete structure, giving explanation to all the observables of long bursts into its theoretical framework, and has given a refined classification of long GRBs according to the original properties of the progenitors. In this article, we present a summary of the BdHN model and the physical processes at work in each of the envisaged Episodes during its occurrence and lifetime, duly contextualized in the framework of GRB observations.

*Keywords*: MG15 Proceedings; High-energy Astrophysics; Gamma-ray Burst; Binary Driven Hypernova.

## 1. Introduction

| Class | Type | Number | *In-state* | *Out-state* | $E_{p,i}$ (MeV) | $E_{iso}$ (erg) | $E_{iso,Gev}$ (erg) |
|---|---|---|---|---|---|---|---|
| Binary Driven | I | 329 | $CO_{core}$-NS | $\nu$NS-BH | $\sim 0.2$–$2$ | $\sim 10^{52}$–$10^{54}$ | $\gtrsim 10^{52}$ |
| Hypernova | II | (30) | $CO_{core}$-NS | $\nu$NS-NS | $\sim 0.01$–$0.2$ | $\sim 10^{50}$–$10^{52}$ | – |
| (BdHN) | III | (19) | $CO_{core}$-NS | $\nu$NS-NS | $\sim 0.01$ | $\sim 10^{48}$–$10^{50}$ | – |
| | IV | 5 | $CO_{core}$-BH | $\nu$NS-BH | $\gtrsim 2$ | $> 10^{54}$ | $\gtrsim 10^{53}$ |

GRBs occur in binary systems of two main classes, binary driven hypernovae (BdHNe) and binary mergers (BMs), observationally corresponding to long and short GRBs. In BdHNe, the long GRB is generated by a type Ic SN explosion of an evolved star occurring in presence of a close-by NS or BH companion. This article is dedicated to the BdHN systems. In BMs, the short GRB is generated from the merger of two compact stars, mostly from the NS-NS systems, and for low energetic short GRBs, the binary white dwarfs could be the progenitors, see Rueda et al. [19,20] and references therein.

The progenitor of a BdHN is a binary system composed of a carbon-oxygen core ($CO_{core}$) and a magnetized neutron star (NS) companion in a tight orbit (period of the order of a few minutes). In some cases, the companion might be a stellar-mass BH (see below). We focus here on the more frequent case of a NS companion. At the end of its thermonuclear evolution, the iron core of the pre-SN star (the $CO_{core}$) undergoes gravitational collapse, forming a new NS (hereafter $\nu$NS) at the SN centre. In the $\nu$NS formation process, a strong shockwave of kinetic energy $\sim 10^{51}$ erg expands outward and when it emerges (SN breakout) expels the $CO_{core}$ outer layers as the SN ejecta. Part of the ejecta is subsequently accreted onto the companion NS and also onto the $\nu$NS by fallback. There are different possible fates for the NS due to the hypercritical accretion process [1,2,4]. For short binary periods ($\lesssim 5$ min), the NS reaches the critical mass for gravitational collapse and forms a BH. We call this subclass BdHN of type I (BdHN I). Thus, a BdHN I leads to a new binary composed of a $\nu$NS originated by the SN, and a BH originated by the collapse of the NS companion. For longer binary periods, the hypercritical accretion onto the NS is not sufficient to bring it to the critical mass, and a more massive NS (MNS) is formed. This subclass is named BdHN of type II (BdHN II). A BdHN II leads to a new binary composed of a $\nu$NS and a massive NS. For very long binary periods, the accretion energy is significantly lower than the above types, and only the hypernova is observed. We call this subclass of sources of type III (BdHN III). In addition, we have BdHN type IV (BdHN IV) for the progenitors of a $CO_{core}$ and a companion BH, and it leads to a new binary of NS and BH.

Having given the physical picture and the classifications of BdHNe, we will present in the following sections the theory and associated observables of the BdHNe. The BdHN starts from the final evolution of the binary stars, including the SN and the accretion of the SN ejecta onto the companion star, to the formation of BH and the particle acceleration mechanisms processing therein, then to the generated relativistic outflow propagates and interacts with the SN ejecta and the interstellar medium (ISM) giving rise to the emissions.

## 2. Binary Accretion

For the binary accretion and the forming of BH, we refer to the theoretical work of Becerra et al. [1–4], Cipolletta et al. [6], Fryer et al. [7,8], Rueda & Ruffini [15] and the observational papers of Izzo et al. [9,10], Ruffini et al. [26,34], Wang et al. [37].

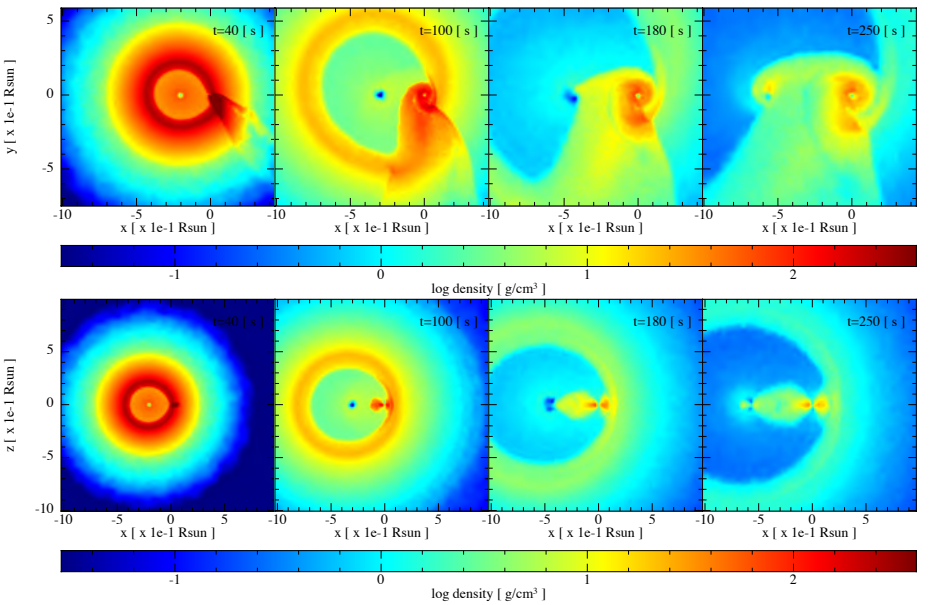

Fig. 1. Snapshot of the SPH simulation of the binary accretion. The initial binary system consists of a $\mathrm{CO}_{rmcore}$ ($M_{rmzams} = 25M_{\odot}$) and an NS ($2M_{\odot}$) with an initial orbital period of about 5 min. The upper panel shows the mass density on the equatorial plane of the binary at different times of the simulation, while the lower panel corresponds to the plane orthogonal to the equator. At $t = 40$ s, particles captured by NS can be seen forming a kind of tail behind them, then these particles form a circle around NS, and at $t = 100$ s a thick disk is observed. At $t = 180$ s, NS starts to accrete the surrounding matters. After about one initial orbital period, at $t = 250$ s, a disk-like structure has formed around the two stars. This figure is cited from Becerra et al. [3].

Rueda & Ruffini [15] has been the first article to consider accretion of SN ejecta onto a very close-by companion star of the binary period of minutes, and it gave the physical picture and the theoretical architectures of a simple one-dimensional model that calculates the Bondi-Hoyle-Lyttleton hypercritical accretion rate. Fryer et al. [8] numerically simulated for the first time the BdHN hypercritical accretion. Following the collapse of the $CO_{\rm core}$ of forming an SN, of which the ejecta falling onto the Bondi-Hoyle surface of the companion with an accretion rate $> 10^{-2}\mathrm{M}_{\odot}\ \mathrm{s}^{-1}$, these one-dimensional numerical simulations give the density and the velocity profiles till the NS reaches the critical mass of BH in tens or hundreds of seconds. Becerra et al. [2] went one step further performing two-dimensional numerical simulations and incorporating angular momentum transport from the SN ejecta to the NS of hypercritical accretion. Those simulation show that under some conditions outflow is necessarily formed because of the excess of angular momentum. Fryer et al. [7] demonstrated that most BdHN with tight orbits (i.e. BdHN I) remain bound after the explosion and accretion, even when a large fraction of mass (over half of the total binary mass) is lost, and a large kick velocity is induced. Becerra et al. [1] performed the first three-dimensional numerical simulations of the BdHNe process,

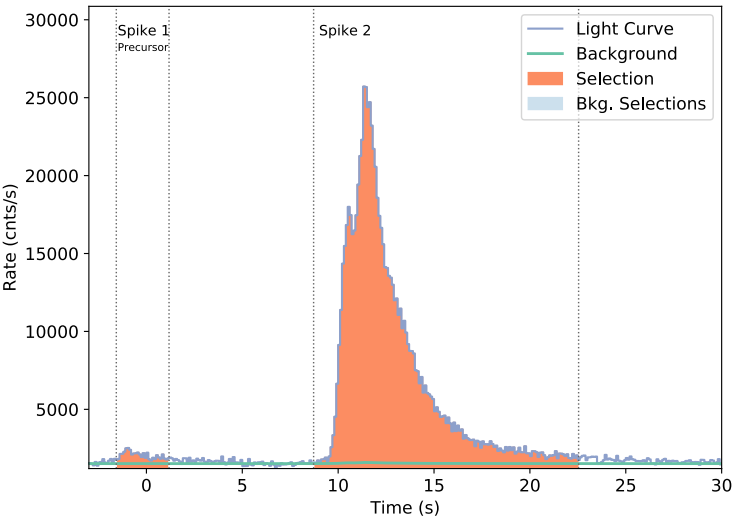

Fig. 2. Light curve of prompt emission of GRB 180728A observed by Fermi-GBM. It contains two pulses. The first pulse ranges from −1.57 s to1.18 s. The second pulse rises at 8.72 s, peaks at 11.50 s, and fades at 22.54 s. This figure is quoted from [37].

which were further upgraded and improved in Becerra et al. [3] via smoothed-particle-hydrodynamics (SPH) simulations, see e.g. in figure 1. A wide selection of initial parameters and several NS equations of state have been there tested. It was there evaluated the outcome of the NS and the $\nu$NS after the hypercritical accretion, namely whether they reach or not the mass-shedding limit, or gravitationally collapses to a BH, or become a more massive and fast-spinning NS. The development of accretion theory and simulations has led to clarifying the physical processes below the Bondi radius: the dominant pressure is supported by the random pressure of the infalling matter, the magnetic pressure is negligible. Such a pressure provides a very high temperature of 1–10 MeV, generating a large abundance of neutrinos and photons. The photons are trapped within the inflowing material, as its diffusion velocity is slower than the inflow velocity. The escape of neutrinos takes away most gravitational energy from the accreted flow, allowing the hypercritical accretion to continue for a given period of time. Becerra et al. [4] further investigated the neutrino flavour oscillations that occur during the propagation of neutrinos emitted from the surface of a neutron star. The final neutrino flow is composed of $\sim 55\%$ ($\sim$62%) of $\sim$ MeV electronic neutrinos for the normal (inverted) neutrino mass hierarchy. In addition, Cipolletta et al. [6] present the numerical calculation and give useful fitting formulas for the location, binding energy and angular momentum of the last stable orbit of test particles around rotating NSs in full general relativity. The results

of this work allows to estimate in full general relativity the amount of energy and angular transferred by the accreting matter to an accreting, rotating NS.

Let us now dive into one specific example. GRB 180728A well demonstrates the binary accretion scenario by its two pulses in the prompt emission[37], see figure 2. At a given time, the $CO_{core}$ collapses, forms a $\nu$NS, and produces an SN explosion. A powerful shockwave is generated and emerges from the SN ejecta. A typical SN shockwave carries $\sim 10^{51}$ erg of kinetic energy, which is partially converted into electromagnetic radiation with an efficiency of $\sim 10\%$. Thus, the energy of $\sim 10^{50}$ erg is consistent with the total energy of the first pulse, which lasts $\sim 2$ s and contains $\sim 8 \times 10^{49}$ erg in keV-MeV photons. The second pulse rises at $\sim 10$ s and subsides at $\sim 10$ s, with a luminosity $\sim 2 \times 51$ erg s$^{-1}$. The distance of the binary separation can be estimated by the delay time between these two pulses, i.e. $\sim 10$ s. Because of the SN ejecta front shell moves at $\sim 0.1c$, we estimate the distance of the binary separation to be about $3 \times 10^{10}$ cm. By given the binary separation and some typical initial parameters, our simulation shows the total mass accreted is $\sim 10^{-2}\ M_\odot$, most of the mass is accreted in $\sim 10$ s with an accretion rate of $\sim 10^{-3}\ M_\odot$ s$^{-1}$. These results are consistent with the second pulse whose total energy is $\sim 10^{51}$ erg, considering an increase in efficiency of $\sim 10\%$, and the luminosity of $\sim 10^{50}$ erg s$^{-1}$ in 10 s duration. The spectrum of the second pulse contains a thermal component which again hints the action of the accretion process. A time-resolved analysis of the thermal component suggests that a mildly relativistic source is expanding and radiating. This radiation is interpreted as an adiabatic expansion heat outflow from the accretion region. The Rayleigh-Taylor convective instability plays a role in the initial accretion phase, driving matter out of the accreting NS with a final velocity of the order of the speed of light. As the matter expands and cools, the temperature evolution from the theory is again consistent with the observations. This kind of thermal emission of BdHN was first found in[9,10]. GRB 180728A offers a good example of BdHN II, and for BdHN I, which has a tighter binary separation, see also the case of GRB 130427A as an example[26,37].

## 3. The Inner Engine and the GeV Emission

We have introduced the inner engine theory for the explanation of the GRB high-energy (GeV) emission observed in some BdHN I after the prompt emission phase. We here summarize the inner engine properties following the calculations presented in Campion et al.[5], Moradi et al.[14], Rueda & Ruffini[16], Ruffini et al.[32]; see also Liang et al.[11], Moradi et al.[12,13], Ruffini et al.[29,33].

Once the NS reaches the critical mass, a fast-rotating BH forms which contains sufficient rotational energy ($> 10^{54}$ erg) to power a GRB. Ruffini et al.[32] proposed an efficient way to extract energy from the newborn, Kerr BH.

The inner engine is composed of this newborn rotating BH, surrounded by the magnetic field inherited from the collapsed NS[17], and the ionized very low density of

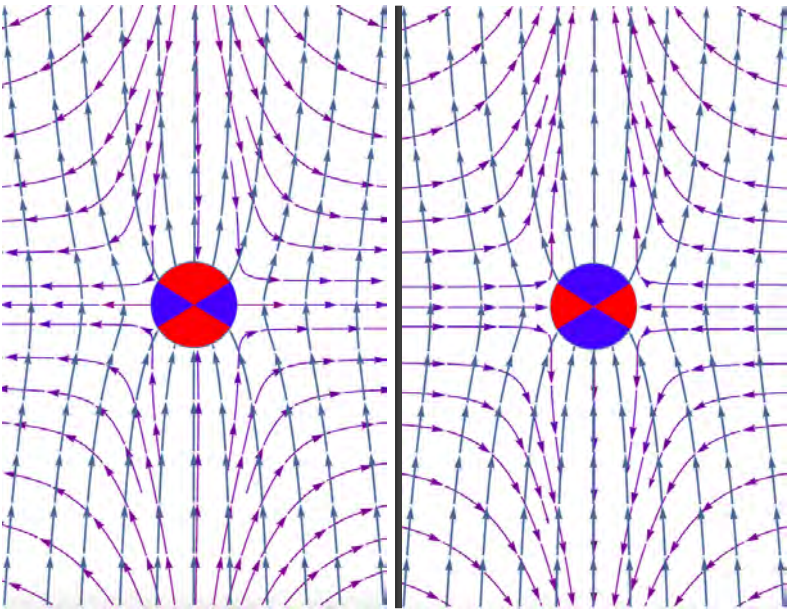

Fig. 3. The electromagnetic field lines of Wald solution. The blue lines indicate the magnetic field lines, and the purple lines indicate the electric field lines. **left:**. The magnetic field is parallel to the spin of the Kerr BH, so parallel to the rotation axis. The electric field lines are inward for the polar angle $\theta <\sim \pi/3$, so the electrons are accelerated away from the BH. For $\theta > \pi/3$, the electric field lines are outward, so the protons are accelerated away from the BH. **right:** The magnetic field is antiparallel to the rotational axis of the Kerr BH. The electric field lines are outward for the polar angle $\theta <\sim \pi/3$, so the protons will be accelerated away from the BH. The electric field lines are inward for $\theta > \pi/3$, so the electrons will be accelerated away from the BH. This figure is quoted from Ruffini et al. [32].

matter ($\sim 10^{-14}$ g cm$^{-3}$) of the SN ejecta [22]. For an aligned magnetic field with the angular momentum of the Kerr BH, an electric field is induced by gravitomagnetic interaction as described by the Wald solution [35]; see figure 3. The medium around the BH provides a sufficient amount of ionized particles that are accelerated to ultra-relativistic energies by the induced electric field, thereby emitting synchrotron and curvature radiation at expenses of the BH rotation energy.

The synchrotron radiation emitted from the accelerated charged particles has been calculated for different polar angles, see figure 4. Along the polar axis, the electric and magnetic fields are aligned, so there are no radiation losses and electrons can reach energies as large as $\sim 10^{18}$ eV, becoming a source of ultrahigh-energy cosmic rays (UHECRs). At larger angles, where electrons propagate across the magnetic lines producing synchrotron photons in the GeV energy domain.

The parameters of the inner engine, namely the BH mass and spin, and the surrounding magnetic field strength have been inferred from the following conditions: 1) the Kerr BH extractable energy accounts for the observed GeV radiation energetics in BdHN I, 2) the synchrotron radiation luminosity explains the observed

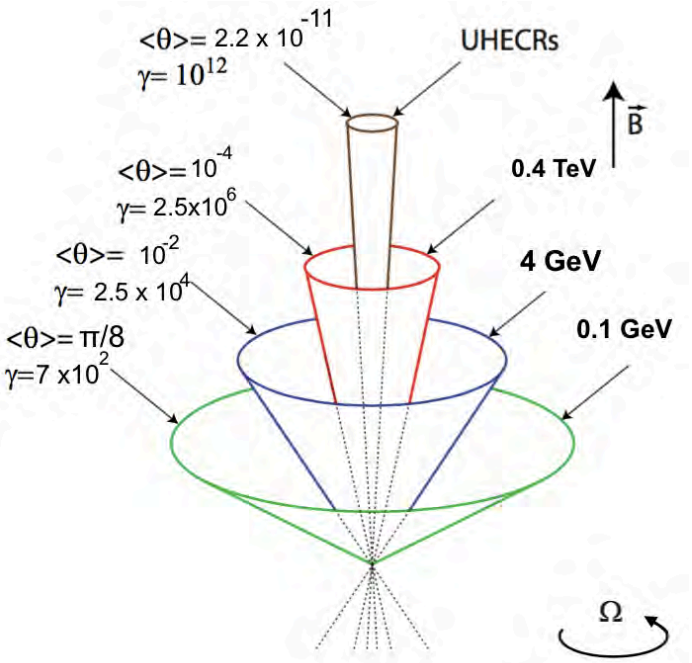

Fig. 4. The radiation emitted by the synchrotron emission of accelerated electrons in the different bands (0.1 GeV to 0.4 TeV) from different angles. And in the narrow polar cone, The UHECRs are produced. Arrows indicate the BH rotational direction and the external magnetic field direction. This figure is quoted from Ruffini et al. [32].

GeV luminosity, and 3) the emitted GeV photons can indeed scape from the system without suffering from magnetic pair production. The case of GRB 130427A has been analyzed in Ruffini et al. [32] and GRB 190114C in Moradi et al. [14]. For instance, in GRB 190114C the accelerated electrons radiate $1.8 \times 10^{53}$ erg in GeV photons via the synchrotron mechanism, and this procedure lasts for years following a power-law decay of light-curve with power-law index $-1.2$.

The mass and spin of the BHs came precisely what expected from the gravitational collapse of the fast rotating NS by accretion, and the strength of the magnetic field surrounding the BH turns out to be a few $10^{10}$ G. Therefore, the intensity of the induced accelerating electric field is undercritical in this BdHN I episode. The above magnetic field strength lower than expected to be inherited from the NS, and that could be the result from a screening process during the GRB prompt emission by electron-positron pairs; see the next section and Campion et al. [5] for details on this interesting physical process. In a recent comprehensive analysis of all the up-to-know identified BdHN I and the GeV emission observed in some of them, it has been inferred that the GeV emission must be emitted within an angle of 60° from the BH rotation axis; see Ruffini et al. [34] for details. This result is in agreement with the theoretical expectation; see Moradi et al. [14].

Another discovery of this inner engine model is that this energetic emission from GRB is not continuous but proceeds in a repetitive sequence of discrete impulse events. Since the inner engine repeats the procedure of charge (BH spin and magnetic field induce electric field) and discharge (electric field accelerates the charged particle that escape from the system), the repetition time grows slowly along with the loss of BH rotational energy. Along the emission of these discrete events the magnetic field keeps constant, but the BH spin decreases after each event by a well defined amount given by the concept of *blackholic quantum* described in Rueda & Ruffini [16]. The blackholic quanta explaining the GeV emission are characterized by an energy $\Delta E_q \sim 10^{38}$ erg, emitted over a timescale $\tau_q \sim 10^{-15}$ s. The fraction of BH angular momentum extracted after each event is $\Delta J_q/J \sim 10^{-16}$, i.e. $\Delta J_q \sim 10^{33}$ g cm$^2$ s$^{-1}$ [14], where $J$ is the Kerr BH angular momentum. This result is indeed unexpected, and it seems to be a general property not only of GRBs but also of the supermassive Kerr BHs in active galactic nuclei; see e.g. Moradi et al. [14] for the analysis of M87*.

## 4. The Prompt and the Afterglow Emission

This section gives the details of the propagation and the radiation of the relativistic outflow, based on the theoretical articles of Ruffini et al. [21,23,24,25] and the observational articles of Rueda et al. [17], Ruffini et al. [26,30,31], Wang et al. [36,37,38].

### 4.1. *The Ultrarelativistic Prompt Emission (UPE) Phase*

Moradi et al. [13] investigated the ultrarelativistic prompt emission (UPE) phase of the BdHN I in which the electric field is overcritical, generating an optically thick electron-positron plasma by vacuum polarization. The plasma expands and self-accelerates to ultra-relativistic by converting its internal energy. Eventually, it reaches the transparency point and releases photons in the MeV energy domain. Campion et al. [5] studied the channel of producing electron-positron pairs via high energy photons interacting with magnetic fields, the motion of these pairs generates a current which induces another dominant magnetic field that screens the original one.

We now focus on the relativistic electron-position plasma that leads to the UPE phase. The hydrodynamics of this plasma have been formulated and simulated in the articles that established the *fireshell* model, and which have been adopted by the BdHN model. Ruffini et al. [23] considered a Reissner-Nordstrom electromagnetic BH generates the electron-positron pairs. The system is expected to be thermalized to a plasma configuration due to the huge pair density and cross-section of the $e^+ + e^- \rightarrow \gamma + \gamma$ process. The evolution of plasma is governed by the hydrodynamic equations including, the conservation of energy-momentum, the conservation of the baryon number, the rate equation for electron-positron annihilation, and the equation of state. By integrating the equations numerically under the Reissner-Nordström metric and compared with the analytical analysis, the temperature drops

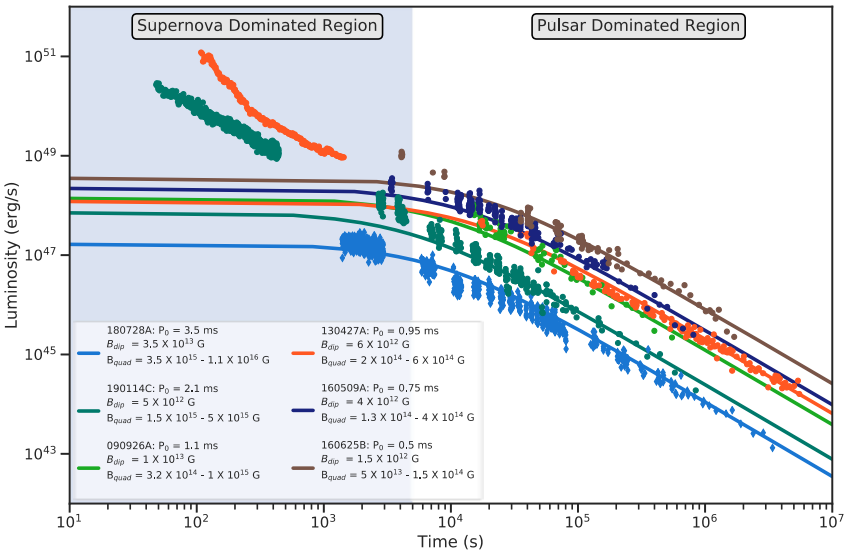

Fig. 5. The brown, dark blue, orange, green, and bright blue dots correspond to the bolometric light curves of GRB 160625B, 160509A, 130427A, 190114C, and 180728A, respectively. The thick lines are energy injection from the NS spin-down, which energizes the late-time afterglow (white background), while in the early time (blue background) the remaining kinetic energy of the outermost shell of the SN ejecta plays a dominant role. This figure is quoted from Rueda et al. [17].

as the internal energy are converted to kinetic energy. The plasma Lorentz factor is accelerated to several hundred, and the radiation releases when reaching the transparency radius. Ruffini et al. [24] adopted a more realistic baryonic environment where the plasma propagates. Baryons are incorporated into the hydrodynamic equations. It is clear by solving the equations that the Lorentz factor of plasma keeps increasing in the beginning until engulfing the baryons, a drop of Lorentz factor occurs, then it goes up again and finally reaches saturation. Ruffini et al. [25] systematically reviewed the creation and annihilation of the electron-positron pairs, thermalization, oscillation and their applications in GRB observations. The plasma penetrates the low-density region of the SN ejecta, see Becerra et al. [1] and Ruffini et al. [30] for details, then propagates in the ISM, and radiates, accounting for the prompt emission. For the observations, the light-curve and spectrum of the prompt emission have been successfully fitted by solving the hydrodynamic equations plus a density profile of the circumburst medium. Izzo et al. [10] offers an example of GRB 090618, of which the system starts by $\sim 2.5 \times 10^{53}$ erg electron-position plasma. The plasma propagates in the circumburst density of 0.6 cm$^{-3}$, and collides with dense clouds of mass $\sim 10^{24}$ g at the distance of $10^{15}$ cm to $10^{16}$ cm. The plasma finally self-accelerates up to transparency reaching a Lorentz factor $\sim 500$, thereby producing the observed emission.

We refer the reader to the most recent analysis of the UPE phase in BdHN I presented in Moradi et al. [13], where the physical origin of the UPE phase has been scrutinized taking as a proxy GRB 190114C. The UPE phase of GRB 190114C is observed in the rest-frame time interval $t_{\rm rf} = 1.9$–$3.99$ s, by the *Fermi*-GBM in 10 keV–10 MeV energy band. Thanks to the high signaltonoise ratio of *Fermi*-GBM data, a time-resolved spectral analysis of the UPE emission has evidenced a sequence of similar blackbody plus cut-off power-law spectra (BB+CPL), on ever decreasing time intervals. In it, the inner engine operates in an overcritical electric field regime. The electron-positron pair electromagnetic plasma in presence of a baryon load, *a PEMB pulse*, is therein originated from a vacuum polarization quantum process. This initially optically thick plasma self-accelerates, giving rise at the transparency radius to the MeV radiation observed by *Fermi*-GBM. For the first time, it has been quantitatively shown how the inner engine, by extracting the rotational energy of the Kerr BH, produces a series of PEMB pulses. Therefore, a quantum vacuum polarization process sequences with decreasing time bins occurs. We compute the Lorentz factors, the baryon loads and the radii at transparency, as well as the value of the magnetic field in each sequence. It has been therefore found there is an underlying fundamental hierarchical structure, linking the quantum electrodynamics regime of the UPE to the classical electrodynamics regime of the GeV emission after the UPE. The PEMB pulses of the UPE have been found to be characterized by the emission of blackholic quanta of energy $\sim 10^{45}$ erg, over a timescale $\sim 10^{-9}$ s.

Let us summarize GRB 190114C. The initial magnetic field left over by the collapse of the accreting NS and rooted in the surrounding material is very strong ($\sim 10^{14}$ G), so it induces a sizeable electric field that surpasses the critical value near the horizon. The overcritical electric field transfers its energy to the electron-positron pairs by the vacuum polarization and is later emitted as the UPE phase of $2.5 \times 10^{53}$ erg. The magnetic field becomes then screened to a few $10^{10}$ G in a few seconds [5], consequently the size of the region above the BH horizon with overcritical electric field (the *dyadoregion*) shrinks, and its energy stored becomes insignificant. This marks the end of the UPE phase and after it, the above inner engine mechanism by which the induced electric field accelerate electrons within a few horizon radii becomes the main channel of taking away the BH rotation energy in form of GeV photons [14].

### 4.2. *The Afterglow Emission Phase*

Another part of the plasma hindered by the SN ejecta accelerates the SN outermost shell to mildly-relativistic velocities. The breakout of the plasma (shockwave) from the outermost shell at $\sim 10^2$ s radiate photons of keV energies which explain the observed X-ray flares [30]. The synchrotron emission in the outermost shell accounts for the early afterglow X-ray emission [26]. Rotational energy from the $\nu$NS rotational is injected into the SN ejecta, then radiated by the synchrotron emission, accounts

for the plateau and late-time ($\sim 10^4$ s) afterglow[17,21,37]. The emission of the $\nu$NS as a pulsar becomes directly observable when the synchrotron luminosity fades off below the pulsar radiation luminosity. About $\sim 15$ days (rest-frame time) after the SN explosion that triggered the BdHN, the optical emission from the nickel decay in the SN ejecta reaches the maximum, there may appear a bump on the optical light-curve[26,37,38].

Ruffini et al.[30], Wang et al.[36] statistically analyzed the X-ray flares observed in the early afterglow. A general pattern of thermal component of temperature $\sim 1$ keV was found, suggesting that the flare is generated from a mildly-relativistic expanding shell of Lorentz factor $< 4$ at a distance $\sim 10^{12}$ cm. The observation of flares is consistent with our simulation of $\sim 10^{53}$ erg of plasma impacts on the SN ejecta of a few solar masses, leading to the formation of a shock propagating inside the SN ejecta until reaching the outermost shell. The density profile and velocity profile of the accelerated ejecta are obtained. Precisely, the shockwave breaks out at $\sim 10^{12}$ cm and the outermost shell is accelerated to Lorentz factor $\sim 2$–$5$. This feature was also extensively studied for GRB 151027A[31]. Along with the conversion of the kinetic energy of the outermost shell into radiation, the early afterglow exhibits a steep decay behaviour. Then, the energy injected from the $\nu$NS dominates the afterglow, the light-curve shows a plateau followed by a normal power-law decay, shown in figure 5. Taking GRB 180728A as an example[37], from the conversion of angular momentum, the $\mathrm{CO_{core}}$ collapses to a fast spinning NS of initial spin period $\sim 3$ ms. Such a newborn NS allows the presence of multipolar magnetic fields, with a quadrupole magnetic field $\sim 10^{15}$ G and a dipole field $\sim 10^{13}$ G, the spin-down of the $\nu$NS injects energy into the outflowing ejecta whose synchrotron emission fits the late-time X-ray afterglow. A comprehensive analysis of the afterglow of a few long GRB afterglows within the above synchrotron mechanism of the BdHN model has been presented in Rueda et al.[17].

## 5. Conclusion

We can draw some general conclusions with the aid of the BdHN evolution shown in figure 6. (a) Our picture starts with a binary system consisting of two main-sequence stars of intermediate mass, say $15M_\odot$ and $12M_\odot$, respectively. (b) At a given time, the more massive star undergoes a core-collapse SN and forms an NS. (c) The system enters the X-ray binary phase. (d) The system has overcome binary interactions and common-envelope phases (not shown in the diagram) which have led to the hydrogen and helium envelopes of the ordinary star to have been stripped off, remaining a star which is rich in carbon and oxygen, referred to as $\mathrm{CO_{core}}$. At this stage, the system is a $\mathrm{CO_{core}}$-NS binary, which is considered as the initial configuration of the BdHN model. (e) At this stage the orbit of the binary has shrink to a period of the order of a few minutes. The $\mathrm{CO_{core}}$ explodes into an SN (of type Ic in view of the absence of hydrogen and helium in its outermost layers), expelling several solar masses. These ejecta begin to expand, and a rapidly rotating $\nu$NS is

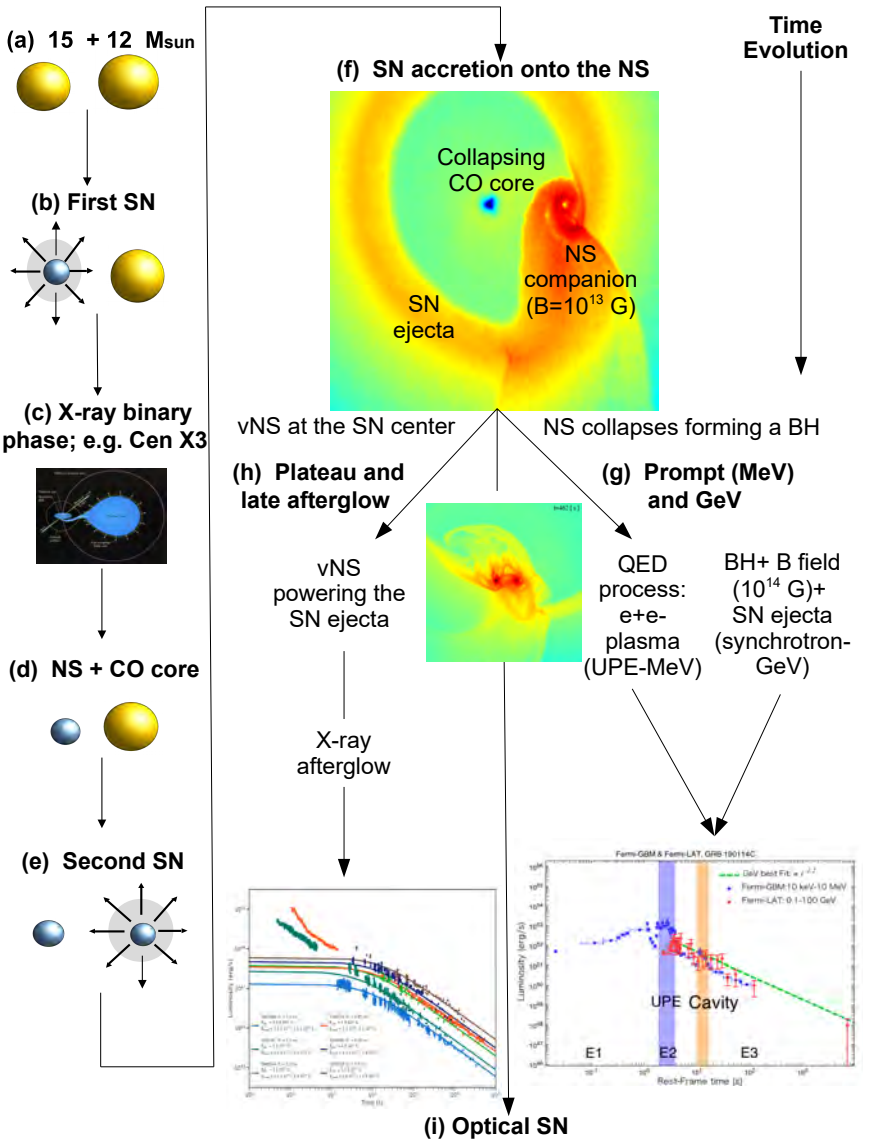

Fig. 6. Diagram of the evolutionary path of BdHN. Including binary evolution, SN explosion, NS accretion, BH formation, GRB prompt and afterglow emissions and SN appearence. This figure is quoted from [17].

left in the centre. (f) Depending on the initial NS mass and binary separation, the SN ejecta accretes onto the NS companion and onto the $\nu$NS, forming a massive NS (BdHN II) or BH (BdHN I; this example). At this stage, the system is a new NS and BH binary surrounded by the expanding ejecta. (g) The inner engine composed by the newborn BH, the surrounding magnetic field and ionized plasma is formed, and

its activity explains the GRB UPE phase and the subsequent GeV emission. The magnetic field in the inner engine at BH formation is overcritical, so it induces (by gravitomagnetic interaction with the BH spin) an overcritical electric field, so the UPE phase operates in an overcritical regime. A quantum electrodynamical process of vacuum polarization takes place leading to an electron-positron pair plasma pulses (PEMB pulses) that expand to ultrarelativistic velocity reaching transparency with a Lorentz factor of up to hundreds, and emitting MeV photons. The magnetic field is then screened to undercritical values by currents produced by the motion of the electron and positrons, and the inner engine classical electrodynamical process of particle acceleration emitting GeV photons by synchrotron radiation becomes the relevant process of emission. (h) The spin-down energy of the $\nu$NS injects energy into the expanding SN ejecta emitting the observed X-ray afterglow by synchrotron radiation. (i) The appearance of the energy release owing to nickel decay in the SN ejecta is observed at optical wavelengths.

## Acknowledgments

We acknowledge the contribution from the ICRANet group and the collaborators of establishing the BdHN model. Remo Ruffini, Jorge Rueda and Yu Wang gave the plenary talks in the MG 15 meeting on behalf of the contributors.

# IceCube: Opening a new window on the universe from the South Pole

Francis Halzen

*Wisconsin IceCube Particle Physics Center*
*Madison, WI 53703 USA*
* *E-mail: halzen@icecube.wisc.edu*

After updating the status of the measurements of the cosmic neutrino flux by the IceCube experiment, we summarize the observations of the first identified source of cosmic rays and speculate on the connection between the two observations.

*Keywords*: multimessenger, neutrinos, cosmic rays, blazars, cosmic accelerators

## 1. Detecting cosmic neutrinos

Cosmic rays have been studied for more than a century. They reach energies in excess of $10^8$ TeV, populating an extreme universe that is opaque to electromagnetic radiation[1,2]. We don't yet know where or how particles are accelerated to these extreme energies, but with the observation of a distant blazar in coincidence with the direction and time of a very high energy muon neutrino, neutrino astronomy has made a breakthrough in resolving this puzzle[3,4]. The rationale for finding cosmic ray sources by observing neutrinos is straightforward: near neutron stars and black holes, gravitational energy released in the accretion of matter can power the acceleration of protons ($p$) or heavier nuclei that subsequently interact with gas ("$pp$") or ambient radiation ("$p\gamma$") to produce neutrinos originating from the decay of pions and other secondary particles. In the case of photoproduction, both neutral and charged pion secondaries are produced in the processes $p + \gamma_{\rm bg} \to p + \pi^0$ and $p + \gamma_{\rm bg} \to n + \pi^+$, for instance. While neutral pions decay as $\pi^0 \to \gamma + \gamma$ and create a flux of high-energy gamma rays, the charged pions decay into three high-energy neutrinos ($\nu$) and anti-neutrinos ($\bar{\nu}$) via the decay chain $\pi^+ \to \mu^+ + \nu_\mu$ followed by $\mu^+ \to e^+ + \bar{\nu}_\mu + \nu_e$, and the charged-conjugate process. We refer to these photons as pionic photons. They provide the rational for multimessenger astronomy and should be distinguished from photons radiated by electrons that may be accelerated along with the cosmic rays.

High-energy neutrinos interact predominantly with matter via deep inelastic scattering off nucleons: the neutrino scatters off quarks in the target nucleus by the exchange of a $Z$ or $W$ weak boson, referred to as *neutral current* and *charged current* interactions, respectively. Whereas the neutral current interaction leaves the neutrino state intact, in a charged current interaction a charged lepton is produced that shares the initial neutrino flavor. The average relative energy fraction transferred from the neutrino to the lepton is at the level of 80% at high energies. The struck nucleus does not remain intact and its high-energy fragments typically initiate hadronic showers in the target medium.

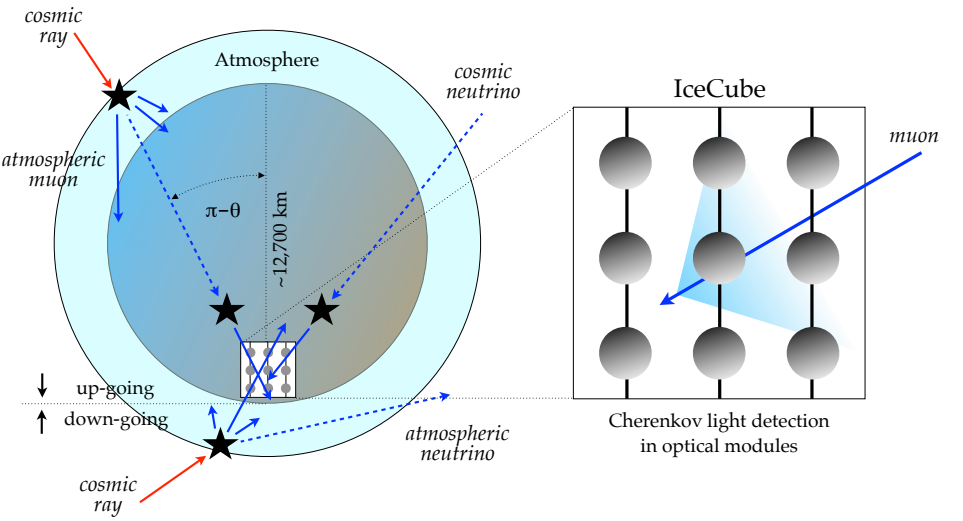

Fig. 1. The principal idea of neutrino telescopes from the point of view of IceCube located at the South Pole. Neutrinos dominantly interact with a nucleus in a transparent medium like water or ice and produce a muon that is detected by the wake of Cherenkov photons it leaves inside the detector. The background of high-energy muons (solid blue arrows) produced in the atmosphere can be reduced by placing the detector underground. The surviving fraction of muons is further reduced by looking for upgoing muon tracks that originate from muon neutrinos (dashed blue arrows) interacting close to the detector. This still leaves the contribution of muons generated by atmospheric muon neutrino interactions. This contribution can be separated from the diffuse cosmic neutrino emission by an analysis of the combined neutrino spectrum.

Immense particle detectors are required to collect cosmic neutrinos in statistically significant numbers. Already by the 1970s, it had been understood[5] that a kilometer-scale detector was needed to observe the cosmogenic neutrinos produced in the interactions of cosmic rays with background microwave photons[6]. The IceCube project has transformed one cubic kilometer of natural Antarctic ice into a Cherenkov detector. Photomultipliers embedded in the ice transform the Cherenkov light radiated by secondary particles produced in neutrino interactions into electrical signals using the photoelectric effect; see Figs. 1 and 2. Computers at the surface use this information to reconstruct the light patterns produced to infer the arrival directions, energies and flavor of the neutrinos.

Two patterns of Cherenkov radiation are of special interest, “tracks” and “cascades.” The term “track” refers to the Cherenkov emission of a long-lived muon passing through the detector after production in a charged current interaction of a muon neutrino inside or in the vicinity of the detector. Because of the large background of muons produced by cosmic ray interactions in the atmosphere, the observation of muon neutrinos is limited to upgoing muon tracks that are produced

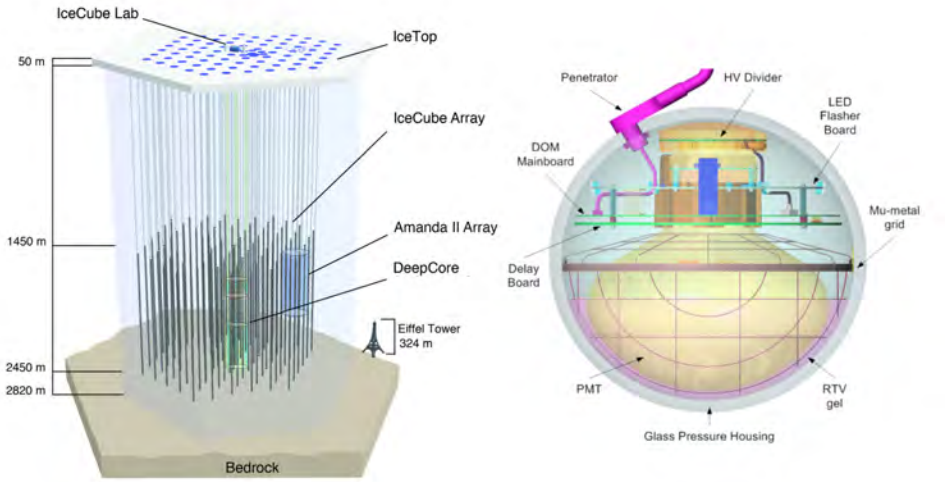

Fig. 2. Architecture of the IceCube observatory (left) and the schematics of a digital optical module (right) (see Ref. 7 for details).

by neutrinos that have passed through the Earth that acts as a neutrino filter. The remaining background consists of atmospheric neutrinos, which are indistinguishable from cosmic neutrinos on an event-by-event basis. However, the steeply falling spectrum ($\propto E^{-3.7}$) of atmospheric neutrinos allows identifying diffuse astrophysical neutrino emission above a few hundred TeV by a spectral analysis. The atmospheric background is also reduced for muon neutrino observation from point-like sources, in particular transient neutrino sources.

Energetic electrons and taus produced in interactions of electron and tau neutrinos, respectively, will initiate an electromagnetic shower that develops over less than 10 meters. This shower as well as the hadronic particle shower generated by the target struck by a neutrino in the ice radiate Cherenkov photons. The light pattern is mostly spherical and referred to as a "cascade." The direction of the initial neutrino can only be reconstructed from the Cherenkov emission of secondary particles produced close to the neutrino interaction point, and the angular resolution is worse than for track events. On the other hand, the energy of the initial neutrino can be constructed with a better resolution than for tracks.

Two methods are used to identify cosmic neutrinos. Traditionally, neutrino searches have focused on the observation of muon neutrinos that interact primarily outside the detector to produce kilometer-long muon tracks passing through the instrumented volume. Although this allows the identification of neutrinos that interact outside the detector, it is necessary to use the Earth as a filter in order to remove the background of cosmic-ray muons. This limits the neutrino view

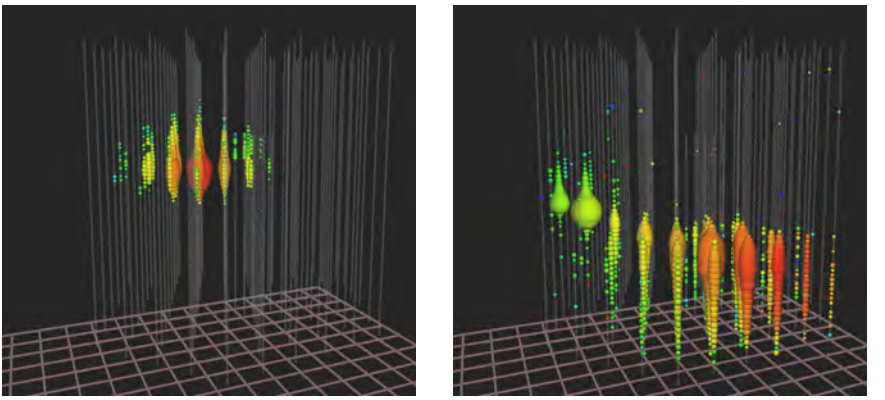

Fig. 3. **Left Panel:** Light pool produced in IceCube by a shower initiated by an electron or tau neutrino. The measured energy is 1.14 PeV, which represents a lower limit on the energy of the neutrino that initiated the shower. White dots represent sensors with no signal. For the colored dots, the color indicates arrival time, from red (early) to purple (late) following the rainbow, and size reflects the number of photons detected. **Right Panel:** An upgoing muon track traverses the detector at an angle of 11° below the horizon. The deposited energy, i.e., the energy equivalent of the total Cherenkov light of all charged secondary particles inside the detector, is 2.6 PeV.

to a single flavor and half the sky. An alternative method exclusively identifies high-energy neutrinos interacting inside the detector, so-called high-energy starting events (HESE). It divides the instrumented volume of ice into an outer veto shield and a $\sim$ 420-megaton inner fiducial volume. The advantage of focusing on neutrinos interacting inside the instrumented volume of ice is that the detector functions as a total absorption calorimeter, measuring the neutrino energy of cascades with a 10-15 % resolution[8]. Furthermore, with this method, neutrinos from all directions in the sky can be identified, including both muon tracks as well as secondary showers, produced by charged-current interactions of electron and tau neutrinos, and neutral current interactions of neutrinos of all flavors. For illustration, the Cherenkov patterns initiated by an electron (or tau) neutrino of about 1 PeV energy and a muon neutrino losing 2.6 PeV energy in the form of Cherenkov photons while traversing the detector are contrasted in Fig. 3.

In general, the arrival times of photons at the optical sensors, whose positions are known, determine the particle's trajectory, while the number of photons is a proxy for the deposited energy, i.e., the energy of all charged secondary particles from the interactions. For instance, for the cascade event shown in the left panel of Fig. 3, more than 300 digital optical modules (DOMs) report a total of more than 100,000 photoelectrons. The two abovementioned methods of separating neutrinos from the cosmic-ray muon background have complementary advantages. The long tracks produced by muon neutrinos can be pointed back to their sources with a $\leq 0.4°$

angular resolution. In contrast, the reconstruction of the direction of cascades in the HESE analysis, in principle possible to a few degrees, is still in the development stage in IceCube[8]. Their reconstruction, originally limited to within $10^\circ \sim 15^\circ$ of the direction of the incident neutrino, has now achieved resolutions closer to $5^\circ$[9]. Determining the deposited energy from the observed light pool is, however, relatively straightforward, and a resolution of better than 15 % is possible; the same value holds for the reconstruction of the energy deposited by a muon track inside the detector.

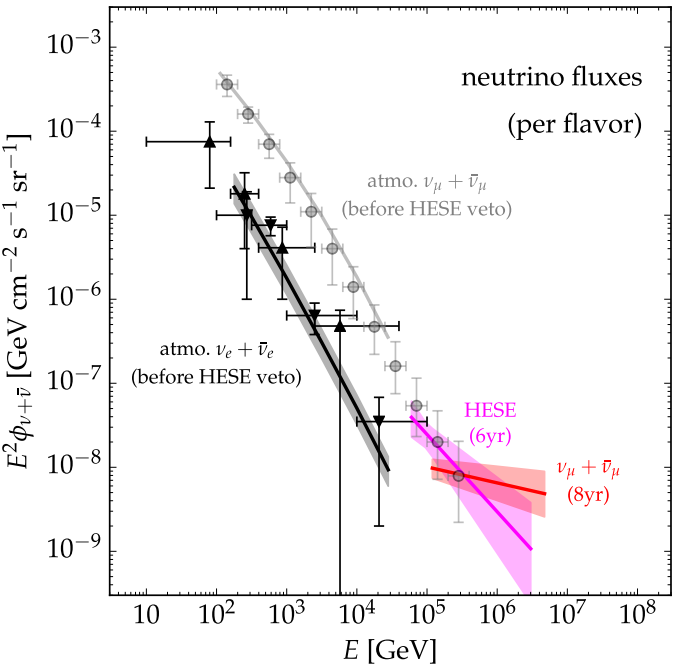

Fig. 4. Summary of diffuse neutrino observations (per flavor) by IceCube. The black and grey data show IceCube's measurement of the atmospheric $\nu_e + \bar{\nu}_e$ [10,11] and $\nu_\mu + \bar{\nu}_\mu$ [12] spectra. The magenta line and magenta-shaded area indicate the best-fit and $1\sigma$ uncertainty range of a power-law fit to the six-year HESE data. Note that the HESE analysis vetoes atmospheric neutrinos and can probe astrophysical neutrinos below the atmospheric neutrino flux. The corresponding fit to the eight-year $\nu_\mu + \bar{\nu}_\mu$ analysis is shown in red. Figure from Ref. 13.

Using the Earth as a filter, a flux of neutrinos has been identified that is predominantly of atmospheric origin. IceCube has measured this flux over three orders of magnitude in energy with a result that is consistent with theoretical calculations. However, with eight years of data, an excess of events is observed at energies beyond 100 TeV[14–16], which cannot be accommodated by the atmospheric flux; see Fig. 4. Allowing for large uncertainties on the extrapolation of the atmospheric

component to higher energy, the statistical significance of the excess astrophysical flux is $6.7\sigma$. While IceCube measures only the energy of the secondary muon inside the detector, from Standard Model physics we can infer the energy spectrum of the parent neutrinos. The cosmic neutrino flux is well described by a power law with a spectral index $\Gamma = 2.19 \pm 0.10$ and a normalization at 100 TeV neutrino energy of $(1.01^{+0.26}_{-0.23}) \times 10^{-18}\,\mathrm{GeV}^{-1}\mathrm{cm}^{-2}\mathrm{sr}^{-1}$ [16]. The neutrino energies contributing to this power-law fit cover the range from 119 TeV to 4.8 PeV.

Using only two years of data, it was the alternative HESE method, which selects neutrinos interacting inside the detector, that revealed the first evidence for cosmic neutrinos [17,18]. The segmentation of the detector into a surrounding veto and active signal region has been optimized to reduce the background of atmospheric muons and neutrinos to a handful of events per year, while keeping most of the cosmic signal. Neutrinos of atmospheric and cosmic origin can be separated not only by using their well-measured energy but also on the basis that background atmospheric neutrinos reaching us from the Southern Hemisphere can be removed because they are accompanied by particles produced in the same air shower where the neutrinos originate. A sample event with a light pool of roughly one hundred thousand photoelectrons extending over more than 500 meters is shown in the left panel of Fig. 3. With PeV energy, and no trace of accompanying muons from an atmospheric shower, these events are highly unlikely to be of atmospheric origin. The six-year data set contains a total of 82 neutrino events with deposited energies ranging from 60 TeV to 10 PeV. The data are consistent with an astrophysical component with a spectrum close to $E^{-2}$ above an energy of $\sim 200$ TeV. In summary, IceCube has observed cosmic neutrinos using both methods for rejecting background. Based on different methods for reconstruction and energy measurement, their results agree, pointing at extragalactic sources whose flux has equilibrated in the three flavors after propagation over cosmic distances [19] with $\nu_e : \nu_\mu : \nu_\tau \sim 1 : 1 : 1$.

An extrapolation of this high-energy flux to lower energy suggests an interesting excess of events in the $30 - 100$ TeV energy range over and above a single power-law fit; see Fig. 5. This conclusion is supported by a subsequent analysis that has lowered the threshold of the starting-event analysis [20] and by a variety of other analyses. The astrophysical flux measured by IceCube is not featureless; either the spectrum of cosmic accelerators cannot be described by a single power law or a second component of cosmic neutrino sources emerges in the spectrum. Because of the self-veto of atmospheric neutrinos in the HESE analysis, i.e., the veto triggered by accompanying atmospheric muons, it is very difficult to accommodate the component below 100 TeV as a feature in the atmospheric background.

In Figure 5 we show the arrival directions of the most energetic events in the eight-year upgoing $\nu_\mu + \bar{\nu}_\mu$ analysis ($\odot$) and the six-year HESE data sets. The HESE data are separated into tracks ($\otimes$) and cascades ($\oplus$). The median angular resolution of the cascade events is indicated by thin circles around the best-fit position.

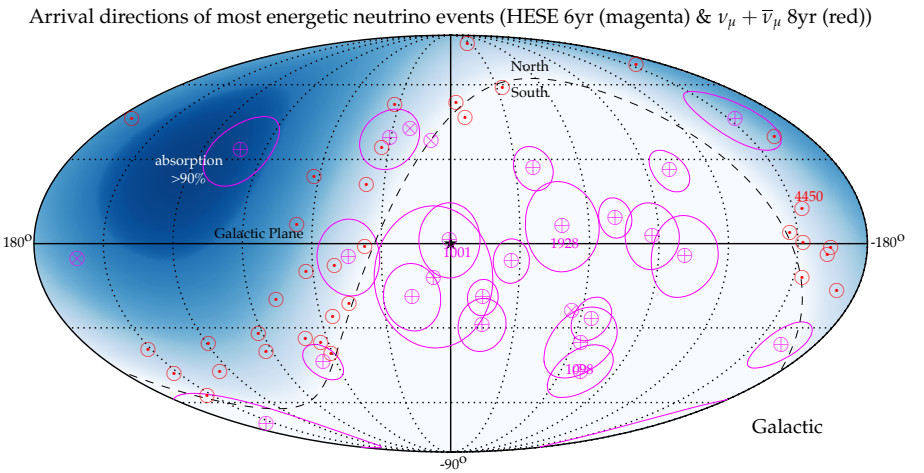

Fig. 5. Mollweide projection in Galactic coordinates of the arrival direction of neutrino events. We show the results of the eight-year upgoing track analysis [16] with reconstructed muon energy $E_\mu \gtrsim 200$ TeV ($\odot$). The events of the six-year high-energy starting event (HESE) analysis with deposited energy larger than 100 TeV (tracks $\otimes$ and cascades $\oplus$) are also shown [16,21,22]. The thin circles indicate the median angular resolution of the cascade events ($\oplus$). The blue-shaded region indicates the zenith-dependent range where Earth absorption of 100 TeV neutrinos becomes important, reaching more than 90% close to the nadir. The dashed line indicates the horizon and the star ($\star$) the Galactic Center. We highlight the four most energetic events in both analyses by their deposited energy (magenta numbers) and reconstructed muon energy (red number). Figure from Ref. 13.

The most energetic muons with energy $E_\mu > 200$ TeV in the upgoing $\nu_\mu + \bar{\nu}_\mu$ data set accumulate near the horizon in the Northern Hemisphere. Elsewhere, muon neutrinos are increasingly absorbed in the Earth causing the apparent anisotropy of the events in the Northern Hemisphere. Also HESE events with deposited energy of $E_{\rm dep} > 100$ TeV suffer from absorption in the Earth and are therefore mostly detected when originating in the Southern Hemisphere. After correcting for absorption, the arrival directions of cosmic neutrinos are isotropic, suggesting extragalactic sources. In fact, no correlation of the arrival directions of the highest energy events, shown in Fig. 5, with potential sources or source classes has reached the level of $3\sigma$ [20].

## 2. IceCube neutrinos and Fermi photons

The most important message emerging from the IceCube measurements of the high-energy cosmic neutrino flux is not apparent yet: the prominent and surprisingly important role of protons relative to electrons in the nonthermal universe. Photons are produced in association with neutrinos when accelerated cosmic rays produce neutral and charged pions in interactions with target photons or nuclei in the vicinity

of the accelerator. Targets include strong radiation fields that may be associated with the accelerator as well as concentrations of matter, such as molecular clouds in their vicinity. Additionally, pions can be produced in the interaction of cosmic rays with the extragalactic background light (EBL) when propagating through the interstellar or intergalactic background. As already discussed in section 1, a high-energy flux of neutrinos is produced in the subsequent decay of charged pions via $\pi^+ \to \mu^+ + \nu_\mu$ followed by $\mu^+ \to e^+ + \nu_e + \bar{\nu}_\mu$ and the charge–conjugate processes. High-energy gamma rays result from the decay of neutral pions, $\pi^0 \to \gamma + \gamma$. Pionic gamma rays and neutrinos carry, on average, 1/2 and 1/4 of the energy of the parent pion, respectively. With these approximations, the neutrino production rate $Q_{\nu_\alpha}$ (units of $\mathrm{GeV}^{-1}\mathrm{s}^{-1}$) can be related to the one for charged pions as

$$\sum_\alpha E_\nu Q_{\nu_\alpha}(E_\nu) \simeq 3\,[E_\pi Q_{\pi^\pm}(E_\pi)]_{E_\pi \simeq 4E_\nu} \ . \tag{1}$$

Similarly, the production rate of pionic gamma-rays is related to the one for neutral pions as

$$E_\gamma Q_\gamma(E_\gamma) \simeq 2\,[E_\pi Q_{\pi^0}(E_\pi)]_{E_\pi \simeq 2E_\gamma} \ . \tag{2}$$

Note, that the relative production rates of pionic gamma rays and neutrinos only depend on the ratio of charged-to-neutral pions produced in cosmic-ray interactions, denoted by $K_\pi = N_{\pi^\pm}/N_{\pi^0}$. Pion production by cosmic rays in interactions with photons can proceed resonantly in the processes $p + \gamma \to \Delta^+ \to \pi^0 + p$ and $p + \gamma \to \Delta^+ \to \pi^+ + n$. These channels produce charged and neutral pions with probabilities 2/3 and 1/3, respectively. However, the additional contribution of nonresonant pion production changes this ratio to approximately 1/2 and 1/2. In contrast, cosmic rays interacting with matter, e.g., hydrogen in the Galactic disk, produce equal numbers of pions of all three charges: $p + p \to N_\pi\,[\,\pi^0 + \pi^+ + \pi^-] + X$, where $N_\pi$ is the pion multiplicity. From above arguments we have $K_\pi \simeq 2$ for cosmic ray interactions with gas ($pp$) and $K_\pi \simeq 1$ for interactions with photons ($p\gamma$) [13].

With this approximation we can combine Eqs. (1) and (2) to derive a powerful relation between the pionic gamma-ray and neutrino production rates:

$$\frac{1}{3}\sum_\alpha E_\nu^2 Q_{\nu_\alpha}(E_\nu) \simeq \frac{K_\pi}{4}\left[E_\gamma^2 Q_\gamma(E_\gamma)\right]_{E_\gamma = 2E_\nu} \ . \tag{3}$$

The prefactor 1/4 accounts for the energy ratio $\langle E_\nu \rangle / \langle E_\gamma \rangle \simeq 1/2$ and the two gamma rays produced in the neutral pion decay.

Note that this relation relates pionic neutrinos and gamma rays without any reference to the cosmic ray beam; it simply reflects the fact that a $\pi^0$ produces two $\gamma$ rays for every charged pion producing a $\nu_\mu + \bar{\nu}_\mu$ pair, which cannot be separated by current experiments.

Before applying this relation to a cosmic accelerator, we have to take into account the fact that, unlike neutrinos, gamma rays interact with photons of the cosmic

microwave background before reaching Earth. The resulting electromagnetic shower subdivides the initial photon energy, resulting in multiple photons in the GeV-TeV energy range by the time the photons reach Earth. Calculating the cascaded gamma-ray flux accompanying IceCube neutrinos is straightforward [23,24].

As an illustration, an example of $\gamma$-ray and neutrino emission is shown as blue lines in Fig. 6 assuming that the underlying $\pi^0$ / $\pi^\pm$ production follows from cosmic-ray interactions with gas in the universe. In this way, the initial emission spectrum of $\gamma$-rays and neutrinos from pion decay is almost identical to the spectrum of cosmic rays (assumed to be a power law, $E^{-2.19}$ as is the case for the diffuse cosmic neutrino flux above and energy of 100 TeV), after accounting for the different normalizations and energy scales. The flux of neutrinos arriving at Earth (blue dashed line) follows this initial CR emission spectrum. However, the observable flux of $\gamma$-rays (blue solid lines) is strongly attenuated above 100 GeV by interactions with extragalactic background photons [13].

The overall normalization of the emission is chosen in a way that the model does not exceed the isotropic $\gamma$-ray background observed by the Fermi satellite (blue data). This implies an upper limit on the neutrino flux shown as the blue dashed line. Interestingly, the neutrino data shown in Fig. 6 saturates this limit above 100 TeV. Moreover, the HESE data that extends to lower energies is only marginally consistent with the upper bound implied by the model (blue dashed line). This example shows that multimessenger studies of $\gamma$-ray and neutrino data are powerful tools to study the neutrino production mechanism and to constrain neutrino source models [25].

The matching energy densities of the extragalactic gamma-ray flux detected by Fermi and the high-energy neutrino flux measured by IceCube suggest that, rather than detecting some exotic sources, it is more likely that IceCube to a large extent observes the same universe conventional astronomy does. Clearly, an extreme universe modeled exclusively on the basis of electromagnetic processes is no longer realistic. The finding implies that a large fraction, possibly most, of the energy in the nonthermal universe originates in hadronic processes, indicating a larger role than previously thought. The high intensity of the neutrino flux below 100 TeV in comparison to the Fermi data might indicate that these sources are even more efficient neutrino than gamma-ray sources [26,27].

Interestingly, the common energy density of photons and neutrinos is also comparable to that of the ultra-high-energy extragalactic cosmic rays (above $10^9$ GeV) observed, for instance, by the Auger observatory [28] (green data). Unless accidental, this indicates a common origin of the signal and illustrates the potential of multi-messenger studies. A scenario where the high-energy neutrinos observed at IceCube could actually originate in the same sources could be realized as follows: the cosmic ray sources can be embedded in environments that act as "storage rooms" for cosmic rays with energies far below the "ankle" ($E_{\rm CR} \ll 1$EeV). This energy-dependent

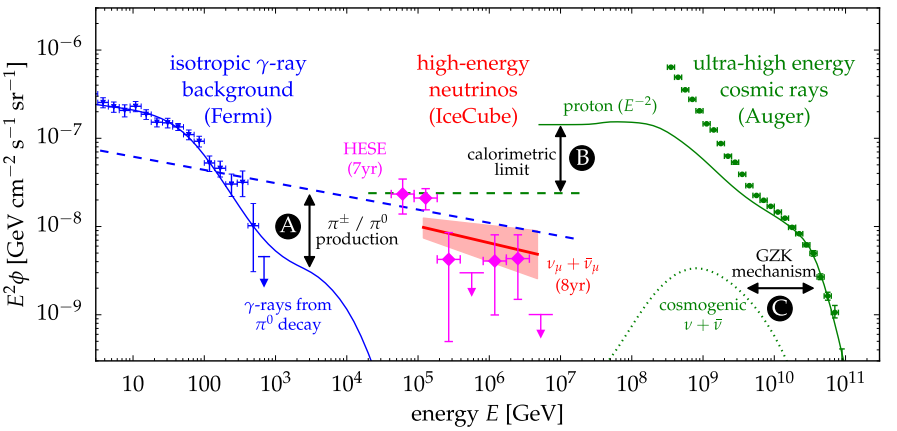

Fig. 6. The spectral flux ($\phi$) of neutrinos inferred from the eight-year upgoing track analysis (red fit) and the seven-year HESE analysis (magenta fit) compared to the flux of unresolved extragalactic γ-ray sources[31] (blue data) and ultra-high-energy cosmic rays[28] (green data). The neutrino spectra are indicated by the best-fit power-law (solid line) and $1\sigma$ uncertainty range (shaded range). We highlight the various multimessenger interfaces: **A:** The joined production of charged pions ($\pi^{\pm}$) and neutral pions ($\pi^0$) in cosmic-ray interactions leads to the emission of neutrinos (dashed blue) and γ-rays (solid blue), respectively. **B:** Cosmic ray emission models (solid green) of the most energetic cosmic rays imply a maximal flux (calorimetric limit) of neutrinos from the same sources (green dashed). **C:** The same cosmic ray model predicts the emission of cosmogenic neutrinos from the collision with cosmic background photons (GZK mechanism). Figure from Ref. 13.

trapping can be achieved via cosmic ray diffusion in magnetic fields. While these cosmic rays are trapped, they can produce γ-rays and neutrinos via collisions with gas. If the conditions are right, this mechanism can be so efficient that the total energy stored in cosmic rays below the ankle is converted to that of γ-rays and neutrinos. These "calorimetric" conditions can be achieved, for instance, in starburst galaxies[29] or galaxy clusters[30].

The extragalactic γ-ray background observed by Fermi[31] has contributions from identified point-like sources on top of an isotropic γ-ray background (IGRB) shown in Fig. 6. This IGRB is expected to consist mostly of emission from the same class of γ-ray sources that are individually below Fermi's point-source detection threshold (see, e.g., Ref. 32). A significant contribution of γ-rays associated with IceCube's neutrino observation would have the somewhat surprising implication that indeed many extragalactic γ-ray sources are also neutrino emitters, while none had been detected so far. This dramatically changed when IceCube developed methods for performing real-time multiwavelength observations in cooperation with some twenty other observatories to identify the sources and build on the discovery of cosmic neutrinos to launch a new era in astronomy[33,34]. This effort led to the identification

of a distant flaring blazar as a cosmic ray accelerator in a multimessenger campaign launched by a 290 TeV energy neutrino detected from the constellation of Orion on September 22, 2017[3].

## 3. The first truly multimessenger campaign

Neutrinos only originate in environments where protons are accelerated to produce pions and other particles that decay into neutrinos. Neutrinos can thus exclusively pinpoint cosmic ray accelerators, and this is exactly what one neutrino did on September 22, 2017.

IceCube detects muon neutrinos, a type of neutrino that leaves a well-reconstructed track in the detector roughly every five minutes. Most of them are low-energy neutrinos produced in the Earth's atmosphere, which are of interest for studying the neutrinos themselves, but are a persistent background when doing neutrino astronomy. In 2016, IceCube installed an online filter that selects from this sample, in real time, very high energy neutrinos that are likely to be of cosmic origin[34]. We reconstruct their energy and celestial coordinates, typically in less than one minute, and distribute the information automatically via the Gamma-ray Coordinate Network to a group of telescopes around the globe and in space for follow-up observations. These telescopes look for electromagnetic radiation from the arrival direction of the neutrino, searching for coincident emission that can reveal its origin.

The tenth such alert[35], IceCube-170922A, on September 22, 2017, reported a well-reconstructed muon neutrino with an energy of 290 TeV and, therefore, with a high probability of originating in an astronomical source. The Fermi telescope detected a flaring blazar aligned with the cosmic neutrino within 0.06 degrees. The source is a known blazar, a supermassive black hole spitting out high-energy particles in twin jets aligned with its rotation axis which is directed at Earth. This blazar, TXS 0506+056, had been relatively poorly studied until now, although it was identified as the highest energy gamma ray source detected by EGRET from any blazar with two photons above 40 GeV[36]. The set of observations triggered by the September 22 neutrino has yielded a treasure trove of multiwavelength data that will allow us to probe the physics of the first cosmic ray accelerator. An optical telescope eventually measured its distance[37], which was found to be 4 billion light-years. Its large distance points to a special galaxy, which sets it apart from the ten-times-closer blazars such as the Markarian sources that dominate the extreme gamma-ray sky observed by NASA's Fermi satellite.

TXS 0506+056 was originally flagged by the Fermi[38] and Swift[39] satellite telescopes. Follow-up observations with the MAGIC air Cherenkov telescope[40] identified it as a rare TeV blazar with the potential to produce the very high energy neutrino detected by IceCube. The source was subsequently scrutinized in X-ray, optical, and radio wavelengths. This is a first, truly multimessenger observation: none of the instruments could have made this breakthrough independently. In total,

more than 20 telescopes observed the flaring blazar as a highly variable source in a high state[3].

It is important to realize that nearby blazars like the Markarian sources are at a redshift that is ten times smaller, and therefore TXS 0506+056, with a similar flux despite the greater distance, is one of the most luminous sources in the Universe. It likely belongs to a special class of blazars that accelerate proton beams as revealed by the neutrino. This is further supported by the fact that a variety of previous attempts to associate the arrival directions of cosmic neutrinos with a variety of Fermi blazar catalogues failed.

Informed by the multimessenger campaign, IceCube searched its archival neutrino data up to and including October 2017 in the direction of IC170922 using the likelihood routinely used in previous searches. This revealed a spectacular burst of over a dozen high-energy neutrinos in 110 days in the 2014-2015 data with a spectral index consistent with the one observed for the diffuse cosmic neutrino spectrum[4].

Interestingly, the AGILE collaboration, which operates an orbiting X-ray and gamma ray telescope, reported a day-long flare in the direction of a previous neutrino alert sent on Juli 31, 2016[41]. The flare occurred more than one day before the time of the alert. In light of the rapid daily variations observed near the peak emission of the TXS 0506+056 flare at the time of IC170922A, this may well be a genuine coincidence.

## 4. Flaring sources and the high-energy neutrino flux

The extraordinary detection of more than a dozen cosmic neutrinos in the 2014 flare despite its 0.34 redshift further suggests that TXS 0506+056 belongs to a special class of sources that produce cosmic rays. The single neutrino flare dominates the flux of the source over the 9.5 years of archival IceCube data, leaving IC170922 as a less luminous second flare in the sample. We will show that a subset of about 5% of all blazars bursting once in 10 years at the level of TXS 0506+056 in 2014, can accommodate the diffuse flux cosmic neutrino flux observed by IceCube. We already pointed out in the previous section that the energy density corresponding to this flux is similar to the one in the highest energy cosmic rays.

In order to calculate the flux of high-energy neutrinos from a population of sources, we follow[42] and relate the diffuse neutrino flux to the injection rate of cosmic rays and their efficiency to produce neutrinos in the source. For a class of sources with density $\rho$ and neutrino luminosity $L_\nu$, the all-sky neutrino flux is

$$\sum_\alpha E_\nu^2 \frac{dN_\nu}{dE_\nu} = \frac{1}{4\pi}\frac{c}{H_0}\xi_z L_\nu \rho, \tag{4}$$

where $\xi_z$ is a factor of order unity that parametrizes the integration over the redshift evolution of the sources. The relation can be adapted to a fraction $\mathcal{F}$ of sources

with episodic emission of flares of duration $\Delta t$ over a total observation time $T$:

$$\sum_\alpha E_\nu^2 \frac{dN_\nu}{dE_\nu} = \frac{1}{4\pi}\frac{c}{H_0}\xi_z L_\nu \rho \mathcal{F}\frac{\Delta t}{T}\,. \tag{5}$$

Applying this relation to the 2014 TXS 0506+056 burst that dominates the flux over the 9.5 years of neutrino observations, yields

$$\begin{aligned} 3\times 10^{-11}\,\mathrm{TeV cm^{-2} s^{-1} sr^{-1}} = & \frac{\mathcal{F}}{4\pi}\left(\frac{R_H}{3\,\mathrm{Gpc}}\right)\left(\frac{\xi_z}{0.7}\right)\left(\frac{L_\nu}{1.2\times 10^{47}\,\mathrm{erg/s}}\right) \\ & \left(\frac{\rho}{1.5\times 10^{-8}\,\mathrm{Mpc^{-3}}}\right)\left(\frac{\Delta t}{110\,\mathrm{d}}\frac{10\,\mathrm{yr}}{T}\right), \end{aligned} \tag{6}$$

a relation which is satisfied for $\mathcal{F}\sim 0.05$. In summary, a special class of BL Lac blazars that undergo $\sim$ 110-day duration flares like TXS 0506+056 once every 10 years accommodates the observed diffuse flux of high-energy cosmic neutrinos. The class of such neutrino-flaring sources represents 5% of the sources. The argument implies the observation of roughly 100 muon neutrinos per year. This is exactly the flux of cosmic neutrinos that corresponds to the $E^{-2.19}$ diffuse flux measured above 100 TeV. (Note that the majority of these neutrinos cannot be separated from the atmospheric background, leaving us with the reduced number of very high energy events discussed in the previous sections).

As previously discussed, he energetics of the cosmic neutrinos is matched by the energy of the highest energy cosmic rays, with [43]

$$\frac{1}{3}\sum_\alpha E_\nu^2 \frac{dN_\nu}{dE_\nu} \simeq \frac{c}{4\pi}\left(\frac{1}{2}(1-e^{-f_\pi})\,\xi_z t_H \frac{dE}{dt}\right). \tag{7}$$

The cosmic rays' injection rate $dE/dt$ above $10^{16}$ eV is $(1-2)\times 10^{44}$ erg Mpc$^{-3}$ yr$^{-1}$ [44,45]. From Eq. 6 it follows that the energy densities match for a pion production efficiency of the neutrino source of $f_\pi \gtrsim 0.4$. This high efficiency requirement is consistent with the premise that a special class of efficient sources is responsible for producing the high-energy cosmic neutrino flux seen by IceCube. The sources must contain sufficient target density in photons, possibly protons, to generate the large value of $f_\pi$. It is clear that the emission of flares producing the large number of cosmic neutrinos detected in the 2014 burst must correspond to major accretion events onto the black hole lasting a few months. The pionic photons will lose energy in the source and the neutrino emission is not accompanied by a flare as was the case for the 2017 event; the Fermi data, consistent with the scenario proposed, reveal photons with energies of tens of GeV, but no flaring activity.

A key question is whether the neutrino and gamma ray spectra for the 2014 neutrino burst from TXS 0506+056 satisfy the multimessenger relationship introduced in section 2. With the low statistics of the very high-energy gamma ray measurements during the burst period, the energetics is a more robust measure for evaluating the connection, especially because the source is opaque to high-energy gamma rays, as indicated by the large value of $f_\pi$, and the pionic gamma rays will

lose energy inside the source before cascading in the microwave photon background; for details see Ref. 43.

It is worth noting that this model for the diffuse neutrino flux clarifies why earlier attempts to associate it with blazars were unsuccessful; see Ref. 46,47. Clearly, the time-integrated studies are not applicable to time-dependent sources. Moreover, with a subclass of more energetic sources with lower density responsible for the diffuse flux, the constraints on blazars obtained from the relation between the point source limits and the diffuse flux are mitigated. Additional issues with this limit arise from the use of point source sensitivity (defined as 90% C.L.) rather than discovery potential (defined as $5\sigma$ C.L.) as a constraint. The former does not provide a robust statistical measure. It has been argued that the limits from the nonobservation of a point source in time-integrated searches would suppress the contribution of blazars to the total neutrino emission because the time-averaged flux of sources is directly correlated with bursts[48]. However, two points are missed in this argument. First, this argument only applies if the duty cycle of the source and the duration of the flare, supplies neutrino bursts shorter than the total time that the detector has been taking data. Second, it neglects the excess buried under the atmospheric background which might not be statistically compelling yet. For instance, in the case of TXS 0506+056, the time-integrated search reports a significance of $2.1\sigma$ only.

We are aware that these speculations are qualitative and that they may be premature and the hope is that multimessenger astronomy will provide us with more clues after the breakthrough event of September 22, 2017 that generated an unmatched data sample over all wavelengths of the electromagnetic spectrum on the first identified cosmic ray accelerator.

## 5. Summary

Getting all the elements of this puzzle to fit together is not easy, but they suggest that the blazar may contain important clues on the origin of cosmic neutrinos and cosmic rays. This breakthrough is just the beginning and raises intriguing questions. What is special about this source? Can a subclass of blazars to which it belongs accommodate the diffuse flux observed by IceCube? Are these also the sources of all high-energy cosmic rays or only of some? The TXS 0506+056 emission over the last 10 years is dominated by the single flare in 2014. If this is characteristic of the subclass of sources that it belongs to, identifying additional sources will be difficult unless more and larger neutrino telescopes yield more frequent and higher statistics neutrino alerts.

Unlike the previous SN1987A and GW170817 multimessenger events, this event could not have been observed with a single instrument. Without the initial coincident observation, IC170922A would be just one more of the few hundred cosmic neutrinos detected by IceCube and the accompanying radiation just one more flaring blazar observed by Fermi-LAT. Neutrino astronomy was born with a supernova

in 1987. Thirty years later, this recent event involves neutrinos that are tens of millions of times more energetic and are from a source a hundred thousand times more distant.

We review our recent theoretical results about inequivalence between passive and active gravitational masses and energy in the semiclassical variant of general relativity, where the gravitational field is not quantized but matter is quantized. To this end, we consider the simplest quantum body with internal degrees of freedom — a hydrogen atom. We concentrate our attention on the following physical effects, related to electron mass. The first one is the inequivalence between passive gravitational mass and energy at the microscopic level. Indeed, the quantum measurement of gravitational mass can give a result which is different from the expected one, $m \neq m_e + \frac{E_1}{c^2}$, where the electron is initially in its ground state; $m_e$ is the bare electron mass. The second effect is that the expectation values of both the passive and active gravitational masses of stationary quantum states are equivalent to the expectation value of the energy. The most spectacular effects are the inequivalence of the passive and active gravitational masses and the energy at the macroscopic level for an ensemble of coherent superpositions of stationary quantum states. We show that, for such superpositions, the expectation values of passive and active gravitational masses are not related to the expectation value of energy by Einstein's famous equation, $m \neq \frac{E}{c^2}$. In this paper, we also improve several drawbacks of the original pioneering works.

*Keywords*: Equivalence principle; mass–energy equivalence; quantum gravity.

## 1. Introduction

The equivalence principle (EP) between gravitational and inertial masses in combination with the local Lorentz invariance of spacetime is known to be a keystone of classical general relativity[1,2]. In the current scientific literature, there exists widespread discussion of whether it can survive in a possible quantum theory of gravity (see, for example, Refs. 3–5). Since quantum gravitation theory has not been elaborated yet, the EP is often studied in the framework of the so-called semiclassical approach to quantum gravity, where the gravitational field is not quantized, but matter is quantized[3–5]. Note that the EP for a composite body is not a trivial notion even in general relativity in the absence of quantum effects. Indeed, as shown in Refs. 6–8, the external gravitational field is coupled not directly with the energy of a composite body but with the combination $R+3K+2P$, where $R$, $K$ and $P$ are the rest, kinetic and potential energies, respectively. As mentioned in Ref. 8, and considered in detail in Ref. 9, the above mentioned combination can be changed into the expected total energy if we choose the proper local coordinates, where the line interval has the Minkowski form. Therefore, in classical general relativity,

passive gravitational mass is equivalent to the inertial one for a composite body [8,9], as expected.

On the other hand, as shown in Ref. 7, active gravitational mass of a composite classical body is equivalent to its energy only after averaging the gravitational mass over time. Semiclassical analysis [5] of Einstein's field equations has demonstrated that the expectation values of active gravitational mass and energy are equivalent only for stationary quantum states of a composite quantum body. The situation is different for an ensemble of coherent quantum superpositions of stationary quantum states, where the expectation values of active gravitational mass can oscillate in time [5] even for superpositions with constant expectation values of energy. The results of Ref. 5 go against the equivalence of active gravitational mass and energy even at the macroscopic level in quantum gravity, which has to modify the EP. Note that quantum effects also change the status of the EP for the passive gravitational mass of a quantum body with internal degrees of freedom. As discussed in Ref. 10, quantum effects break the equivalence of passive gravitational mass and energy at the microscopic level.

Let us consider this phenomenon in more detail. Suppose there is a hydrogen atom in its ground state, $E_1$, and we switch on the gravitational field to measure the electron mass, which is expected to be equal to $m = m_e + \frac{E_1}{c^2}$, where $m$ is the electron passive gravitational mass and $m_e$ is the bare electron mass. Contrary to the above mentioned common expectation, it has been shown in Ref. 10 that quantum measurements of the mass can give the following result $m = m_e + \frac{E_n}{c^2}$, where $E_n$ is energy of electron $nS$ orbital in a hydrogen atom, although the corresponding probabilities are very small. Note that the influence of quantum effects on the EP is even more dramatic and, as shown in Ref. 11, the equivalence between passive gravitational mass and energy is broken even at the macroscopic level. Indeed, the above-mentioned equivalence exists for the expectation values of the mass and energy only for stationary quantum states. In accordance with results of Ref. 11, the equivalence between the expectation values of passive gravitational mass and energy is broken for an ensemble of coherent quantum superpositions of stationary quantum states in a hydrogen atom. Of course, all these statements are not restricted by this atom but are common properties of any quantum body with internal degrees of freedom.

## 2. Goal

In Sec. 3, we discuss that there is no equivalence between passive gravitational mass and energy of electron in a hydrogen atom at a microscopic level, using the local Lorentz invariance, which defines electron wave functions in a gravitational field (we call it method-1). We start from quantum state with a definite electron energy in the absence of external gravitational field, $E_1$, and show that quantum

measurement of the mass in the field can give values different from expected one, $m \neq m_e + \frac{E_1}{c^2}$, although the corresponding probabilities are small. In Sec. 4, we discuss the same results, using corrections to the Schrödinger equation for electron in a hydrogen atom, which contain the so-called virial term in the gravitational field. We stress the importance of the virial term for the breakdown of the above mentioned equivalence (and, thus, for the breakdown of the EP) at a microscopic level (we call this method-2). In Sec. 5, we discuss the breakdown of the equivalence between passive gravitational mass and energy (and, as a result — breakdown of the EP) at macroscopic level. We show that this equivalence survives for macroscopic ensemble of stationary quantum electron states in a hydrogen atom due to the so-called quantum virial theorem. On the other hand, it is also shown that for coherent ensembles of superpositions of stationary quantum states, the above mentioned equivalence is not survived due to the quantum virial term. During our calculations in Secs. 2–4, we use property of the local Lorentz invariance of a spacetime in general relativity as well as consider passive gravitational mass to be a quantity proportional to weight of a composite body whose center-of-mass is fixed in gravitational field by some forces of nongravitational origin. Finally, in Sec. 6, we discuss the EP between active gravitational mass and energy for electron in a hydrogen atom at macroscopic level. Our results are similar to that for passive gravitational mass. Indeed, we show that the equivalence (and, thus, the EP) survives for macroscopic ensembles of stationary quantum states, whereas for macroscopic coherent ensembles of superpositions of quantum states, the equivalence is broken. In Sec. 7, we come to the conclusion that the EP has to be seriously reformulated in the presence of quantum effects in general relativity.

## 3. Inequivalence of Passive Gravitational Mass and Energy at Microscopic Level (Method-1)

### 3.1. *Electron wave function in a hydrogen atom with a definite energy in the absence of gravitational field*

Suppose that, at $t < 0$, there is no gravitational field and electron is in a ground state of a hydrogen atom, characterizing by the following wave function:

$$\Psi_1(r,t) = \exp\left(\frac{-im_e c^2 t}{\hbar}\right) \exp\left(\frac{-iE_1 t}{\hbar}\right) \Psi_1(r), \tag{1}$$

which is solution of the corresponding Schrödinger equation:

$$i\hbar \frac{\partial \Psi_1(r,t)}{\partial t} = \left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r}\right] \Psi_1(r,t). \tag{2}$$

[Here, $E_1$ is electron ground state energy, $r$ is distance between electron with coordinates $(x, y, z)$ and proton; $\hbar$ is the Planck constant, $c$ is the velocity of light.]

### 3.2. *Electron wave functions in a hydrogen atom in the presence of gravitational field*

At $t = 0$, we perform the following Gedanken experiment. We switch on a weak centrosymmetric (e.g. the Earth's) gravitational field, with position of center-of-mass of the atom (i.e. proton) being fixed in the field by some nongravitational forces. It is known that, in a weak field approximation, curved spacetime is characterized by the following interval[1,2]:

$$ds^2 = -\left(1 + 2\frac{\phi}{c^2}\right)(cdt)^2 + \left(1 - 2\frac{\phi}{c^2}\right)(dx^2 + dy^2 + dz^2), \quad \phi = -\frac{GM}{R}. \tag{3}$$

Below we introduce the proper local coordinates,

$$\tilde{t} = \left(1 + \frac{\phi}{c^2}\right)t, \quad \tilde{x} = \left(1 - \frac{\phi}{c^2}\right)x, \quad \tilde{y} = \left(1 - \frac{\phi}{c^2}\right)y, \quad \tilde{z} = \left(1 - \frac{\phi}{c^2}\right)z, \tag{4}$$

where interval has Minkowski's form[1,2],

$$d\tilde{s}^2 = -(cd\tilde{t})^2 + (d\tilde{x}^2 + d\tilde{y}^2 + d\tilde{z}^2). \tag{5}$$

[Here, we stress that, since we are interested in calculations of some quantum transition amplitudes with the first-order accuracy with respect to the small parameter, $|\frac{\phi}{c^2}| \ll 1$, we disregard in Eqs. (3)–(5) and therein below all terms of the order of $\frac{\phi^2}{c^4}$. We pay attention that near the Earth's surface the above discussed parameter is small and is equal to $|\frac{\phi}{c^2}| \sim 10^{-9}$.]

Due to the local Lorentz invariance of a spacetime in general relativity, if we disregard the so-called tidal terms in the Hamiltonian [i.e. if we don't differentiate the potential $\phi(R)$], then new wave functions, written in the local proper coordinates (4) (with fixed proton's position), satisfy at, $t$, $\tilde{t} > 0$, the similar Schrödinger equation:

$$i\hbar\frac{\partial\tilde{\Psi}(\tilde{r},\tilde{t})}{\partial\tilde{t}} = \left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial\tilde{x}^2} + \frac{\partial^2}{\partial\tilde{y}^2} + \frac{\partial^2}{\partial\tilde{z}^2}\right) - \frac{e^2}{\tilde{r}}\right]\tilde{\Psi}(\tilde{r},\tilde{t}). \tag{6}$$

[Note that it is easy to show that the above disregarded tidal terms have relative order of $\frac{r_0}{R_0}$, where $r_0$ is the Bohr radius and $R_0$ is distance between a hydrogen atom and center of source of gravitational field. Near the Earth's surface they are very small and are of the relative order of $\frac{r_0}{R_0} \sim 10^{-17}$.]

We stress that it is very important that the wave function (1) is not a solution of the Schrödinger equation (6) anymore and, thus, is not characterized by definite energy and weight in the gravitational field (3). Moreover, a general solution of

Eq. (6) can be written in the proper local coordinates in the following way:

$$\tilde{\Psi}(\tilde{r},\tilde{t}) = \exp\left(\frac{-im_e c^2 \tilde{t}}{\hbar}\right) \sum_{n=1}^{\infty} \tilde{a}_n \Psi_n(\tilde{r}) \exp\left(\frac{-iE_n \tilde{t}}{\hbar}\right), \tag{7}$$

where the wave functions $\Psi_n(\tilde{r})$ are solutions[12] for the so-called $nS$ atomic orbitals of a hydrogen atom with energies $E_n$ and are normalized in the proper local space,

$$\int \Psi_n^2(\tilde{r}) d^3\tilde{r} = 1. \tag{8}$$

[It is possible to show that only $1S \to nS$ quantum transitions amplitudes are nonzero in a hydrogen atom in the gravitational field (3), which corresponds only to real wave functions. Therefore, we keep in Eq. (7) only $nS$ atomic orbitals and everywhere below disregard difference between $\Psi_n(r)$ and $\Psi_n^*(r) = \Psi_n(r)$.]

Note that the normalized wave function (1) can be rewritten in the proper local spacetime coordinates (4) in the following way:

$$\Psi_1(\tilde{r},\tilde{t}) = \exp\left[\frac{-im_e c^2 \left(1-\frac{\phi}{c^2}\right)\tilde{t}}{\hbar}\right] \exp\left[\frac{-iE_1 \left(1-\frac{\phi}{c^2}\right)\tilde{t}}{\hbar}\right]$$
$$\times \left(1+\frac{\phi}{c^2}\right)^{3/2} \Psi_1\left[\left(1+\frac{\phi}{c^2}\right)\tilde{r}\right]. \tag{9}$$

It is important that the gravitational field (3) can be considered as a sudden perturbation to the Hamiltonian (2), therefore, at $t = \tilde{t} = 0$, the wave functions (7) and (9) have to be equal to each other:

$$\left(1+\frac{\phi}{c^2}\right)^{3/2} \Psi_1\left[\left(1+\frac{\phi}{c^2}\right)\tilde{r}\right] = \sum_{n=1}^{\infty} \tilde{a}_n \Psi_n(\tilde{r}). \tag{10}$$

From Eq. (10), it directly follows that

$$\tilde{a}_1 = \left(1+\frac{\phi}{c^2}\right)^{3/2} \int_0^{\infty} \Psi_1\left[\left(1+\frac{\phi}{c^2}\right)\tilde{r}\right] \Psi_1(\tilde{r}) d^3\tilde{r}, \tag{11}$$

and

$$\tilde{a}_n = \left(1+\frac{\phi}{c^2}\right)^{3/2} \int_0^{\infty} \Psi_1\left[\left(1+\frac{\phi}{c^2}\right)\tilde{r}\right] \Psi_n(\tilde{r}) d^3\tilde{r}, \quad n > 1. \tag{12}$$

### 3.3. *Probabilities and amplitudes*

Below, we calculate quantum mechanical amplitudes (11) and (12) in a linear approximation with respect to the gravitational potential,

$$\tilde{a}_1 = 1 + O\left(\frac{\phi^2}{c^4}\right), \tag{13}$$

and

$$\tilde{a}_n = \left(\frac{\phi}{c^2}\right)\int_0^\infty \left[\frac{d\Psi_1(\tilde{r})}{d\tilde{r}}\right]\tilde{r}\Psi_n(\tilde{r})d^3\tilde{r}, \quad n>1. \tag{14}$$

We stress that the wave function (7) is a series of wave functions, which have definite weights in the gravitational field (3). This means that they are characterized by the following definite electron passive gravitational masses:

$$m_n = m_e + \frac{E_n}{c^2}. \tag{15}$$

In accordance with the most general properties of quantum mechanics, this means that, if we do a measurement of gravitational mass for wave function (1) and (9), we obtain quantum values (15) with the probabilities: $\tilde{P}_n = |\tilde{a}_n|^2$, where $\tilde{a}_n$ are given by Eqs. (13) and (14).

Let us show that

$$\int_0^\infty \left[\frac{d\Psi_1(\tilde{r})}{d\tilde{r}}\right]\tilde{r}\Psi_n(\tilde{r})d^3\tilde{r} = \frac{V_{1n}}{E_n - E_1}, \quad n>1, \tag{16}$$

where $\hat{V}(\tilde{r})$ is the so-called quantum virial operator [12]:

$$\hat{V}(r) = -2\frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial\tilde{x}^2}+\frac{\partial^2}{\partial\tilde{y}^2}+\frac{\partial^2}{\partial\tilde{z}^2}\right) - \frac{e^2}{\tilde{r}}, \tag{17}$$

and

$$V_{1,n} = \int_0^\infty \Psi_1(\tilde{r})\hat{V}(\tilde{r})\Psi_n(\tilde{r})d^3\tilde{r}. \tag{18}$$

To this end, we rewrite the Schrödinger equation in gravitational field (6) in terms of the initial coordinates $(x, y, z)$

$$(m_e c^2 + E_1)\Psi_1\left[\left(1-\frac{\phi}{c^2}\right)r\right] = \left[m_e c^2 - \frac{1}{\left(1-\frac{\phi}{c^2}\right)^2}\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right) - \frac{1}{\left(1-\frac{\phi}{c^2}\right)}\frac{e^2}{r}\right]\Psi_1\left[\left(1-\frac{\phi}{c^2}\right)r\right]. \tag{19}$$

Then, keeping as usual only terms of the first order with respect to the small parameter $|\frac{\phi}{c^2}| \ll 1$, we obtain

$$E_1\Psi_1(r) - \frac{\phi}{c^2}E_1 r\left[\frac{d\Psi_1(r)}{dr}\right] = \left[-\frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r} + \frac{\phi}{c^2}\hat{V}(r)\right] \times \left[\Psi_1(r) - \frac{\phi}{c^2}r\left[\frac{d\Psi_1(r)}{dr}\right]\right], \tag{20}$$

and as a result

$$-E_1 r\left[\frac{d\Psi_1(r)}{dr}\right] = \left[-\frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r}\right]\left[-r\frac{d\Psi_1(r)}{dr}\right] + \hat{V}(r)\Psi_1(r). \tag{21}$$

Let us multiply Eq. (21) on $\Psi_1(r)$ and integrate over space,

$$-E_1 \int_0^\infty \Psi_n(r) r \left[\frac{d\Psi_1(r)}{dr}\right] d^3r = \int_0^\infty \Psi_n(r) \left[-\frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right)-\frac{e^2}{r}\right] \times \left[-r\frac{d\Psi_1(r)}{dr}\right] d^3r + \int_0^\infty \Psi_n(r)\hat{V}(r)\Psi_1(r)d^3r. \tag{22}$$

Taking into account that the Hamiltonian operator is the Hermitian one, we rewrite Eq. (22) as

$$E_1 \int_0^\infty \Psi_n(r) r \left[\frac{d\Psi_1(r)}{dr}\right] d^3r = E_n \int_0^\infty \Psi_n(r) r \left[\frac{d\Psi_1(r)}{dr}\right] d^3r - \int_0^\infty \Psi_1(r)\hat{V}(r)\Psi_n(r)d^3r. \tag{23}$$

Then, Eqs. (16)–(18) directly follow from Eq. (23).

As a result, the calculated amplitudes (14) and the corresponding probabilities for $n \neq 1$ can be rewritten as functions of matrix elements (18) of the virial operator (17),

$$\tilde{a}_n = \left(\frac{\phi}{c^2}\right)\frac{V_{1,n}}{E_n - E_1}, \tag{24}$$

and

$$\tilde{P}_n = |\tilde{a}_n|^2 = \left(\frac{\phi}{c^2}\right)^2 \left(\frac{V_{1,n}}{E_n - E_1}\right)^2. \tag{25}$$

Note that near the Earth's surface, where $\frac{\phi^2}{c^4} \approx 0.49 \times 10^{-18}$, the probability for $n = 2$ in a hydrogen atom can be calculated as

$$\tilde{P}_2 = |\tilde{a}_2|^2 = 1.5 \times 10^{-19}, \tag{26}$$

where

$$\frac{V_{1,2}}{E_2 - E_1} = 0.56. \tag{27}$$

It is important that nonzero matrix elements (18) of the virial operator (17) for $n \neq 1$ are also responsible for breakdown of the equivalence between active gravitational mass and energy for a quantum body with internal degrees of freedom [5].

## 4. Inequivalence of Passive Gravitational Mass and Energy at Microscopic Level (Method-2)

### 4.1. *Schrödinger equation with a definite energy in the absence of gravitational field*

As in the previous section, at $t < 0$, gravitational field is zero and electron occupies ground state in a hydrogen atom, characterizing by the wave function (1). As we

have already discussed, the wave function (1) corresponds to the $1S$ electron orbital and is known to be a ground state solution of Eq. (2).

### 4.2. *Schrödinger equation in the presence of gravitational field*

Let us consider the same Gedanken experiment as in Sec. 3. We switch on the weak gravitational field (3) and obtain Eq. (6) for the wave functions in the proper local spacetime coordinates (4). But, in this section, we rewrite Eq. (6) in the initial spacetime coordinates, $(t, x, y, z)$,

$$i\hbar\frac{\partial\Psi(\mathbf{r},t)}{\partial t} = \left\{\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r}\right]\right.$$
$$\left. + \left(\frac{\phi}{c^2}\right)\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r} + \hat{V}(\mathbf{r})\right]\right\}\Psi(\mathbf{r},t), \tag{28}$$

where the virial operator [12], $\hat{V}(r)$, is equal to (17). From Eq. (28), it directly follows that the external gravitational field (3) is coupled not only to Hamiltonian (2) but also to the virial operator (17). It is important that the virial term (17) does not commute with the Hamiltonian (2), therefore, it breaks the equivalence of the passive gravitational mass and energy for electron in a hydrogen atom.

#### 4.2.1. *More general Lagrangian*

Here, we derive Hamiltonian (28) from more general Lagrangian. Let us consider the Lagrangian of a three-body system: a hydrogen atom and the Earth in inertial coordinate system, treating gravitation (3) as a small perturbation in Minkowski's spacetime. In this case, we can make use of the results of Ref. 7, where the corresponding $n$-body Lagrangian is calculated as a sum of the following four terms:

$$L = L_{\rm kin} + L_{\rm em} + L_G + L_{e,G}, \tag{29}$$

where $L_{\rm kin}$, $L_{\rm em}$, $L_G$, and $L_{e,G}$ are kinetic, electromagnetic, gravitational and electric-gravitational parts of the Lagrangian, respectively. We recall that, in our approximation, we keep in the Lagrangian and Hamiltonian only terms of the order of $(v/c)^2$ and $|\phi|/c^2$ as well as keep only classical kinetic and the Coulomb electrostatic potential energies couplings with external gravitational field. It is possible to show that, in our case, different contributions to the Lagrangian (29) can be simplified:

$$L_{\rm kin} + L_{\rm em} = -Mc^2 - m_p c^2 - m_e c^2 + m_e\frac{\mathbf{v}^2}{2} + \frac{e^2}{r}, \tag{30}$$

$$L_G = G\frac{m_p M}{R} + G\frac{m_e M}{R} + \frac{3}{2}G\frac{m_e M}{R}\frac{\mathbf{v^2}}{c^2}, \tag{31}$$

$$L_{e,G} = -2G\frac{M}{Rc^2}\frac{e^2}{r}, \tag{32}$$

where, as usual, we use the inequality $m_p \gg m_e$, with $m_p$ being the bare proton mass.

If we keep only those terms in the Lagrangian which are related to electron motion (as usual, proton is supposed to be supported by some nongravitational forces in the gravitational field), then we can write the Lagrangian (30)–(32) in the following form:

$$L = -m_e c^2 + m_e \frac{\mathbf{v}^2}{2} + \frac{e^2}{r} - \frac{\phi(R)}{c^2}\left[m_e + 3m_e\frac{\mathbf{v}^2}{2} - 2\frac{e^2}{r}\right], \quad \phi(R) = -G\frac{M}{R}. \tag{33}$$

It is easy to show that the corresponding electron Hamiltonian is

$$\tilde{H} = \left\{\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r}\right] + \left(\frac{\phi}{c^2}\right)\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r} + \hat{V}(\mathbf{r})\right]\right\}. \tag{34}$$

Note that Eq. (34) exactly coincides with electron Hamiltonian (28), obtained by us in the previous section.

4.2.2. *More general Hamiltonian*

Let us derive the Hamiltonian (28) and (34) from more general arguments. The so-called gravitational Stark effect (i.e. the mixing effect between even and odd wave functions in a hydrogen atom in gravitational field) was studied in Ref. 13 in the weak external gravitational field (3). Note that the corresponding Hamiltonian was derived in $1/c^2$ approximation and a possibility of center-of-mass of the atom motion was taken into account. The main peculiarity of the calculations in the above-mentioned paper was the fact that not only terms of the order of $\phi/c^2$ were calculated, as in our case, but also terms of the order of $\phi'/c^2$. Here, we use a symbolic notation $\phi'$ for the first derivatives of gravitational potential. In accordance with the existing tradition, we refer to the latter terms as to the tidal ones. Note that the Hamiltonian (3.24) was obtained in Ref. 13 directly from the Dirac equation in a curved spacetime of general relativity. As shown in Ref. 13, it can be rewritten for the corresponding Schrödinger equation as a sum of the four terms:

$$\hat{H}(\hat{\mathbf{P}}, \hat{\mathbf{p}}, \tilde{\mathbf{R}}, r) = \hat{H}_0(\hat{\mathbf{P}}, \hat{\mathbf{p}}, r) + \hat{H}_1(\hat{\mathbf{P}}, \hat{\mathbf{p}}, \tilde{\mathbf{R}}, r) + \hat{H}_2(\hat{\mathbf{p}}, \mathbf{r}) + \hat{H}_3(\hat{\mathbf{P}}, \hat{\mathbf{p}}, \tilde{\mathbf{R}}, r), \tag{35}$$

$$\hat{H}_0(\hat{\mathbf{P}}, \hat{\mathbf{p}}, r) = m_e c^2 + m_p c^2 + \left[\frac{\hat{\mathbf{P}}^2}{2(m_e + m_p)} + \frac{\hat{\mathbf{p}}^2}{2\mu}\right] - \frac{e^2}{r}, \tag{36}$$

$$\hat{H}_1(\hat{\mathbf{P}}, \hat{\mathbf{p}}, \tilde{\mathbf{R}}, r) = \left\{m_e c^2 + m_p c^2 + \left[3\frac{\hat{\mathbf{P}}^2}{2(m_e + m_p)} + 3\frac{\hat{\mathbf{p}}^2}{2\mu} - 2\frac{e^2}{r}\right]\right\}\left(\frac{\phi - \mathbf{g}\tilde{\mathbf{R}}}{c^2}\right), \tag{37}$$

$$\hat{H}_2(\hat{\mathbf{p}},\mathbf{r}) = \frac{1}{c^2}\left(\frac{1}{m_e}-\frac{1}{m_p}\right)[-(\mathbf{gr})\hat{\mathbf{p}}^2 + i\hbar\mathbf{g}\hat{\mathbf{p}}]$$
$$+\frac{1}{c^2}\mathbf{g}\left(\frac{\hat{\mathbf{s}}_\mathbf{e}}{m_e}-\frac{\hat{\mathbf{s}}_p}{m_p}\right)\times\hat{\mathbf{p}} + \frac{e^2(m_p-m_e)}{2(m_e+m_p)c^2}\frac{\mathbf{gr}}{r}, \tag{38}$$

$$\hat{H}_3(\hat{\mathbf{P}},\hat{\mathbf{p}},\tilde{\mathbf{R}},r) = \frac{3}{2}\frac{i\hbar\mathbf{gP}}{(m_e+m_p)c^2} + \frac{3}{2}\frac{\mathbf{g}(\mathbf{s_e}+\mathbf{s_p})\times\mathbf{P}}{(m_e+m_p)c^2}$$
$$-\frac{(\mathbf{gr})(\mathbf{Pp})+(\mathbf{Pr})(\mathbf{gp})-i\hbar\mathbf{gP}}{(m_e+m_p)c^2}, \tag{39}$$

where $\mathbf{g} = -G\frac{M}{R^3}\mathbf{R}$. Note that we use the following notations in Eqs. (35)–(39): $\tilde{\mathbf{R}}$ and $\mathbf{P}$ stand for coordinate and momentum of a hydrogen atom center-of-mass, respectively; whereas, $\mathbf{r}$ and $\mathbf{p}$ stand for relative electron coordinate and momentum in center-of-mass coordinate system; $\mu = m_e m_p/(m_e+m_p)$ is the so-called reduced electron mass. We point out that $\hat{H}_0(\hat{\mathbf{P}},\hat{\mathbf{p}},r)$ is the Hamiltonian of a hydrogen atom in the absence of the field. It is important that the Hamiltonian $\hat{H}_1(\hat{\mathbf{P}},\hat{\mathbf{p}},\tilde{\mathbf{R}},r)$ describes couplings not only of the bare electron and proton masses with the gravitational field (3) but also couplings of electron kinetic and potential energies with the field. And finally, the Hamiltonians $\hat{H}_2(\hat{\mathbf{p}},\mathbf{r})$ and $\hat{H}_3(\hat{\mathbf{P}},\hat{\mathbf{p}},\tilde{\mathbf{R}},r)$ describe only the tidal effects.

Let us strictly derive the Hamiltonian (28) and (34), which has already been semi-quantitatively derived, from the more general Hamiltonian (35)–(39). As already mentioned, we use the approximation, where $m_p \gg m_e$, and, therefore, $\mu = m_e$. In particular, this allows us to consider proton as a heavy classical particle. We recall that we need to derive the Hamiltonian of the atom, whose center-of-mass is at rest with respect to the Earth. Thus, we can omit the center-of-mass kinetic energy and center-of-mass momentum. As a result, the first two contributions to electron part of the total Hamiltonian (35)–(39) can be written in the following way:

$$\hat{H}_0(\hat{\mathbf{p}},r) = m_e c^2 + \frac{\hat{\mathbf{p}}^2}{2m_e} - \frac{e^2}{r}, \tag{40}$$

and

$$\hat{H}_1(\hat{\mathbf{p}},r) = \left\{m_e c^2 + \left[3\frac{\hat{\mathbf{p}}^2}{2m_e} - 2\frac{e^2}{r}\right]\right\}\left(\frac{\phi}{c^2}\right), \tag{41}$$

where we place the center-of-mass of the atom at point $\tilde{\mathbf{R}} = 0$. Now, let us study the first tidal term (38) in the total Hamiltonian (35). At first, we pay attention that $|\mathbf{g}| \simeq |\phi|/R_0$. Then, as is well known, in a hydrogen atom $|\mathbf{r}| \sim \hbar/|\mathbf{p}| \sim r_B$ and $\mathbf{p}^2/(2m_e) \sim e^2/r_B$. These values allow us to evaluate the first tidal term (38) in the Hamiltonian (35) as $H_2 \sim (r_B/R_0)(|\phi|/c^2)(e^2/r_B) \sim 10^{-17}(|\phi|/c^2)(e^2/r_B)$. Note that this value is $10^{-17}$ times smaller than $H_1 \sim (|\phi|/c^2)(e^2/r_B)$ and $10^{-8}$ times smaller than the second correction with respect to the small parameter $|\phi|/c^2$. Therefore, we can disregard the contribution (38) to the total Hamiltonian (35).

As to the second tidal term (39) in the total Hamiltonian, we pay attention that it is exactly zero in the case, where $\mathbf{P} = 0$, considered in this review. Therefore, we can conclude that the Hamiltonian (40) and (41), derived in this section, exactly coincides with in the one that was semi-quantitatively derived by us earlier [see Eqs. (28) and (34)].

### 4.3. *Gravitational field as a perturbation to the Hamiltonian*

It is important that the gravitational field (3), under the condition of our Gedanken experiment, can be considered as the following sudden perturbation, $\hat{U}_1(\mathbf{r}, t)$, to the Hamiltonian (2) in the absence of gravitational field:

$$\hat{U}_1(\mathbf{r}, t) = \left(\frac{\phi}{c^2}\right)\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r} + \hat{V}(\mathbf{r})\right]\Theta(t), \quad (42)$$

where $\Theta(t)$ is the so-called step function. Then, a general solution of Eq. (28) can be written in the following way:

$$\Psi(r,t) = \exp\left(\frac{-i\tilde{m}_e c^2 t}{\hbar}\right)\Psi_1^1(r)\exp\left(\frac{-i\tilde{E}_1 t}{\hbar}\right) + \exp\left(\frac{-im_e c^2 t}{\hbar}\right)\sum_{n>1}^{\infty} a_n \Psi_n(r)\exp\left(\frac{-iE_n t}{\hbar}\right), \quad (43)$$

where the wave functions $\Psi_n(r)$ are solutions for the $nS$ orbitals in a hydrogen atom and are normalized,

$$\int [\Psi_1^1(r)]^2 d^3r = 1; \quad \int [\tilde{\Psi}_n(r)]^2 d^3r = 1, \quad n > 1. \quad (44)$$

[It is easy to show that perturbation (42) can result only in nonzero quantum transitions between $1S$ and $nS$ electron orbitals, therefore, we keep in Eq. (43) only $\Psi_n(r)$ wave functions which are real.]

According to the standard time-dependent perturbation theory [12], the corrected wave function of ground state, $\Psi_1^1(r)$, as well as the corrections to mass and energy of ground state in Eq. (43) can be written as

$$\Psi_1^1(r) = \Psi_1(r) + \left(\frac{\phi}{c^2}\right)\sum_{n>1}^{\infty}\frac{V_{n,1}}{E_1 - E_n}\Psi_n(r),$$
$$\tilde{m}_e = \left(1 + \frac{\phi}{c^2}\right)m_e, \quad \tilde{E}_1 = \left(1 + \frac{\phi}{c^2}\right)E_1, \quad (45)$$

where $V_{n,1}$ is matrix element of the virial operator (17):

$$V_{n,1} = \int \Psi_n(r)\left[-2\frac{\hbar^2}{2m}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r}\right]\Psi_1(r)d^3\mathbf{r}. \quad (46)$$

Note that the very last term in Eq. (45) corresponds to the so-called red shift in gravitational field. It is due to the expected contribution to passive gravitational

mass from electron binding energy in the atom. As to the coefficients $a_n$ with $n \neq 1$ in Eq. (43), they can be also written in terms of the virial operator matrix elements,

$$a_n = -\left(\frac{\phi}{c^2}\right)\left(\frac{V_{n,1}}{E_1 - E_n}\right), \tag{47}$$

and coincides with Eq. (24). Note that the wave function in (43)–(47), which corresponds to electron ground energy level in the presence of the gravitational field (3) (i.e. at $t > 0$), is a series of eigenfunctions of electron energy operator, taken in the absence of the field. Therefore, if we measure energy, in electron quantum state (43)–(47), we obtain the following quantized values for electron gravitational mass:

$$m_n = m_e + \frac{E_n}{c^2}, \tag{48}$$

where we omit the red shift effect. From Eqs. (43)–(48), we can state that the expected Einstein's equation, $m = m_e + \frac{E_1}{c^2}$, survives in our case with probability close to 1, whereas with the following small probabilities,

$$P_n = |a_n|^2 = \left(\frac{\phi}{c^2}\right)^2 \frac{V_{n,1}^2}{(E_n - E_1)^2}, \quad n \neq 1, \tag{49}$$

it is broken. The reason for this breakdown is that, the virial term (17) does not commute with the Hamiltonian (2) in the absence of gravitational field. As a result, electron wave functions with definite passive gravitational masses are not characterized by definite energies in the absence of gravitational field. It is important that our current results coincide with that obtained in Sec. 3 by a different method.

### 4.4. *Experimental aspects*

Here, let us describe another Gedanken experiment, where gravitational field is adiabatically switched on. To this end, we consider wave function (1) to be valid at $t \to -\infty$ and apply the following perturbation, due to the gravitational field (3), for the Hamiltonian (2):

$$\hat{U}_2(\mathbf{r}, t) = \left(\frac{\phi}{c^2}\right)\left[m_e c^2 - \frac{\hbar^2}{2m_e}\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}\right) - \frac{e^2}{r} + \hat{V}(\mathbf{r})\right]\exp(\lambda t), \quad \lambda \to 0. \tag{50}$$

Then, at $t \simeq 0$ (i.e. in the presence of the field), the electron wave function can be written as

$$\Psi(r, t) = \exp\left(\frac{-i\tilde{m}_e c^2 t}{\hbar}\right)\Psi_1^1(r)\exp\left(\frac{-i\tilde{E}_1 t}{\hbar}\right) + \exp\left(\frac{-im_e c^2 t}{\hbar}\right)\sum_{n>1}^{\infty} a_n \Psi_n(r)\exp\left(\frac{-iE_n t}{\hbar}\right). \tag{51}$$

Application of the standard time-dependent perturbation theory [12] in the case of adiabatic switching on gravitational field results in

$$\Psi_1^1(r) = \Psi_1(r) + \left(\frac{\phi}{c^2}\right) \sum_{n>1}^{\infty} \frac{V_{n,1}}{E_1 - E_n} \Psi_n(r),$$
$$\tilde{m}_e = \left(1 + \frac{\phi}{c^2}\right) m_e, \quad \tilde{E}_1 = \left(1 + \frac{\phi}{c^2}\right) E_1, \tag{52}$$

and

$$a_n = 0, \quad P_n = 0. \tag{53}$$

Thus, in adiabatic limit, the phenomenon of quantization of passive gravitational mass (15) and (48) disappears. This means that the possible experimental observation of the above mentioned phenomenon has to be done in quickly changing gravitational field. It is important that the step-like function, $\Theta(t)$, which was used to derive Eq. (48), does not mean motion of a source of gravity with velocity higher than the speed of light. We can use the step-like function if significant change of gravitational field happens quicker than the characteristic period of quasiclassical rotation of electron in a hydrogen atom. In the case under consideration, we need the time of about $\delta t \leq t_0 = \frac{2\pi\hbar}{E_2 - E_1} \sim 10^{-15} s$. Of course, there exist much more convenient quantum systems with higher values of the parameter $t_0$, where the above discussed phenomenon could be observed. We recall that all excited energy levels are quasistationary and, thus, decay with time by emitting photons. Therefore, it is much more efficient to detect emitted photons than to directly measure a weight. As to the relatively small probabilities (24) of the mass quantization, it is not too small and can be compensated by large value of the Avogadro number, $N_A \approx 6 \times 10^{23}$. In other words, for macroscopic number of the atoms, we may have large number of emitted photons. For instance, the number of excited electrons (i.e. emitted photons) for 1000 moles of the atoms is estimated as

$$N_n = 2.95 \times 10^8 \times \left(\frac{V_{n,1}}{E_n - E_1}\right)^2, \quad N_2 = 0.9 \times 10^8. \tag{54}$$

## 5. Inequivalence Between Passive Gravitational Mass and Energy at Macroscopic Level

In Sec. 5, we perform our Gedanken experiment, where we switch on the gravitational field (3) for $t > 0$, using the gravitational field as a sudden perturbation (42). We consider two different cases: macroscopic ensemble of stationary quantum states and macroscopic ensemble of coherent superpositions of stationary quantum states. In this section, we disregard small probabilities of the order of $\frac{\phi^2}{c^2}$ [see Eqs. (25) and (49)] and, thus, ignore mass quantization phenomenon.

### 5.1. *Equivalence between passive gravitational mass and energy of stationary quantum states*

Suppose that, at $t < 0$, there is no gravitational field and we have macroscopic ensemble of hydrogen atoms with electrons being in their ground states (1). At $t > 0$, we perform our Gedanken experiment: we switch on gravitational field, which is treated as the perturbation (42) in inertial system. Let us for the moment consider one atom. At $t > 0$, general solution for electron wave function is

$$\Psi(r,t) = \exp\left(\frac{-i\tilde{m}_e c^2 t}{\hbar}\right)\Psi_1^1(r)\exp\left(\frac{-i\tilde{E}_1 t}{\hbar}\right) + \exp\left(\frac{-im_e c^2 t}{\hbar}\right)\sum_{n>1}^{\infty} a_n \Psi_n(r)\exp\left(\frac{-iE_n t}{\hbar}\right). \tag{55}$$

If we disregard small probabilities $a_n$ for $n > 1$, which were considered in Secs. 3 and 4, we can rewrite Eq. (55) as

$$\Psi(r,t) = \exp\left(\frac{-i\tilde{m}_e c^2 t}{\hbar}\right)\Psi_1^1(r)\exp\left(\frac{-i\tilde{E}_1 t}{\hbar}\right). \tag{56}$$

In accordance with the quantum perturbation theory [12], first-order correction to energy of wave function (56) can be written as

$$\tilde{m}_e = \left(1 + \frac{\phi}{c^2}\right) m_e, \quad \tilde{E}_1 = \left(1 + \frac{\phi}{c^2}\right) E_1, \tag{57}$$

which is a well known redshift [1]. It is important that, in Eq. (57), there is no correction due to the quantum virial term (42) and (46). The virial term correction is zero due to the so-called quantum virial theorem [12], which claims that for any value of $n$, including $n = 1$,

$$V_{n,n} = \int \Psi_n(r)\hat{V}(\mathbf{r})\Psi_n(r)d^3\mathbf{r} = 0. \tag{58}$$

Equation (57) directly demonstrates the equivalence of gravitational mass and energy at macroscopic level.

### 5.2. *Inequivalence between passive gravitational mass and energy for macroscopic coherent ensemble of superpositions of stationary quantum states*

Suppose that, in the absence of gravitational field (i.e. at $t < 0$), we have macroscopic ensemble of coherent superpositions of two wave functions, corresponding to ground state wave function, $\Psi_1(r)$, and first excited energy level wave function, $\Psi_2(r)$, in a hydrogen atom:

$$\Psi(r,t) = \frac{1}{\sqrt{2}}\exp\left(\frac{-im_e c^2 t}{\hbar}\right)\left[\exp\left(\frac{-iE_1 t}{\hbar}\right)\Psi_1(r) + \exp\left(\frac{-iE_2 t}{\hbar}\right)\Psi_2(r)\right]. \tag{59}$$

Coherent ensemble of such wave functions, where the difference between phases of functions $\Psi_1(r)$ and $\Psi_2(r)$ is fixed, is possible to create by using lasers. We perform the same Gedanken experiment and, therefore, suddenly switch on the gravitational field (3) at $t > 0$ [see the corresponding perturbation (42) to the Hamiltonian (2)]:

$$U_1(\mathbf{r}, t) = \frac{\phi}{c^2}[m_e c^2 + \hat{H}_0(\mathbf{r}) + \hat{V}(\mathbf{r})]\Theta(t). \tag{60}$$

Then, if we disregard small probabilities of the order of $\frac{\phi^2}{c^4}$ [see Eq. (25)] and, thus, don't take into account the mass quantization phenomenon (15), we can consider wave function (59) as wave function of two-level system and can use the corresponding variant of the time-dependent perturbation theory. In accordance with this theory [12], the wave functions in the gravitational field (3) can be written as

$$\Psi^1(r,t) = \exp\left(\frac{-im_e c^2 t}{\hbar}\right)\left[\exp\left(\frac{-iE_1 t}{\hbar}\right) a_1(t)\Psi_1(r) + \exp\left(\frac{-iE_2 t}{\hbar}\right) a_2(t)\Psi_2(r)\right]. \tag{61}$$

Using the results of the time-dependent perturbation theory, it is possible to find equations to determine the functions $a_1(t)$ and $a_2(t)$:

$$\begin{aligned} \frac{da_1(t)}{dt} &= -iU_{11}(t)a_1(t) - iU_{12}(t)\exp\left[-i\frac{(E_2 - E_1)t}{\hbar}\right] a_2(t), \\ \frac{da_2(t)}{dt} &= -iU_{22}(t)a_2(t) - iU_{21}(t)\exp\left[-i\frac{(E_1 - E_2)t}{\hbar}\right] a_1(t), \end{aligned} \tag{62}$$

where

$$\begin{aligned} U_{11}(t) &= \Theta(t)\frac{\phi}{c^2}\int \Psi_1^*(r)[m_e c^2 + \hat{H}(\mathbf{r}) + \hat{V}(\mathbf{r})]\Psi_1(r)d^3\mathbf{r} = \Theta(t)\frac{\phi}{c^2}(m_e c^2 + E_1), \\ U_{12}(t) &= \Theta(t)\frac{\phi}{c^2}\int \Psi_1^*(r)[m_e c^2 + \hat{H}(\mathbf{r}) + \hat{V}(\mathbf{r})]\Psi_2(r)d^3\mathbf{r} = \Theta(t)\frac{\phi}{c^2}V_{12}, \\ U_{22}(t) &= \Theta(t)\frac{\phi}{c^2}\int \Psi_2^*(r)[m_e c^2 + \hat{H}(\mathbf{r}) + \hat{V}(\mathbf{r})]\Psi_2(r)d^3\mathbf{r} = \Theta(t)\frac{\phi}{c^2}(m_e c^2 + E_2), \\ U_{21}(t) &= \Theta(t)\frac{\phi}{c^2}\int \Psi_2^*(r)[m_e c^2 + \hat{H}(\mathbf{r}) + \hat{V}(\mathbf{r})]\Psi_1(r)d^3\mathbf{r} = \Theta(t)\frac{\phi}{c^2}V_{21}, \end{aligned} \tag{63}$$

where $V_{ij}$ are matrix elements of the virial operator (17). After substitution of Eq. (63) in Eq. (62), it possible to find that the function (59) is

$$\Psi^1(r,t) = \exp\left(\frac{-im_e c^2 t}{\hbar}\right)[\Psi_1^1(r,t) + \Psi_2^1(r,t)], \tag{64}$$

where

$$\Psi_1^1(r,t) = \frac{1}{\sqrt{2}} \exp\left[-i\frac{(m_e c^2 + E_1)\phi t}{c^2\hbar}\right] \exp\left(-i\frac{E_1 t}{\hbar}\right) \left[1 - \frac{\phi V_{12}}{c^2(E_2 - E_1)}\right] \Psi_1(r) + \frac{1}{\sqrt{2}} \exp\left(-i\frac{E_2 t}{\hbar}\right) \frac{\phi V_{12}}{c^2(E_2 - E_1)} \Psi_1(r), \tag{65}$$

and

$$\Psi_2^1(r,t) = \frac{1}{\sqrt{2}} \exp\left[-i\frac{(m_e c^2 + E_2)\phi t}{c^2\hbar}\right] \exp\left(-i\frac{E_2 t}{\hbar}\right) \left[1 - \frac{\phi V_{21}}{c^2(E_1 - E_2)}\right] \Psi_2(r) + \frac{1}{\sqrt{2}} \exp\left(-i\frac{E_1 t}{\hbar}\right) \frac{\phi V_{21}}{c^2(E_1 - E_2)} \Psi_2(r). \tag{66}$$

It is possible to demonstrate that with accuracy to the first order of the small parameter, $\frac{|\phi|}{c^2} \ll 1$, the wave function (64)–(66) can be written as

$$\Psi^1(r,t) = \frac{1}{\sqrt{2}} \exp\left[-i\frac{(m_e c^2 + E_1)(1+\phi)t}{c^2\hbar}\right] \left\{ \left[1 - \frac{\phi V_{12}}{c^2(E_2 - E_1)}\right] \Psi_1(r) + \frac{\phi V_{21}}{c^2(E_1 - E_2)} \Psi_2(r) \right\} + \frac{1}{\sqrt{2}} \exp\left[-i\frac{(m_e c^2 + E_2)(1+\phi)t}{c^2\hbar}\right] \left\{ \left[1 - \frac{\phi V_{21}}{c^2(E_1 - E_2)}\right] \Psi_2(r) + \frac{\phi V_{12}}{c^2(E_2 - E_1)} \Psi_1(r) \right\}, \tag{67}$$

where the wave function is normalized with the same accuracy:

$$\int [\Psi^1(r,t)]^* \Psi^1(r,t) d^3 r = 1 + O\left(\frac{\phi^2}{c^4}\right). \tag{68}$$

Taking into account that we consider macroscopic coherent ensemble of superposition of quantum states (59) and (67), it is easy to calculate the expectation value of energy per one electron in gravitational field for wave function (67):

$$\langle E \rangle = m_e c^2 \left(1 + \frac{\phi}{c^2}\right) + \frac{(E_1 + E_2)}{2c^2} \left(1 + \frac{\phi}{c^2}\right) + V_{12}\frac{\phi}{c^2}. \tag{69}$$

Note that the first term and the second one are expected. On the other hand, the last term contains contribution to the weight of macroscopic coherent ensemble from the virial term (17) and breaks the equivalence of passive gravitational mass and energy for quantum superposition of stationary state.

Note that so far we have considered macroscopic coherent ensemble of superposition of stationary wave functions, which is characterized by constant difference of phases, $\alpha = 0$, between the first and the second quantum states. If we introduce

more general macroscopic coherent ensemble,

$$\Psi(r,t) = \frac{1}{\sqrt{2}} \exp\left(\frac{-im_e c^2 t}{\hbar}\right) \left[\exp\left(\frac{-iE_1 t}{\hbar}\right) \Psi_1(r) + \exp(i\alpha) \exp\left(\frac{-iE_2 t}{\hbar}\right) \Psi_2(r)\right], \tag{70}$$

the expectation value of energy in the gravitational field (3) is changed,

$$\langle E \rangle = m_e c^2 \left(1 + \frac{\phi}{c^2}\right) + \frac{(E_1 + E_2)}{2c^2} \left(1 + \frac{\phi}{c^2}\right) + V_{12} \cos\alpha \frac{\phi}{c^2}. \tag{71}$$

It is important that Eqs. (69) and (71) directly demonstrate the breakdown of the equivalence between gravitational mass and energy at macroscopic level for coherent ensemble of superposition of stationary quantum state. On the other hand, for the noncoherent ensembles, phase $\alpha$ is not fixed in Eq. (71) and, thus, the last virial terms quickly averages to zero.

## 6. Inequivalence Between Active Gravitational Mass and Energy at Macroscopic Level

In this section, we review our results [5,10], where we showed that active gravitational mass and energy were inequivalent to each other at macroscopic level for coherent ensembles of quantum superpositions of stationary states.

### 6.1. *Active gravitational mass in classical physics*

Here, we determine electron active gravitational mass in a classical model of a hydrogen atom, which takes into account electron kinetic and potential energies [7]. More specifically, we consider a particle with small bare mass $m_e$, moving in the Coulomb electrostatic field of a heavy particle with bare mass $m_p \gg m_e$. Our task is to find gravitational potential at large distance from the atom, $R \gg r_B$, where $r_B$ is the the so-called Bohr radius (i.e. effective "size" of a hydrogen atom). Below, we use the so-called weak field gravitational theory [1,7], where the post-Newtonian gravitational potential can be represented as [5,10]

$$\phi(R,t) = -G\frac{m_p + m_e}{R} - G\int \frac{\Delta T^{\rm kin}_{\alpha\alpha}(t,\mathbf{r}) + \Delta T^{\rm pot}_{\alpha\alpha}(t,\mathbf{r})}{c^2 R} d^3\mathbf{r}, \tag{72}$$

where $\Delta T^{\rm kin}_{\alpha\beta}(t,\mathbf{r})$ and $\Delta T^{\rm pot}_{\alpha\beta}(t,\mathbf{r})$ are contributions to stress–energy tensor density, $T_{\alpha\beta}(t,\mathbf{r})$, due to kinetic and the Coulomb potential energies, respectively. We point out that, in Eq. (72), we disregard all retardation effects. Thus, in the above-discussed approximation, electron active gravitational mass is equal to

$$m^a_e = m_e + \frac{1}{c^2}\int [\Delta T^{\rm kin}_{\alpha\alpha}(t,\mathbf{r}) + \Delta T^{\rm pot}_{\alpha\alpha}(t,\mathbf{r})] d^3\mathbf{r}. \tag{73}$$

Let us calculate $\Delta T^{\rm kin}_{\alpha\alpha}(t,\mathbf{r})$, using the standard expression for stress–energy tensor density of a moving relativistic point mass [1,2]:

$$T^{\alpha\beta}_{\rm kin}(\mathbf{r},t)=\frac{m_e v^{\alpha}(t)v^{\beta}(t)}{\sqrt{1-\dfrac{v^2(t)}{c^2}}}\delta^3[\mathbf{r}-\mathbf{r}_e(t)], \tag{74}$$

where $v^{\alpha}$ is a four-velocity, $\delta^3(\ldots)$ is the three-dimensional Dirac $\delta$-function, and $\mathbf{r}_e(t)$ is a three-dimensional electron trajectory.

From Eqs. (73) and (74), it directly follows that

$$\Delta T^{\rm kin}_{\alpha\alpha}(t)=\int \Delta T^{\rm kin}_{\alpha\alpha}(t,\mathbf{r})d^3\mathbf{r}=\frac{m_e[c^2+v^2(t)]}{\sqrt{1-\dfrac{v^2(t)}{c^2}}}-m_e c^2. \tag{75}$$

Note that, although calculations of the contribution from potential energy to stress–energy tensor are more complicated, they are straightforward and can be done by using the standard formula for stress–energy tensor of electromagnetic field [2],

$$T^{\mu\nu}_{\rm em}=\frac{1}{4\pi}\left[F^{\mu\alpha}F^{\nu}_{\ \alpha}-\frac{1}{4}\eta^{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}\right], \tag{76}$$

where $\eta_{\alpha\beta}$ is the Minkowski metric tensor, $F^{\alpha\beta}$ is the so-called tensor of electromagnetic field [2]. In this paper, we use approximation, where we do not take into account magnetic field and keep only the Coulomb electrostatic field. In this approximation, we can simplify Eq. (76) and obtain from it the following expression:

$$\Delta T^{\rm pot}_{\alpha\alpha}(t)=\int \Delta T^{\rm pot}_{\alpha\alpha}(t,\mathbf{r})d^3\mathbf{r}=-2\frac{e^2}{r(t)}, \tag{77}$$

where $e$ is the electron charge. As directly follows from Eqs. (75) and (77), electron active gravitational mass can be represented in the following way:

$$m^a_e=\frac{\left[\dfrac{m_e c^2}{\left(1-\dfrac{v^2}{c^2}\right)^{1/2}}-\dfrac{e^2}{r}\right]}{c^2}+\frac{\left[\dfrac{m_e v^2}{\left(1-\dfrac{v^2}{c^2}\right)^{1/2}}-\dfrac{e^2}{r}\right]}{c^2}. \tag{78}$$

We note that the first term in Eq. (78) is the expected one. Indeed, it is the total energy contribution to the mass, whereas the second term is the so-called relativistic virial one [12]. It is important that it depends on time. Therefore, in classical physics, active gravitational mass of a composite body depends on time too. Nevertheless, in this situation, it is possible to introduce averaged over time electron active gravitational mass. This procedure results in the expected equivalence between averaged over time active gravitational mass and energy [7]:

$$\langle m^a_e\rangle_t=\frac{\left\langle\dfrac{m_e c^2}{\left(1-\dfrac{v^2}{c^2}\right)^{1/2}}-\dfrac{e^2}{r}\right\rangle_t}{c^2}+\frac{\left\langle\dfrac{m_e v^2}{\left(1-\dfrac{v^2}{c^2}\right)^{1/2}}-\dfrac{e^2}{r}\right\rangle_t}{c^2}=m_e+\frac{E}{c^2}. \tag{79}$$

We point out that, in Eq. (79), the averaged over time virial term is zero due to the classical virial theorem. It is easy to show that for nonrelativistic case, our Eqs. (78) and (79) can be simplified to

$$m_e^a = m_e + \frac{\left(\dfrac{m_e v^2}{2} - \dfrac{e^2}{r}\right)}{c^2} + \frac{\left(2\dfrac{m_e v^2}{2} - \dfrac{e^2}{r}\right)}{c^2}, \tag{80}$$

and

$$\langle m_e^a \rangle_t = m_e + \frac{\left\langle \dfrac{m_e v^2}{2} - \dfrac{e^2}{r} \right\rangle_t}{c^2} + \frac{\left\langle 2\dfrac{m_e v^2}{2} - \dfrac{e^2}{r} \right\rangle_t}{c^2} = m_e + \frac{E}{c^2}. \tag{81}$$

### 6.2. *Active gravitational mass in quantum physics*

In this section, we consider the so-called semiclassical theory of gravity [14], where, in the Einstein's field equation, gravitational field is not quantized but the matter is quantized:

$$R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} = \frac{8\pi G}{c^4} \langle \hat{T}_{\mu\nu} \rangle. \tag{82}$$

Here, $\langle \hat{T}_{\mu\nu} \rangle$ is the expectation value of quantum operator, corresponding to the stress–energy tensor. To make use of Eq. (82), we have to rewrite Eq. (80) for electron active gravitational mass using momentum, instead of velocity. Then, we can quantize the obtained result:

$$\hat{m}_e^a = m_e + \frac{\left(\dfrac{\hat{\mathbf{p}}^2}{2m_e} - \dfrac{e^2}{r}\right)}{c^2} + \frac{\left(2\dfrac{\hat{\mathbf{p}}^2}{2m_e} - \dfrac{e^2}{r}\right)}{c^2}. \tag{83}$$

Note that Eq. (83) represents electron active gravitational mass operator. As directly follows, the expectation value of electron active gravitational mass can be written as

$$\langle \hat{m}_e^a \rangle = m_e + \frac{\left\langle \dfrac{\hat{\mathbf{p}}^2}{2m_e} - \dfrac{e^2}{r} \right\rangle}{c^2} + \frac{\left\langle 2\dfrac{\hat{\mathbf{p}}^2}{2m_e} - \dfrac{e^2}{r} \right\rangle}{c^2}, \tag{84}$$

where third term is the virial one.

#### 6.2.1. *Equivalence of the expectation values of active gravitational mass and energy for stationary quantum states*

Now, we consider a macroscopic ensemble of hydrogen atoms with each of them being in the $n$th energy level. For such ensemble, the expectation value of the mass (83) is

$$\langle \hat{m}_e^a \rangle = m_e + \frac{E_n}{c^2}. \tag{85}$$

In Eqs. (84) and (85), we take into account that the expectation value of the virial term is equal to zero in stationary quantum states due to the quantum virial theorem [12]. Thus, we can make the following important conclusion: in stationary quantum states, active gravitational mass of a composite quantum body is equivalent to its energy at a macroscopic level [5,10].

### 6.2.2. *Inequivalence between active gravitational mass and energy for macroscopic coherent ensemble of quantum superpositions of stationary states*

Below, we introduce the simplest macroscopic coherent ensemble of quantum superpositions of the following stationary states in a hydrogen atom,

$$\Psi(r,t) = \frac{1}{\sqrt{2}} \exp\left(-i\frac{m_e c^2 t}{\hbar}\right) \left[\Psi_1(r) \exp\left(-i\frac{E_1 t}{\hbar}\right) + \exp(i\alpha)\Psi_2(r) \exp\left(-i\frac{E_2 t}{\hbar}\right)\right], \tag{86}$$

where $\Psi_1(r)$ and $\Psi_2(r)$ are the normalized wave functions of the ground state (1S) and first excited state (2S), respectively. We stress that it is possible to create the coherent superposition, where $\alpha = \text{const}$ for all macroscopic ensemble, by using lasers. It is easy to show that the superposition (86) corresponds to the following constant expectation value of energy in the absence of gravitational field,

$$\langle E \rangle = m_e c^2 + \frac{E_1 + E_2}{2}. \tag{87}$$

Nevertheless, as seen from Eq. (84), the expectation value of electron active gravitational mass operator for the wave function (86) is not constant and exhibits time-dependent oscillations:

$$\langle \hat{m}_e^a \rangle = m_e + \frac{E_1 + E_2}{2c^2} + \frac{V_{1,2}}{c^2} \cos\left[\alpha + \frac{(E_1 - E_2)t}{\hbar}\right], \tag{88}$$

where $V_{1,2}$ is matrix element of the virial operator,

$$V_{1,2} = \int \Psi_1(r) \left(2\frac{\hat{\mathbf{p}}^2}{2m_e} - \frac{e^2}{r}\right) \Psi_2(r)\, d^3\mathbf{r}, \tag{89}$$

between the above-mentioned two stationary quantum states. It is important that the oscillations (88) and (89) directly demonstrate breakdown of the equivalence between the expectation values of active gravitational mass and energy for coherent quantum superpositions of stationary states [5,10]. We pay attention to the fact that such quantum time-dependent oscillations are very general and are not restricted by the case of a hydrogen atom. They are of a pure quantum origin and do not have classical analogs.

### 6.3. *Experimental aspects*

In this section, we suggest an idealized experiment, which allows to observe quantum time-dependent oscillations of the expectation values of active gravitational mass (88). In principle, it is possible to create a macroscopic ensemble of the coherent quantum superpositions of electron stationary states in some gas with high density. It is important that these superpositions have to be characterized by the feature that each atom (or molecule) has the same phase difference between two wave function components, $\Psi_1(r)$ and $\Psi_2(r)$. In this case, the macroscopic ensemble of the atoms (or molecules) generates gravitational field, which oscillates in time similar to Eq. (88), which, in principle, can be measured. It is important to use such geometrical distributions of the molecules and a test body, where oscillations (88) are "in phase" and, thus, do not cancel each other.

## 7. Summary

In Conclusion, in this paper, we have discussed in detail the breakdown of the equivalence between active and passive gravitational masses of an electron and its energy in a hydrogen atom. We stress that the considered phenomena are very general and are not restricted by atomic physics and the Earth's gravitational field. In other words, the above discussed phenomena exist for any quantum system with internal degrees of freedom and at any gravitational field. In this paper, we also have improved several drawbacks of the original pioneering works.

Cosmological and astrophysical surveys from radio to far-infrared, in both temperature and polarization, offer a unique view of the Universe properties and of the formation and evolution of its structures. The last release, close to be finalized, of the *Planck* mission results sets the scene for cosmological models and parameters, while the comparison with other types of data sets raises the issue of possible tensions about some parameters, first of all the Hubble constant. At the same time, on the extragalactic side, *Planck* carried out the deepest systematic all-sky survey of SZ galaxy clusters and detected thousands of dusty galaxies and many hundreds of extragalactic radio sources, also allowing us to investigate many specific topics, including molecular hydrogen clouds in galactic halos. The exploitation of future generation of CMB missions and the next radio facilities will allow us to deeply investigate several topics in cosmology and astrophysics, from the existence of primordial gravitational waves to the energy releases in the primeval plasma, from the dawn ages and the epoch of reionization to the formation and evolution of early galaxies and clusters, while a wide set of open astrophysical problems can be studied with future IR missions.

*Keywords*: Cosmology; Background radiations; Radio, microwave; Origin and formation of the Universe; Observational cosmology; Large scale structure of the Universe; Galaxies.

## 1. Introduction

The past and recent surveys from radio to far-infrared have offered fundamental probes to answer to many questions of cosmology and on the formation and evolution of the cosmic structures at different scales and times. In particular, the accurate observations of cosmic microwave background (CMB) properties sanctioned

*Based on talks presented at the Fourteenth Marcel Grossmann Meeting on General Relativity, Rome, July 2015.

the passage to the so-called precision cosmology, calling for a further progress to unravel the mysteries of the early Universe and of its evolution up to the present epoch and beyond. At the same time, the information contained in the radio sky is of increasing relevance to unveil the complexity of the early stages of stars and galaxies stored in the imprints left in the cosmic background by the 21-cm redshifted line from neutral hydrogen from the dark and dawn ages to the epoch of reionization (EoR), accessible thanks to the enormous improvement of recent and future radio projects and facilities. Sub-millimetre to infrared (IR) observations offer powerful diagnostics for a broad set of astrophysical mechanisms and conditions, also because, due to the reprocessing and the cosmic expansion, a large fraction of the optical and ultraviolet radiation from stars in galaxies comes to us at longer wavelengths. The exploitation of these surveys also revealed the close connection between our comprehension of the global properties of the Universe and the detailed understanding of the astrophysical processes operating in bounded objects and in the diffuse medium at different scales.

The structure of this paper is as follows. In Sect. 2.1 we report on some of the main cosmological results from the *Planck* mission, focussing on the precise determination of cosmological parameters in the $\Lambda$ cold dark matter ($\Lambda$CDM) model and in some extensions, and discuss the issue of possible tensions about some parameters, first of all the Hubble constant. The estimation of a particular parameter combination based on the analysis of the diffuse thermal Sunyaev-Zeldovich (SZ) effect coming from all the galaxies clusters and the related so-called bias problem are discussed. In Sect. 3 we briefly describe recent proposals of future CMB missions and their main scientific purposes. Sect. 4 is dedicated to some specific topics in astrophysical cosmology, namely the study of CMB spectral distortions and of cosmic IR background (CIB) spectrum through the analysis of the cosmic dipole frequency behaviour aimed at constraining the (early and late) thermal and star formation histories, the cosmological evolution of neutral hydrogen at high redshifts through the analysis of the 21-cm redshifted line and the imprints of black holes high mass X-ray binaries microquasars in cosmic backgrounds. In Sect. 5 we move to extragalactic astrophysics. After a brief description of the *Planck* contribution in the field, we illustrate two new promising research paths, the study of early phases of galaxy evolution exploiting the strong gravitational lensing and of the cluster evolution, in relation to the prospects of future CMB experiments. We then report on an investigation of the molecular hydrogen clouds in galactic halos using *Planck* observations of the Doppler asymmetry in CMB radiation. We finally illustrate a wide set of open astrophysical problems that can be investigated with a future IR space mission.

## 2. Cosmological parameters

### 2.1. *Planck results*

The *Planck* satellite[a], launched in 2009, was equipped with a Gregorian dual reflector telescope of 1.5m diameter, whose focal plane was able to collect the microwave photons owing to two wide band cooled receiver arrays, the Low Frequency Instrument (LFI) made up of radiometers operative at 20 K, and the High Frequency Instrument (HFI) composed of bolometers working at 100 mK. The two instruments observed the sky in 9 frequency bands, performing respectively 8 and 5 nearly all sky surveys, LFI at 30, 44 and 70 GHz and HFI at 100, 143, 217, 353, 545, 857 GHz, with telescope optical axis pointing at 85° from the spin axis[1,2]. *Planck* observed the sky from a large Lissajous orbit around the Sun-Earth L2 Lagrange point in order to offer stable observing conditions and minimize contamination from side lobe pick-up of stray radiation from the Sun, Earth, and Moon, scanning the sky while spinning at 1 rpm in almost great circles. The *Planck* full width half maximum (FWHM) resolution ranges from $33.3'$ to $4.3'$ from 30 GHz to 857 GHz, and the final sensitivity per FWHM$^2$ resolution element span $\sim 2-14$ $\mu$K/K in terms of $\delta T/T$ for frequencies $\nu \leq 353$GHz.

Reprocessing LFI and HFI data, the *Planck* Collaboration released maps in temperature at the nine frequency bands and in polarization at the seven polarization sensitive bands up to 353 GHz, and extracted Stokes $T, Q, U$ parameter maps of CMB anisotropies on the whole sky with unprecedented sensitivity and resolution. For many investigations, the anisotropy signals of billions of pixels are compressed in several thousand of numbers, namely the correlators $C_\ell^{XY}$, where $X$ and $Y$ stands for $T, E, B$, at the multipole $\ell \sim 180°/\theta$, $\theta$ being the angular scale of interest. A linear combination of $Q, U$ allows us to define, in Fourier space, the pure polarization angular power spectra (APS), the so-called $E$-modes (gradient component) and $B$-modes (curl component). Together with temperature anisotropies, four APS, $C_\ell^{TT}$, $C_\ell^{EE}$, $C_\ell^{BB}$, $C_\ell^{TE}$, the latter being the temperature polarization cross correlation, were extracted. Under the assumption of random Gaussian fluctuations, the CMB APS $C_\ell^{XY}$ contain all the relevant statistical information that was indeed mainly analyzed through Markov chain Monte Carlo methods ingesting the corresponding theoretical predictions of Boltzmann codes to derive the cosmological parameters characterizing sets of models, marginalizing also over instrument and foreground residual parametrizations[3].

Cosmological results based on *Planck* observations were presented in three (2013, 2015 and 2018) subsequent releases. The temperature and polarization CMB APS are consistent with the standard spatially-flat six-parameter ΛCDM cosmology with a power-law spectrum of adiabatic scalar perturbations (denoted "base ΛCDM").

[a] *Planck* hosted instruments provided by two scientific Consortia funded by European Space Agency (ESA) member states (in particular the lead countries: France and Italy) with contributions from National Aeronautics and Space Administration (NASA), USA, and telescope reflectors provided in a collaboration between ESA and a scientific Consortium led and funded by Denmark.

Table 1. Estimation and 68 % C.L. intervals for the six-parameters of the base ΛCDM model and five derived parameters from the 2018 *Planck* release of CMB APS in $TT$ and low-$\ell$ $EE$ modes (second column) and in $TT$, $EE$ and $TE$ modes in combination with CMB lensing reconstruction and BAO (third column).

| Six-parameters of the base ΛCDM model | | |
|---|---|---|
| $\Omega_{\rm b}h^2$ | $0.02212 \pm 0.00022$ | $0.02242 \pm 0.00014$ |
| $\Omega_{\rm c}h^2$ | $0.1206 \pm 0.0021$ | $0.11933 \pm 0.00091$ |
| $100\theta_{\rm MC}$ | $1.04077 \pm 0.00047$ | $1.04101 \pm 0.00029$ |
| $\tau$ | $0.0522 \pm 0.0080$ | $0.0561 \pm 0.0071$ |
| $\ln(10^{10}A_{\rm s})$ | $3.040 \pm 0.016$ | $3.047 \pm 0.014$ |
| $n_{\rm s}$ | $0.9626 \pm 0.0057$ | $0.9665 \pm 0.0038$ |
| Derived parameters | | |
| $H_0$ [km/s/Mpc] | $66.88 \pm 0.92$ | $67.66 \pm 0.42$ |
| $\Omega_{\rm m}$ | $0.321 \pm 0.013$ | $0.3111 \pm 0.0056$ |
| $\sigma_8$ | $0.8118 \pm 0.0089$ | $0.8102 \pm 0.0060$ |
| $10^9 A_{\rm s}e^{-2\tau}$ | $1.884 \pm 0.014$ | $1.881 \pm 0.010$ |
| Age of the Universe [Gyr] | $13.830 \pm 0.037$ | $13.787 \pm 0.020$ |

Cosmological parameter results[4] from the final full-mission *Planck* measurements[5–7] have been presented in the 2018 release, combining information from the temperature and polarization maps and the lensing reconstruction and including the information from baryonic acoustic oscillations (BAO) (see Tab. 1).[b]

Compared to the 2015 results[3], the improved measurement of large-scale polarization, foreground cleaning and likelihood analysis allow us to measure the value of $\tau$ (see also Sects. 4.1 and 4.2) with higher precision, suggesting a mid-point reionization redshift in the range $\simeq 7.1 - 7.8$ only slightly dependent on the explored data set (namely, $z_{\rm re} = 7.50 \pm 0.82$ or $z_{\rm re} = 7.8 \pm 0.7$ with reference to the cases in Tab. 1), in agreement with astrophysical observations of quasar absorption lines and supporting models in which reionization happened relatively fast and late. Extensions to more general reionization models indicate that the results found for the other cosmological parameters are essentially insensitive to uncertainties in the reionization history.

The refined analysis of the small-scale polarization provided a more robust determination of many parameters, the uncertainties in the treatment of various types of residuals affecting their estimation only at the $0.5\,\sigma$ level. A remarkable, good consistency of the six parameters of the base ΛCDM model was found when considering

[b] According to ref.[4] $h = H_0/(100\,\mathrm{km/s/Mpc})$, $H_0$ being the Hubble constant; $\Omega_{\rm b}$, $\Omega_{\rm c}$ and $\Omega_{\rm m}$ are respectively the baryon, cold dark matter (CDM) and (global, non-relativistic) matter density parameters; $\tau$ is the Thomson optical depth of cosmological reionization; $\theta_{\rm MC}$ is an approximation to the acoustic scale angle $\theta_* \equiv r_*/D_{\rm M}$ where $r_*$ is the comoving sound horizon at recombination quantifying the distance the photon-baryon perturbations can influence, and $D_{\rm M} = (1+z)D_{\rm A}$, where $D_{\rm A}$ is the usual angular diameter distance, is the comoving angular diameter distance that maps this distance into an angle on the sky; $A_{\rm s}$ and $n_{\rm s}$ are the amplitude and spectral index of the power spectrum of primordial scalar perturbations; $\sigma_8$ is the matter fluctuation amplitude on a scale of $8h^{-1}$Mpc.

polarization, temperature, and lensing data, separately and in combination. Even considering many typical extensions of this model, the results found for these parameters remain substantially stable, with only a weak dependence on the adopted cosmological model and only slightly increased uncertainties in their estimation.

### 2.2. *Model extensions and the tension on the Hubble constant*

Various types of extensions of the base ΛCDM model were considered in the *Planck* 2018 release, finding no compelling evidence supporting extensions to the base ΛCDM model.

Relativistic particle influence CMB anisotropies, mainly at intermediate and small angular scales. *Planck* data in combination with BAO measurements (and considering single-parameter extensions) constrain the effective extra relativistic degrees of freedom to be $N_{\rm eff} = 2.99 \pm 0.17$, in agreement with the Standard Model prediction $N_{\rm eff} = 3.046$, and tightly constrain the neutrino mass to $\sum m_\nu < 0.12$ eV.

Standard big-bang nucleosynthesis predictions for the helium and deuterium abundances for the base ΛCDM cosmology are in excellent agreement with observations.

The CMB spectra prefer higher lensing amplitudes than predicted in base ΛCDM model at over $2\,\sigma$, which pulls some parameters that affect the lensing amplitude away from the ΛCDM model; however, this is not supported by the lensing reconstruction[8] or (in models that also change the background geometry) BAO data.

The joint constraint with BAO measurements on spatial curvature is consistent with a flat universe, $\Omega_K = 0.001 \pm 0.002$, while combining with Type Ia supernovae (SNe), the dark energy (DE) equation of state parameter is measured to be $w_0 = -1.03 \pm 0.03$, with no significant deviations from an interpretation in terms of a cosmological constant.

At the scales measured by *Planck* the primordial spectrum has been found to be well described by a pure power-law. The joint analysis of CMB polarization from *Planck*, BICEP2 and Keck Array data, in combination with measurements from BAO, sets the ratio between primordial tensor and scalar perturbations to $r < 0.07$ at the wavenumber $k = 0.002$, constraining inflationary models[9] and setting the scene for future projects (see Sect. 3).

The *Planck* base ΛCDM results are in good agreement with BAO, SNe, and some galaxy lensing observations, but in slight tension with the Dark Energy Survey's combined-probe results including galaxy clustering (which prefer lower fluctuation amplitudes or matter density parameters).

The value of the $H_0$ for the *Planck* base ΛCDM cosmology results in substantial tension, at $\simeq 3.6\,\sigma$ level, with the local determination through Type Ia SNe by ref.[10] and even more, at $\simeq 4.4\,\sigma$ level, with the most recent one by ref.[11] which implies a higher value, $H_0 = (74.03 \pm 1.5)$km/s/Mpc, while the *Planck* measurement is in excellent agreement with independent inverse-distance ladder measurements using BAO, SNe, and element abundance results. Model extensions have been

investigated in ref.[4] to resolve the tension with the value of $H_0$ from Type Ia SNe, including, other than those mentioned above, also modified gravity, DE models, recombination history, primordial scalar perturbations with running spectral index possibly combined with tensor modes, but none of these models convincingly resolves this problem.

An attempt to solve this tension involves the observational evidence of the existence of local radial inhomogeneities extending in different directions up to a redshift $z \simeq 0.07$ that could affect a significant fraction ($\sim 40\%$) of the Cepheids used for SNe calibration. Different methods used in ref.[12] to compute the effects of these inhomogeneities on the low-redshift luminosity and angular diameter distance, using an exact solution of the Einstein's equations, linear perturbation theory and a low-redshift expansion, point towards the relevance of the non-relativistic Doppler redshift correction (proportional to the volume averaged density contrast and to the comoving distance from the center). Using a new direct relation between the luminosity distance and the monopole of the density contrast, which does not involve any metric perturbation, the monopole of the density field was reconstructed through a new inversion method from the deviations of the redshift uncorrected observed luminosity distance respect to the ΛCDM prediction based on cosmological parameters obtained from large scale observations. The method suggests the existence of inhomogeneities effects not previously taken into account in density field maps at $z \leq 0.06$, used to obtain the peculiar velocity for redshift correction, i.e. at a scale not large enough for detecting inhomogeneities up to $z = 0.07$, underlying the relevance of accurately normalizing the density field respect to the average large scale density of the Universe. Of course, the CMB high-$z$ measure of $H_0$ are insensitive to local inhomogeneities.

Other methods explore observations at intermediate redshifts. For example, in ref.[13] the joint use of four different observables (SZ effect combined with X-ray surface brightness of galaxy clusters, ages of old high-redshift galaxies, observational measurements of the Hubble parameter, and BAO peak) proposed in ref.[14] was revised reconsidering the sample of galaxy clusters and performing a new characterization of systematic uncertainties, and a value of $H_0$ fully consistent with *Planck* results was inferred.

Forthcoming cosmological surveys in various bands, including those aimed at filling the gap between low and high redshifts measures of $H_0$, will allow us to firmly understand if the tension comes from observational or data analysis issues or reflects instead the imprint of physics beyond ΛCDM possibly involving, e.g., specific neutrino sector[15] or early DE[16] models.

### 2.3. *Constraints from thermal SZ power spectrum*

The *Planck* mission performed multifrequency surveys of the SZ effect, the Second *Planck* catalogue of SZ galaxy clusters (PSZ2) being the largest and deepest all-sky selected galaxy clusters archive, enclosing 1653 sources[17], $\sim 73\%$ of them with

counterparts in external data sets (see also ref.[5]). Remarkably, the *Planck* surveys allowed us to study the diffuse thermal SZ (tSZ) effect coming from all the galaxies clusters in the observable Universe through the analysis of the fluctuations of the Comptonization parameter, $y$, representing an important tool to probe clusters physics and evolution as well as cosmology[18]. In particular, the angular power spectrum of the tSZ[19], $C_\ell^{\rm tSZ} = \int {\rm d}z[{\rm d}V/({\rm d}z{\rm d}\Omega)] \int {\rm d}M({\rm d}n/{\rm d}M)\,|y_\ell\,(M,z)|^2$, depending on the halo mass function, ${\rm d}n/{\rm d}M$, and the squared amplitude of two dimensional Fourier transform of the electron pressure profile, $|y_\ell|^2$, integrated over the redshift, with the differential volume element, and over the masses, provides information on certain combinations of cosmological parameters[20].

At large scales ($\ell \lesssim 10^3$) $C_\ell^{\rm tSZ}$ reflects the Poisson random distribution of the sources and the evolution of the halo mass function related to the amplitude of matter clustering, i.e., to $\sigma_8$. The electron pressure profile is instead relevant at all scales, affecting the $C_\ell^{\rm tSZ}$ amplitude and, at smaller scales, the $C_\ell^{\rm tSZ}$ shape, because of the halos morphology, resulting in a peak in $\ell(\ell+1)C_\ell^{\rm tSZ}$ at $\ell \simeq 3000$. The determination of the electron pressure profile dependence on the cluster mass is based on the relation between the SZ flux and the mass. The latter is typically inferred from X-ray observations and suffers from a relevant mismatch with that derived from lensing observations, when available, that are in principle sensitive to the true cluster mass, thus calling for the introduction of a bias parameter, $B = (1-b)^{-1}$, in the formula of the electron pressure profile, $(1-b)$ being the usual mass bias factor accounting for any difference between the X-ray mass proxies used to establish the scaling relations and the true (halo) mass.

At $\ell \lesssim 10^3$, $C_\ell^{\rm tSZ}$ is found to be mainly dependent on the parameter combination $F = \sigma_8\,(\Omega_{\rm m}/B)^{0.40}\,h^{-0.21}$ through the approximate relation $\ell(\ell+1)C_\ell^{\rm tSZ} \propto F^{8.1}$, and $F$ can be then estimated from data with likelihood methods including also proper parametrizations of noise and the other ("foreground") contributions to $C_\ell$. The value $F = 0.460 \pm 0.012$ at 68% CL retrieved in this way can be compared with that of $FB^{0.40} = 0.568 \pm 0.015$ at 68% CL derived from *Planck* CMB temperature and low-$\ell$ polarization anisotropy for the base $\Lambda$CDM model in the second release[3] (or only slightly changed when using the values in Tab. 1), thus requiring $B = 1.71 \pm 0.17$ at 68% CL, i.e. $1 - b \simeq 0.58$, consistent with results from SZ number counts[21], i.e. the mass estimated from X-rays is about 40% lower than their true mass[22]. Including deviations from hydrostatic equilibrium by non-thermal pressure could partially alleviate this problem, while forthcoming X-ray measurements by, e.g., eROSITA, will greatly reduce uncertainties in X-ray data and, together with next SZ observations, e.g., from NIKA2, could solve this bias problem, making galaxies clusters competitive to constrain some cosmological parameters, or, maybe, reveal new physics[20].

## 3. Future CMB missions

Recent proposals of CMB missions are based on concepts and designs aimed at improving the measure of polarization anisotropies and at minimizing the impact of foregrounds using a large number of frequency channels (see also the CM1 session, and related contributions in these proceedings, for their complementarities with ground-based and balloon-borne projects).

The Primordial Inflation Explorer[23] (PIXIE) is an Explorer-class mission submitted to NASA in 2011 aimed at the mapping with high signal to noise ratio in absolute intensity and linear polarization the CMB and the diffuse astrophysical foregrounds over the full sky, from 30 GHz to 6 THz (1 cm to 50 $\mu$m) with degree resolution. It is designed to perform absolute spectroscopy measurements and to simultaneously observe the large-scale CMB B-modes. It will provide crucial constraints on Universe ionization history, on CIB spectrum and anisotropies. Great hopes on CMB spectral distortion parameters (see also the CM3 session and related contributions in these proceedings) are expected from PIXIE, thanks to its absolute calibration of the CMB temperature measure with a precision about $10^3$ times better than COBE/FIRAS.

LiteBIRD[24] is a degree resolution Lite (Light) Satellite for the studies of B-mode polarization and Inflation from cosmic background Radiation Detection at the extremely early Universe proposed to the Japan Aerospace Exploration Agency (JAXA) in 2015. It is a highly-targeted mission, with the primary aim of the B-modes detection at the level of $r \sim 10^{-3}$, about one order of magnitude lower than that achievable from the ground, performed in combination with ground based, high-resolution telescopes helping the accurate subtraction of the lensing contribution to B-mode.

The Cosmic ORigins Explorer (CORE)[25], submitted to the ESA in 2016 in response to a call for future medium-sized space mission proposals for the M5 launch opportunity of ESA Cosmic Vision programme, is a satellite dedicated to microwave polarization. CORE is targeted to provide and exploit definitive maps of CMB polarization anisotropies at large and medium angular scales, with a suppression of all systematic effects at an extremely accurate level over 19 frequency channels spanning the 60-600 GHz range, relevant to characterize astrophysical foreground emissions.

The Probe of Inflation and Cosmic Origin (PICO)[26] is currently one of the 8 Probe-Scale – \$ 400M – \$ 1000 M – space missions proposed to NASA whose study is being funded. The concept and performance of PICO are similar to those of CORE, but with 21 frequency bands in the 21-799 GHz range, i.e. a larger frequency coverage for a better control of foreground signals and astrophysical studies.

CMB Bharat[c] is a satellite, proposed in response to the Announcement of Opportunity for future Astronomy missions by the Indian Space Research Organisation

[c] http://cmb-bharat.in/

(ISRO), dedicated to microwave polarization with concept and performance similar to those of CORE but with a proposed frequency coverage up to about 900 GHz to further improve CIB science and foreground mitigation, and, possibly, equipped with a dedicated spectrometer to perform absolute spectrum measurements and useful also for high level calibration of the differential polarization signal.

Remarkably, the next generation of CMB missions, and, if funded, a large mission, as, e.g., in the view proposed for the Polarized Radiation Imaging and Spectroscopy Mission (PRISM)[27], far from being limited to the scientific outcomes driven by their main goals, will allow us to significantly improve the current results in parameter estimation and large scale structure, to characterize a wide set of cosmological model extensions, to answer fundamental physics questions, and, in the case of a detection of primordial gravitational waves, to determine the shape of their spectrum with great implications for our understanding of the early Universe (see, e.g., refs.[28,29] for detailed forecasts based on CORE specifications), offering at the same time exquisite all-sky surveys for astrophysical studies, both Galactic and extragalactic (see Sect. 5.1).

## 4. Astrophysical cosmology

### 4.1. *Thermal and star formation history from cosmic dipoles*

The analysis of cosmic dipoles is crucial in cosmology, being linked with the isotropy and homogeneity of the Universe at the largest scales. The observed dipole comes from different contributions, of both cosmological and astrophysical (extragalactic and Galactic) origin. The frequency spectral behaviour of the dipole effect due to the observer motion with respect to the CMB rest frame offers the opportunity to be investigated to constrain the CMB and CIB frequency spectra thanks to future missions, described in Sect. 3, without requiring an independent absolute calibration (see Trombetti, these proceedings).

#### 4.1.1. *CMB and CIB spectra: from monopoles to dipoles*

The precise interpretation of tiny CMB spectral distortions predicted at different cosmic times provides information on cosmological and astrophysical processes, some of them unavoidable, otherwise unexplored. The analysis of CIB spectrum, still not well known, can provide instead a better understanding of the dust-obscured star-formation phase of galaxy evolution. Since FIRAS, no remarkable improvements have been achieved in the knowledge of CMB spectrum at $\nu \gtrsim 30$ GHz, while, in spite of its absolute calibration precision of 0.57 mK, the FIRAS characterization CIB amplitude and shape still presents a substantial uncertainty.

At early times, a Bose-Einstein (BE) like distorted spectrum with a positive (dimensionless) chemical potential, $\mu$, is produced by the dissipation of primordial perturbations at small scales[30,31]. Moreover, the matter temperature faster decrease with respect to that of radiation temperature in an expanding Universe produces

a spectral distortion mainly characterized by a BE-like spectrum with a negative chemical potential. The chemical potential quantifies the fractional energy, $\Delta\varepsilon/\varepsilon_i$, exchanged in the plasma during the interaction; for small distortions, $\mu \simeq 1.4\Delta\varepsilon/\varepsilon_i$. The photon occupation number of the BE spectrum is $\eta_{BE} = 1/(e^{x_e+\mu} - 1)$, where $x_e = x/\phi(z)$, $\phi(z) = T_e(z)/T_{CMB}(z)$, being $T_e(z)$ the electron temperature, $T_{CMB} = T_0(1 + z)$ and $x = h\nu/(kT_{CMB})$ a redshift independent, dimensionless frequency. The electron heating during the cosmological reionization associated with the early stages of structure and star formation is responsible for late type distortions, described, at high frequency, by a Comptonization spectrum[32] with Comptonization parameter $u(t) = \int_{t_i}^{t}[(\phi - \phi_i)/\phi](k_B T_e/m_e c^2) n_e \sigma_T c dt$. For small energy injections and integrating over the relevant epochs $u \simeq (1/4)\Delta\varepsilon/\varepsilon_i$. CMB spectrum studies can also constrain many types of non-standard processes, i.e. non evaporating BH spin, small scale magnetic fields power spectra, vacuum energy density and particle decay.

The analytic form of the CIB spectrum, observed at present time, is[33] $\eta_{CIB} = [c^2/(2h\nu^3)]I_{CIB}(\nu) = I_0\,[k_B T_{CIB}/(h\nu_0)]^{k_F}\, x_{CIB}^{k_F}/(e^{x_{CIB}} - 1)$, with $T_{CIB} = (18.5 \pm 1.2)$ K, $x_{CIB} = h\nu/k_B T_{CIB} = 7.78(\nu/\nu_0)$, $\nu_0 = 3 \times 10^{12}$ Hz and $k_F = 0.64 \pm 0.12$. Here $I_0$ sets the CIB spectrum amplitude, its best-fit value being $(1.3 \pm 0.4) \times 10^{-5}$. Indeed, the direct determination of the CIB spectrum is not trivial, requiring absolute intensity measurements and being limited by foreground signals.

A relative velocity between an observer and the CMB rest frame induces a dipole (the so called $\ell = 1$ anisotropy) in the CMB sky temperature through the Doppler effect, dominated by the velocity of the Solar System, $\vec{\beta_S} = \vec{v_S}/\vec{c}$, with respect to the CMB (Solar dipole), with a seasonal modulation due to the velocity of the Earth or the satellite, $\vec{\beta_o}$, with respect to the Sun (orbital dipole). Neglecting the orbital dipole (useful for calibration aims), we will denote with $\vec{\beta}$ the relative velocity of the Solar dipole.

The dipole amplitude is directly proportional to the first (logarithmic) derivative with respect to the frequency of the photon occupation number[34]. More in general, the full pattern at a given observational frequency, $\nu_{obs}$, can be computed from the photon distribution function, $\eta^{BB,dist}$, for the assumed type of distortions (BB, CIB, BE or Comptonization (C)) at the frequency $\nu_{obs}$ multiplied by $(1-\hat{n}\cdot\vec{\beta})/(1-\beta^2)^{1/2}$ to account for all the possible sky directions with respect to the observer peculiar velocity[35]. The observed signal map in thermodynamic temperature is given by $T_{therm}^{BB/dist}(\nu, \hat{n}, \vec{\beta}) = xT_0/\ln(1/(\eta(\nu, \hat{n}, \vec{\beta})^{BB,dist} + 1))$, where $\eta(\nu, \hat{n}, \vec{\beta}) = \eta(\nu')$ with $\nu' = \nu((1 - \hat{n}\cdot\vec{\beta})/(1 - \beta^2)^{1/2}$. Decomposing the maps into spherical harmonics and reproducing them from the $a_{\ell m}$ up to a desired multipole $\ell_{max}$, it is possible to compute the signal map for each $\ell$: at the accuracies of the discussed projects, it is found to be important for the dipole, possibly appreciable for the quadrupole and of strongly decreasing relevance at higher multipoles.

4.1.2. *Results and perspectives*

Detailed simulations allow us to quantify the sensitivity of a given project to measure spectral distortion parameters and CIB amplitude in the presence of only ideal noise or including also potential (calibration and foreground) residuals through $\Delta\chi^2$ analyses based on the comparison of the adopted input sky with different model assumptions, possibly applying suitable sky masks like those publicly available from the *Planck* Legacy Archive (PLA)[d]. Calibration errors and foreground residuals can be modeled generating random fluctuations, depending also on sky signal, parametrizing their overall fractional levels at a certain pixel scale with two key parameters (namely $E_{\rm cal}$ and $E_{\rm for}$).

The joint exploitation of all frequency channels (assumed independent from each other) and of the combinations of the maps differences from pairs of frequency bands is found to be particularly advantageous, being sensitive to both amplitude and spectral shape of the considered dipole signal, while the use of a suitable mask can improve parameters reconstruction. Tab. 2 summarizes the main results, obtained for the CORE specifications, expressed in terms of a factor characterizing the improvement with respect to FIRAS. Even under pessimistic assumptions, a clear improvement in the CIB spectrum amplitude and a marginal detection of the energy release associated to astrophysical reionization models are foreseen, while improvements in foreground mitigation and calibration will allow us to derive more

Table 2. Predicted improvement in the recovery of CIB spectrum amplitude and the CMB distortion parameters with respect to FIRAS for different calibration and foreground residual assumptions. "P76" stands for the *Planck* common mask (in temperature) of the PR2–2015 release covering about 76% of the sky and "P76ext" denotes its extension that excludes all the pixels at $|b| \leq 30^\circ$. When not stated, all values refer to $E_{\rm cal}$ and $E_{\rm for}$ at $N_{\rm side} = 64$; the values in round brackets possibly refer to the corresponding frequency range (in GHz). From ref.[35] .

precise results or constraints on dissipation mechanisms occurring at any epoch, including primeval processes.

### 4.2. *21-cm signal of neutral hydrogen from high cosmological redshifts*

The evolution history of the neutral Universe in the first few hundred million years after the Big Bang, as well as the processes of the primordial star formation and reionization, remains poorly constrained. Theoretical modelling bridges between existing observations of the two dimensional surface of recombination at redshift $z \sim 1100$ probed by the CMB radiation, and the epoch of galaxy formation with the most distant detected galaxy located at $z = 11.1$ [36].

The 21-cm signal of neutral hydrogen provides a unique way to constrain the first few hundred million years (see Fialkov, these proceedings). The hyper-fine splitting of the lowest hydrogen energy level gives rise to the rest-frame $\nu_{21} = 1.42$ GHz radio signal with the equivalent wavelength of 21 cm (see ref. [37] for a recent review). The cumulative signal of neutral intergalactic medium observed against the background radiation depends on the processes of cosmic heating and ionization and, to the leading order, scales as $T_{21} \propto x_{\rm HI}\left(1 - T_{\rm rad}T_{\rm S}^{-1}\right)$ where $T_{\rm rad}$ is the brightness temperature of the background radiation at 1.42 GHz and $T_{\rm S}$ is the spin temperature of the transition which at cosmic dawn is close to the kinetic temperature of the gas, $T_{\rm K}$. Owing to its dependence on the underlying astrophysics and cosmology, this signal is a powerful tool to characterize the formation and the evolution of the first populations of astrophysical sources and, potentially, properties of dark matter (DM), across cosmic time. Uncertainties in the high-redshift astrophysical processes result in a large variety of the possible 21-cm signals (see grey lines in Fig. 1).

Observations with the High-Band antenna of the Experiment to Detect the Global EoR Signature (EDGES) [39–41] and the Shaped Antenna measurement of the background RAdio Spectrum2 (SARAS2) [42,43] yield upper limits on the 21-cm signal from redshifts $z \sim 6-15$. In the framework of standard astrophysical modelling, the data require star formation in small DM halos [41] and rule out extremely non-efficient X-ray heating sources [41–43].

Recently, the first detection of the sky-averaged (global) 21-cm signal of neutral hydrogen from $z \sim 13 - 27$ has been claimed based on two years of observations with the EDGES Low-Band antenna in the $50 - 100$ MHz frequency range [44]. If confirmed, this is the only existing observation from the intermediate redshift range and is the first observational evidence of the primordial star formation at $z \sim 20$ ($\sim 180$ million years after the Big Bang) and early X-ray heating. The reported cosmological 21-cm signal is centered at $z = 17.2$ (which corresponds to $\nu = 78.2$ MHz), and features an absorption trough of $T_{21} = -500^{+200}_{-500}$ mK, where the error corresponds to 99% confidence including both thermal and systematic noise. The depth of the feature is at least twice as strong as predicted in standard astrophysical scenarios (based on the assumption of $\Lambda$CDM cosmology and hierarchical structure

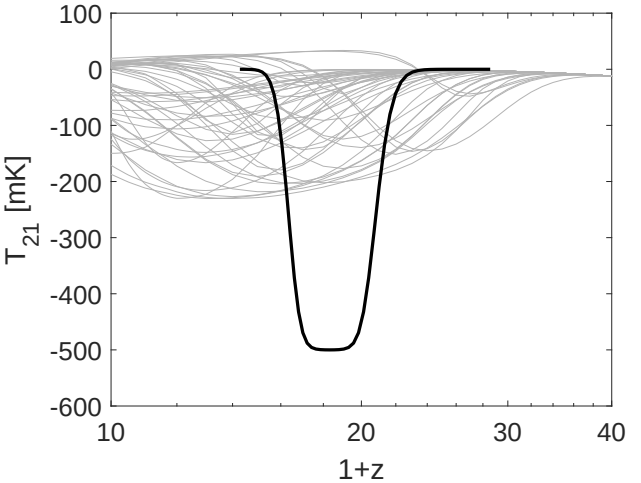

Fig. 1. The variety of plausible predicted 21-cm signals (grey lines – computed here for 50 models according to ref.[38]) and the best-fit profile of the EDGES Low-band detection (thick black line).

formation) where the strongest possible feature at $z \simeq 17$ is $\simeq -209$ mK, assuming the CMB as the background radiation with $T_{CMB} \simeq 49.5$ K and the coldest possible temperature of the intergalactic medium (IGM) of $\sim 7.2$ K obtained in the absence of X-ray heating sources. The observed $T_{21} < -300$ mK requires either the gas to be much colder (around 5.2 K) or the background radiation to be much stronger (around 67.2 K), which is hard to explain by astrophysics alone. The frequency of the detected feature can be related to the formation of the first stars which couple the spin temperature to the temperature of the gas via absorption and re-emission of Ly-$\alpha$ photons; while the narrowness of the feature indicates a relatively rapid onset of X-ray heating.

To explain the depth of the reported feature exotic mechanisms have to be added to the standard picture. The amplitude of the observed 21-cm feature can be explained by non-gravitational interaction between DM and baryons, e.g., via Rutherford-like scattering which could drain excess energy from the gas lowering its kinetic temperature (see, e.g., ref.[45]). Even though this scenario is strongly constrained by observations, it is not completely ruled out and is still plausible for a narrow range of parameters including the DM mass, electric charge of DM particle and cross-section (see, e.g., ref.[46]). A smoking gun signature of the baryon-dark matter (b-dm) scattering with a velocity-dependent cross-section, first proposed in ref.[45] as a solution to the EDGES Low-Band anomaly, was shown to be an enhanced pattern of BAO in the 21-cm power spectrum[47]. The power spectrum itself is boosted by as much as three orders of magnitude which renders the fluctuations detectable by telescopes such as the low band antennas of LOFAR.

An excess radio background at the rest-frame 1.42 GHz at $z = 17$ would also explain the large contrast observed between the background temperature and the spin temperature of the 21-cm transition[44,48]. Interestingly, evidence of excess radio background above the CMB at low radio frequencies was detected by ARCADE2 at $3 - 90$ GHz[49] and recently confirmed by LWA1 at $40 - 80$ MHz[50]. However, it is still not clear what part of the observed excess is extragalactic[51]. If it exists, the excess radio background is also expected to boost the 21-cm power spectrum[52].

Verification of the EDGES-Low signal is on the way with instruments such as the EDGES Mid-Band antenna, SARAS3, LEDA, and the LOFAR Low Band.

#### 4.2.1. *Black holes high mass X-ray binaries microquasars and cosmic backgrounds*

A possible explanation of the EDGES excess involving black hole high mass X-ray binary microquasars (BH-HMXB-MQs) has been recently proposed in ref.[53]. There is indeed an increasing evidence of a high formation rate of BH-HMXBs at high redshifts, theoretically advanced in ref.[54]. According to this model, a significant fraction of Pop III stars with mass $\gtrsim 20$ $M_\odot$ and low metallicity, $Z \leq 0.001$ $Z_\odot$, in binaries or larger multiple systems is predicted to collapse with no energetic SN kicks and to remain in situ, finally resulting into BH-HMXB-MQs of Pop III. These objects are likely sources of a substantial synchrotron radio emission, with a relatively smooth spectrum, able to produce a cosmic background that could significantly enhance the absorption feature of the redshifted 21-cm line by neutral hydrogen produced at redshifts $z \sim 17$. The absence of a cosmic far-IR thermal background associated with a cosmic radio background can be explained in this model by the fact that BH-HMXB-MQs in stellar clusters of Pop III are formed before the appearance of SN explosions, neutron stars and dust. BH-HMXB-MQs promptly inject hard X-rays and relativistic jets in the cold hydrogen that enshrouds the slowly expanding HII regions ionized by the most massive progenitor stars of Pop III. The high column depths for the cold hydrogen IGM largely block the X-rays from inner sources but are essentially transparent to the radio synchrotron emission.

Crucial tests of this scenario will be based on the next generation of multi-wavelength / multi-messenger surveys, including interferometric observations of the HI redshifted 21-cm line able to provide an accurate tomographic view of HI inhomogeneities, X-ray missions that will allow us a better understanding of the HMXBs role, and gravitational waves observatories providing a larger statistics of HMXBs and BBHs useful for cosmological investigations and, hopefully, a measure of the spectrum of gravitational wave background that, in this model, is predicted to have a flattening of the spectral index at frequencies as low as $\sim 30$ Hz.

## 5. Extragalactic astrophysics

### 5.1. *Extragalactic point sources*

Although the main goal of *Planck* was to provide accurate all-sky CMB temperature and polarisation maps, it has supplied unprecedented data of astrophysical interest in several fields. On the extragalactic side, *Planck* carried out the deepest systematic all-sky survey of galaxy clusters seen via the SZ effect. It also detected thousands of dusty galaxies as well as many hundreds of extragalactic radio sources in a spectral range difficult or impossible to explore from the ground and only lightly surveyed by other space missions.

Because of its quite limited angular resolution ($\simeq 5'$ at sub-mm wavelengths) *Planck* was confusion limited at quite bright flux density levels, so that the overwhelming majority of dusty galaxies it detected are very local, at distances generally below 100 Mpc[55]. *Planck* offered the first opportunity to accurately determine their sub-mm properties[56].

Even more interestingly, *Planck* opened new paths to the study of early phases of galaxy evolution, exploiting the strong gravitational lensing (Sect. 5.1.1), and of cluster evolution (Sect. 5.1.2); see De Zotti et al., these proceedings.

#### 5.1.1. *Strongly lensed galaxies*

Somewhat unexpectedly (but see the predictions by ref.[57]) *Planck* also succeeded at detecting some high-$z$ galaxies whose flux densities were boosted by extreme gravitational magnifications[58] (see the left panel of Fig. 2.)

The 11 strongly lensed galaxies discovered on *Planck* maps[58] have redshifts in the range 2.2–3.6. This offers the exciting possibility of exploiting high spatial and spectral resolution follow-up to address major, still open issues on galaxy formation and evolution: which are the main physical mechanisms shaping the galaxy properties: in situ processes? interactions? mergers? cold flows from the intergalactic medium? How do feedback processes work? To settle these issues we need direct information on the structure and the dynamics of high-$z$ galaxies. But these are compact, with typical sizes of 1–2 kpc (e.g., ref.[59]), corresponding to angular sizes of 0.1–0.2 arcsec at $z \simeq 2$–3. Thus they are hardly resolved even by ALMA and by the HST. If they are resolved, high enough S/N ratios per resolution element are achieved only for the brightest galaxies, probably not representative of the general population. Strong lensing offers a way out of all these difficulties.

#### 5.1.2. *Proto-clusters*

Classical techniques for detecting galaxy clusters (optical/near-IR "red sequence", X-ray emission, SZ effect) preferentially or exclusively select evolved objects, with mature galaxy populations and a hot intra-cluster medium. As a result most known clusters are at $z < 1.5$, i.e. below the peak of global star-formation activity.

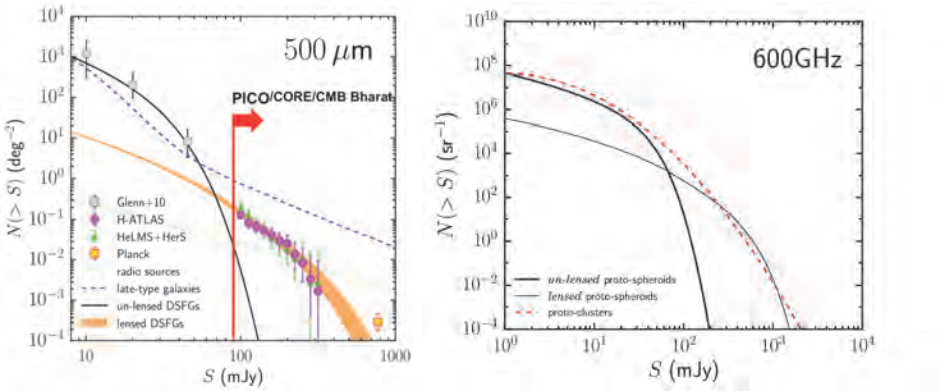

Fig. 2. **Left panel:** integral counts of the main extragalactic source populations at 500 $\mu$m (600 GHz). The counts of unlensed (solid black line) and strongly lensed (orange band) high-$z$ galaxies (labelled DSFGs) are compared with observational determinations from *Herschel* surveys. The yellow square on the bottom-right corner shows the estimated counts of strongly lensed galaxies detected by *Planck*. The dashed blue line shows the counts of late-type (normal plus starburst) galaxies. All these lines show predictions of the model by ref.[60]. The dotted green line shows the counts of radio sources predicted by the C2Ex model of ref.[61]. The vertical red line shows the estimated detection limits of planned next generation CMB experiments, PICO, CORE and CMB Bharat. Adapted from ref.[62] [©SISSA Medialab Srl. Reproduced by permission of IOP Publishing. All rights reserved]. **Right panel:** integral counts of proto-clusters at 600 GHz, predicted by the model of ref.[63], compared with the counts of high-$z$ lensed and unlensed proto-spheroidal galaxies.

At higher redshifts cluster members enter the active star-formation phase and the hot intergalactic gas is no longer necessarily in place. But then strong galaxy overdensities stand out as intensity peaks in the low angular resolution maps of CMB experiments, as clearly demonstrated by *Planck*[64]. Thus CMB experiments offer the possibility of extending the investigation of cluster evolution up to much higher redshifts than would be possible by other means.

However, *Planck*'s resolution was too poor to detect individual proto-clusters[63]. As illustrated by the right panel of Fig. 2, next generation experiments will detect many tens of thousands of these objects as peaks in sub-mm maps, in addition to the evolved ones, detected by the SZ effect. This will constitute a real breakthrough in the observational validation of models for structure formation.

### 5.2. *Virial clouds in the galactic halos*

The rotation of the galactic objects and disks of various nearby edge-on spiral galaxies has been studied by using the Doppler asymmetry in the CMB radiation[65–70]. It was proposed that the asymmetry is caused by molecular hydrogen clouds which are exactly merged with the CMB, i.e. they are at the CMB temperature[71]. An objection was raised that the effect might not be due to pure molecular hydrogen clouds, it might be due to clouds completely made of interstellar dust or clouds

containing some fraction of $H_2$ and dust. In order to address the issue in this paper we only modeled the clouds with the assumption that they are composed of pure $H_2$ molecules (single fluid model). After modeling the clouds we tried to estimate the luminosity caused by the clouds (see Qadir et al., these proceedings). Further, we want to extend the analysis (in a later work) to a two-fluid model. The hope is that by comparing it with the *Planck* data we can constrain the missing baryonic distribution in the galactic halos.

Since, the clouds are immersed in a heat bath which is CMB, so, they are isothermal and we called them "virial clouds". They are formed due to the Jeans instability, so, they should have a precise Jeans mass and radius. The density of the clouds should be flat at the center and then it goes exactly zero at the the Jeans radius in order to give a definite boundary. The density distribution can be given by the isothermal Lane-Emden equation but the density profile in that case will not be exactly zero at the boundary. In this case the density distribution had to be put on ad-hoc basis. We do not have to do this. Instead of using the isothermal Lane-Emden equation we used the canonical ensemble distribution to obtain the mass density profile. We also introduced the speed of sound $c_s$ which is given by $c_s = \sqrt{(\gamma k T_{CMB})/m_H}$, where, $\gamma$ is the adiabatic factor. At the CMB temperature no higher degrees of freedom would excite, so, we only have the translational degree, making the ideal gas approximation extremely good and so $\gamma = 5/3$. For our purpose, $m_H \approx 2.016$ g/mol and $T \approx 2.726\,\mathrm{K}$, so $c_s \simeq 1.110 \times 10^4$ km s$^{-1}$. The virial theorem $2K + U = 0$ gives the Jeans mass squared as[72]

$$M_J^2 \simeq \left(\frac{81}{32\pi\rho_c}\right)\left(\frac{3c_s^2}{5G}\right)^3 , \tag{1}$$

and the corresponding Jeans radius squared as

$$R_J^2 = \frac{27c_s^2}{20\pi\rho_c G} , \tag{2}$$

where $\rho_c$ is the central density of the virial cloud. We obtained a differential equation as

$$r\frac{d\rho(r)}{dr} - r^2\left(\frac{4\pi G m_H}{kT_{CMB}}\right)\rho^2(r) - \rho(r)\ln\left(\frac{\rho(r)}{\zeta}\right) = 0 . \tag{3}$$

where, $\zeta = 8m_H^{5/2}(G\rho_c/3kT_{CMB})^{3/2}$. We have the initial condition $\rho'(r)|_{r=0} = 0$ and the boundary condition that $\rho(R_J) = 0$. As such, we can solve it numerically. The resulting density profile is shown in Fig. 3. The obtained central density of the cloud is $\rho_c \simeq 1.60 \times 10^{-18}$ kg m$^{-3}$, the radius is $R_J \simeq 0.030$pc, and the mass is $M_J \simeq 0.798 M_\odot$.

Since the virial clouds are at the CMB temperature, their luminosity is the CMB luminosity, except for their Doppler shift. Thus, we only need to look at the differential frequency shift, $\Delta\nu/\nu = -(v_{rot}/c)\cos\theta$, where $v_{rot}$ is the galactic halo rotational velocity and the luminosity of a single cloud, $L_c$, could be given by $L_c = (\Delta\nu/\nu)L \simeq 1.486 \times 10^{-4} L\cos\theta$, being $\theta$ the angle between the direction of the

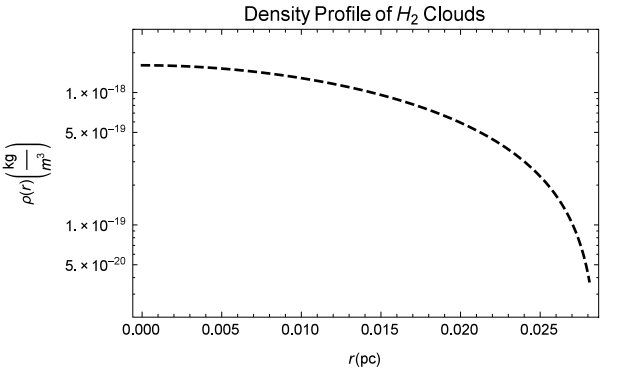

Fig. 3. The density of the virial molecular hydrogen cloud. It decreases monotonically from the central density, $\rho_c \simeq 1.60 \times 10^{-18}$ kg m$^{-3}$, to zero at $r = R_J \simeq 0.030$ pc.

velocity and the line of sight and $L$ the observed luminosity. This would directly give an estimate of the total number of clouds being seen.

### 5.3. *Perspectives from SPICA*

IR observations allowed us to study the obscured Universe, providing information about the physical state and energy balance of the cool matter relevant for the study of many physical processes occurring during the formation and evolution of galaxies and stars. Indeed, a large fraction ($\sim 50\%$ or more) of the energy emitted by stars in galaxies in form of optical and ultraviolet radiation is absorbed and reprocessed by dust grains and re-emitted in the IR, and, for distant objects, the cosmic expansion implies a further substantial redshift of the observed photons. For these reasons, galactic evolution, with a peak of activity at z$\sim$1-4 corresponding to a Universe age of about 2-3 Gyr, can be profitably investigated in the (mid- and far-) IR domain. Furthermore, improving our understanding of fundamental processes of star formation and evolution, including dust and gas physics of pre-stellar cores and proto-planetary discs, that can be more accurately studied in our galaxy in the IR band, allows us a better modeling of high-$z$ phenomena.

The physical conditions, such as excitation, density and metallicity, of nuclei of galaxies as well as of stars and planets formation regions can be investigated analyzing ionic, atomic, molecular and dust features in the IR. The star formation rate, the stellar type and the density of the gas in HII regions around hot young stars can be investigated using ionic fine structure lines, e.g., [NeII], [SIII], [OIII], while the AGN accretion rate is traced by spectral lines of highly ionized species, e.g., [OIV], [NeV] (see the expected potentials of far-IR spectroscopic observations for studying galaxy/AGN co-evolution presented in ref.[73]). Photo-dissociation regions can be studied via the [CII] and [OI] lines and the emission from small dust grains and PAHs. Also, the cooling of diffuse warm gas in galaxies, through, e.g., [NII],

probing ISM physics, is accessible to IR observations. Pure rotational lines from $H_2$, HD and OH, mid- to high-J CO and $H_2O$ lines, and PAH emission features appear in the object rest-frame IR band, the latter, containing several per cent of of the star-forming galaxies IR emission, being crucial for dust-obscured objects redshift determination. Other interesting dust features from minerals, e.g., olivine, calcite and dolomite, and $CO_2$ ice, $C_2H_2$ molecules and fullerenes are also observable in the IR.

The above tracers have been only partially studied with previous IR missions, mainly because of limitations in telescope sizes and cryogenic performances.

To overcome these limits, a mid- and far-IR mission concept, the Space Infrared Telescope for Cosmology and Astrophysics (SPICA)[74], was proposed to JAXA and ESA as a collaboration mission between Japanese and European scientists. It was selected in May 2018 by ESA as a finalist for the next Medium class Mission 5 of the Cosmic Vision programme for a proposed launch date of 2032. The spacecraft is designed to be deployed in a halo orbit around the Sun-Earth L2 Lagrange point to minimize systematic effects. The mission foresees a 2.5-meter diameter telescope cooled to below 8 K. A combination of passive cooling and mechanical coolers, that will cool the telescope and the instruments, will enable a mission lifetime significantly beyond a nominal requirement of three years. Combining a large and cold telescope with instruments employing state-of-the-art ultra-sensitive detectors, an improvement in IR spectroscopic sensitivity (achieving the – $5\sigma$/1hr – level of $\sim 5 \times 10^{-20}$ W/m$^2$) of more than two orders of magnitude with respect to Herschel, Spitzer and SOFIA is planned. SPICA will offer spectral resolving power ranging from $R \sim$50 through 11000 in the 17-230 $\mu$m domain as well as $R \sim$28.000 spectroscopy between 12 and 18 $\mu$m. Furthermore, SPICA will perform efficient 30-37 $\mu$m broad band mapping, and small field spectroscopic and polarimetric imaging in the 100-350 $\mu$m range.

A wide set of questions in astrophysics, e.g., the role in galaxy evolution of star formation, BHs and SNe explosions, metal and dust history, the matter cycle from galactic scale to larger structures and IGM, the formation of first galaxies and BHs, will get benefit from deep analyses of the IR tracers made possible by such a mission.

# Understanding accretion flow properties of black hole candidates after implementation of the TCAF solution in XSPEC

Dipak Debnath[1]*, Sandip K. Chakrabarti[1], Santanu Mondal[1], Arghajit Jana[1], Debjit Chatterjee[1], Aslam Ali Molla[1], Kaushik Chatterjee[1], Riya Bhowmick[1]

*1. Indian Centre For Space Physics, 43 Chalantika, Garia Station Road, Kolkata, 700084, India; *E-mail: dipakcsp@gmail.com*

Understanding accretion flow dynamics around black hole (BH) sources one needs to make detailed study of spectral as well as temporal properties of these objects during their active phases. We believe that studying accretion flow properties of BHs, it is necessary analyze observed data with a generalized physical model. Recently after the implementation of the generalized two Component Advective Flow (TCAF) solution as a local additive table model into HeaSARC's spectral analysis package XSPEC, a more clear picture about the flow nature around the BHs are obtained. TCAF model fitted spectral parameters (two types of accretion rates: Keplerian disk and sub-Keplerian halo, and two types of shock parameters: location and strength of the shock) allow us to find a better physical picture about the physical processes associated with BHs. One can also predict frequency of primary dominating QPOs from TCAF model fitted shock parameters. Based on evolution of halo to disk accretion rate ratio (ARR), quasi-periodic oscillation (QPOs; if present) frequencies, a physical understanding of different observed spectral states and their transitions are done. We are able to estimate intrinsic source parameters (mass, spin), jet X-ray fluxes, etc. from spectral analysis with TCAF model. This makes this model as an ideal tool to study BHs.

## 1. Introduction

Compact objects such as black hole (BH), neutron star (NS), white dwarf (WD) are the end products of the main sequence stars. BHs are more massive objects which are invisible due to their high gravity. They are only observable when they accrete matter from their massive companions. Depending upon their flaring activity, they are classified mainly into two types: transient and persistent. Transient black hole candidates (BHCs) are very interesting objects to study in X-rays as they exhibit rapid evolutions in their temporal and spectral properties during outbursts. In the literature many works are reported based on the variation of spectral and temporal properties of these objects (see, e.g., 1, 3, 4 and references therein). During an outburst, transient BHCs generally show four primary spectral states: *hard (HS), hard-intermediate (HIMS), soft-intermediate (SIMS)* and *soft (SS)*. According to Debnath et al.[4], classical or type-I transient BHCs show all four spectral states in the sequence : HS→HIMS→SIMS→SS→SIMS →HIMS→HS, while harder or type-II sources do not show SS (sometimes no SIMS). These transient BHCs also exhibit low and high frequency quasi-periodic oscillations (QPOs) in some of these spectral states (see, 3 and references therein). The frequencies of QPOs are found to evolve with time during the rising and declining phases (more precisely, during HS and

HIMS) of the outbursts (see, 3, 5 and references therein). Jets or outflows are also found to be associated with hard and intermediate spectral states.

Studying spectral data with the informations of temporal nature provides a better picture about the physics of accretion around a BH. One may fit spectra with in-build or local phenomenological or theoretical model(s) in commonly used HeaSARC's spectral analysis software package XSPEC. But we believe that to find real physical picture about the accretion flow dynamics of BHs, one must study with a generalized theoretical model which should address all aspects of the observational data. Two component advective flow (TCAF) solution (see, 6, hereafter CT95) is a generalized transonic flow solution of radiative transfer equations. It consists of two types of accretion (Keplerian and sub-Keplerian) rates separated by the critical viscosity. Formation of shock (where flowing velocity suddenly jumps from supersonic to subsonic branch) is a natural solution of the model. As matter slows down at the shock location, post-shock region puffs up in the vertical direction, and forms the CENtrifugal pressure dominated BOundary Layer or CENBOL. This CENBOL acts as 'hot' Compton cloud where thermal seed photon from the Keplerian disk upscatters via inverse-Compotonization and becomes hard.

The TCAF solution has been implemented as an additive table model in HeaSARC's spectral analysis software package XSPEC to fit BH spectra (7, 8), which requires only four physical flow parameters (Keplerian disk rate $\dot{m}_d$ and sub-Keplerian halo rate $\dot{m}_h$, shock location $X_s$ and compression ratio $R = \rho_+/\rho_-$, where $\rho_+$, $\rho_-$ are post- and pre-shock matter densities respectively) excluding mass of the BH ($M_{BH}$) and normalization ($N$) to fit a spectrum from a BHC. Detailed study of several transient as well as persistent BHCs with the model, allowed us to find accurate picture of the accretion flow dynamics of these sources. Physical explanation of various observed spectral states during an outburst of a transient BHC has been done quite successfully based on evolution of the TCAF model fitted flow parameters. TCAF model fitted shock parameters ($X_s$ and $R$) also allow us to estimate frequencies of the dominating type-C QPOs (if observed in PDS; see, 7, 9), which is a temporal property. Since, in TCAF model $M_{BH}$ is an important model input parameter, one may predict mass of an unknown BHC by keeping it as a free parameter while fitting spectra. Masses of several BHCs are estimated with better accuracy from our spectral study with the TCAF model *fits* file[4,9–12]. In 13, we introduced a new method to separate jet X-ray fluxes from total X-rays based on the variation of the TCAF model normalization[13–15].

## 2. Implementation of TCAF Solution as a Table Model in XSPEC

TCAF solution has been implemented successfully as an additive local model into HeaSARC's spectral analysis software package XSPEC in 2014 (see, 7, 8). To generated table model *fits* file, a large number ($\sim 10^6$) of theoretical model spectra are used. They are generated by varying five model input parameters ($M_{BH}$, $\dot{m}_d$, $\dot{m}_h$, $X_s$, $R$) in the modified CT95 code as described in 8. A direct spectral fit

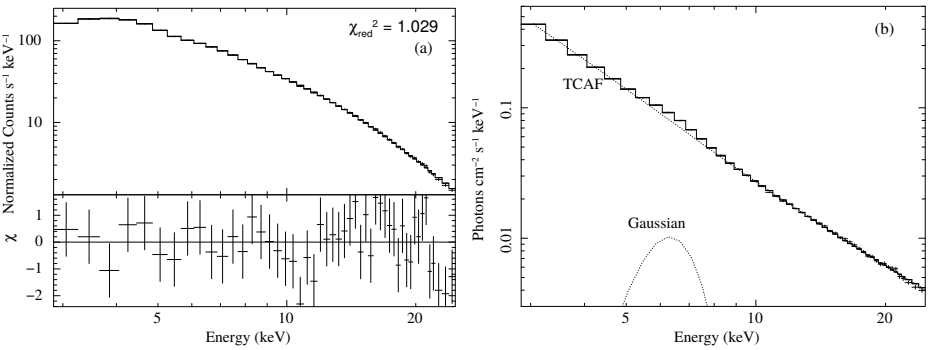

Fig. 1. (a) TCAF model fitted 2.5 − 25 keV PCA spectrum of GX 339-4 (Observation ID = 95409-01-14-04; MJD = 55300) with variation of $\Delta\chi$ is shown in the left panel. The value of the model fitted reduced $\chi^2$ is written down. (b) The unfolded model components of the spectral fit are shown on the right panel. Adopted from Debnath, Chakrabarti & Mondal (2014).

could be done using TCAF model program as a local model in XSPEC, where it will generate spectra while fitting. But this method is time consuming as to fit one spectrum may take time up to few minutes to hours. In Fig. 1(a-b), TCAF model fitted GX 339-4 spectrum of observation ID = 95409-01-14-04 and MJD = 55300 is shown. While fitting spectra, we found that TCAF model normalization ($N$) for a BHC generally do not vary (if observed with a particular instrument), since it is a function of $M_{BH}$, distance ($D$), and disk inclination angle ($i$) of the system.

## 3. Physical Explanation of Various Observational Aspects

Successful implementation of the generalized accretion flow solution TCAF into XSPEC, allowed us to find informations about the physical flow parameters directly from spectral fits. Both spectral and timing properties of BHCs are now understandable from physical point of views. One may find a more clear physical picture about the accretion processes around BHs. Measurement of intrinsic source parameters are also could be done from spectral analysis with the TCAF model.

### 3.1. *Spectral states and their evolution*

After the successful implementation of the TCAF solution as an additive table model in XSPEC, we studied accretion flow properties of several transient and persistent BHCs (see, 7, 16, 8, 4, 17, 12, 9, 10, 11, 18, 15, 19, 20, 21). Transient sources show rapid transition between different spectral states, where as persistent sources prefer to stay longer time in one states (although there has some exceptions, for e.g., GRS 1915+105). Evolution of TCAF model fitted flow parameters allow us to find physical explanation behind these nature of the sources.

Studying spectral properties with phenomenological models, for example with a combined thermal disk blackbody and non-thermal power-law models gives rough idea about the variation of thermal and non-thermal flux components without

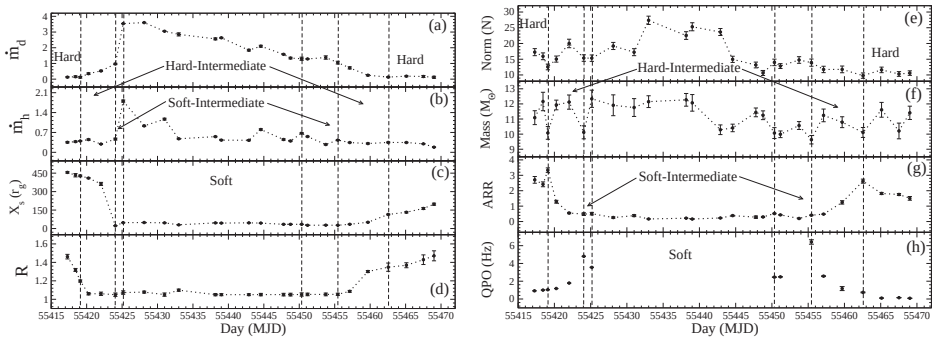

Fig. 2. In left panel, variations of TCAF model fitted parameters : (a) Keplerian disk rate $\dot{m}_d$ (in $\dot{M}_{Edd}$), (b) sub-Keplerian halo rate $\dot{m}_h$ (in $\dot{M}_{Edd}$), (c) shock location $X_s$ (in Schwarzchild radius $r_g$), and (d) compression ratio $R$ with time (in MJD) for 2010 outburst of H 1732-322 are shown. In right panel, variation of (e) TCAF model normalization $N$, (f) mass of the BH ($M_{BH}$ in $M_\odot$), (g) ARR ($=\dot{m}_h/\dot{m}_d$), and (h) observed QPO frequency (in Hz) are shown. Adopted from Mondal, Debnath & Chakrabarti (2014) and Molla et al. (2017).

knowing real physical cause of their origin. One may classify an outburst into different spectral states based on degree of importance of thermal and non-thermal fluxes and nature (shape, frequency, $Q$ value, rms% etc.) of QPOs (if present). But variation of the TCAF model fitted flow parameters, accretion rate ratio (ARR=$\dot{m}_h/\dot{m}_d$), nature of QPOs (if present) provide better physical picture on the accretion flow properties. Properties of different spectral states (HS, HIMS, SIMS, SS) and their transitions are understood more physically (see, 22 for a review).

The variation of TCAF fitted parameters ($\dot{m}_d$, $\dot{m}_h$, $X_s$, $R$, $N$, $M_{BH}$) during the 2010 outburst of H 1743-322 are shown in Fig. 2(a-f). In Fig. 2(g-h), variation of ARR and observed QPO frequency are shown. During the rising phase, as day progresses, both accretion rates increase with inward movement of the shock wave with reducing strength. Due to this process, ARR reaches maximum on HS (rising) to HIMS (rising) transition day and then rapidly reaches to a lower value on HIMS (rising) to SIMS (rising) transition day. Also, on this transition (HIMS to SIMS) day, observed frequency of the monotonically increasing QPO becomes maximum. The opposite is true during the declining phase of the outburst, where both the accretion rates decrease with time with outward movement of the shock and increasing shock strength. Here also ARR becomes maximum on HIMS (declining) to HS (declining) transition day and QPO frequency starts to decrease monotonically with time from the SIMS (declining) to HIMS (declining) transition day. During SS, no QPOs are observed with lower (roughly constant) ARR value. A somewhat similar nature of variations of TCAF model fitted physical flow parameters are observed for different spectral states of other transient BHCs as well.

### 3.2. *Prediction of type-C QPO frequency*

In 7, 9, we showed that temporal properties such as frequency of the dominating type-C QPOs could be predicted from the TCAF model fitted shock parameters

(location $X_s$ and compression ratio $R$). This is because the same shock which defines the CENBOL boundary, i.e., the size of the 'hot' Compton cloud, also causes low frequency QPOs as it oscillates. The frequency of the QPO is inversely proportional to the infall time ($t_{infall}$) in post-shock region when resonance condition between cooling and infall time scales is satisfied[23,24]. The frequency ($\nu_{QPO}$) of the observed QPOs determined by the relation,

$$\nu_{QPO} \sim t_{infall}^{-1} = C/[R\ X_s(X_s-1)^{1/2}],$$

where $C$ is a constant $= M_{BH} \times 10^{-5}$.

### 3.3. *Mass estimation of unknown BH sources*

Knowledge of the mass of the compact object (here BH) is very important while studying these objects. In TCAF model $M_{BH}$ is an important input parameter. So if $M_{BH}$ is not well known, one may keep it as free while fitting spectrum. Each spectral fit with the model *fits* file gives us to one best-fitted mass value of the source. The variation of the $M_{BH}$ (see Fig. 2e; not actual change in mass of the source, since here it is a model fitted parameter, which may vary due to fitting or data quality errors) from spectral fitting of several observations allows us to predict probable mass range of the source. In this way, recently we measured masses of several BHCs (for example: MAXI J1659-152[10], MAXI J1543–564[9], MAXI J1836-194[12], H 1743-322[11], Swift J1753.5-0127[4], XTE J1118+480[15], MAXI J1535-571[20], Cygnus X-1[21]) quite successfully in a better accuracy (narrow range).

### 3.4. *Estimation of jet X-ray fluxes*

A model normalization is a multiplicative 'factor' that converts observed spectrum to match with the theoretical model spectrum emitted from the source. In general in spectral fits, it varies. But unlike other models, TCAF model normalization does not vary in observations as it is a function of intrinsic source parameters ($M_{BH}$, $D$, $i$). In TCAF, flow parameters not only takes care of the shape of the observed spectrum but also changes in intensity or flux. Although one may require higher $N$ values if there is a jet activity or precession in disk or presence of any dominating physical processes whose effects are not included in the model *fits* file.

If variation of $N$ are not constant i.e., not in a narrow range, we look at the variation of $N$ and radio flux ($F_R$). If on the minimum $N$ observation day $F_R$ also at its minimum, then we assume that requirement of higher $N$ values in other observations, are due to excess X-ray flux from jets. Then we refit all spectra by keeping $N$ frozen at its minimum observed value and calculate fluxes, which are defined as flux contribution from accretion disk or inflowing matter ($F_{inf}$). Now taking difference of $F_{inf}$ from $F_X$ (which is the earlier calculated flux when all model parameters are kept free), we get flux contribution from jets or outflows ($F_{ouf}$).

Jana et al.[13,14] estimated jet X-ray fluxes for two Galactic BHCs: Swift J1753.5-0127, and MAXI J1836-194. Jet X-rays are found to be higher in intermediate

spectral states (here HIMS) than HS. This is consistent with the theory (see, 25). The maximum contribution of jet X-rays are found to be 32% during 2005 outburst of Swift J1753.5-0127, and 86% during 2011 outburst of MAXI J1836-194. The correlation study of $F_{ouf}$, $F_X$, $F_{inf}$ with $F_R$ using relation $F_R \sim F_X^b$, where $b$ is the correlation index. The $b$ values are found at $0.59 \pm 0.11$ for Swift J1753.5-0127 and $0.61 \pm 0.08$ for MAXI J1836-194. The correlation values are within the standard correlation limit $(0.6 - 0.7)$. Further strong correlations are found during entire outburst of MAXI J1836-194 and HS of Swift J1753.5-0127, implies compact jet. A weak correlation is found in HIMS of the 2005 outburst of Swift J1753.5-0127, implies nature of jet as blobby or discrete.

## 4. Concluding Remarks

After the successful implementation of the TCAF solution as an additive table model in XSPEC, one gets direct estimation of flow parameters. This parameters enable us not only to understand spectral properties of the BHCs but also to predict other timing and physical parameters associated with the BHs. One can see direct correlation between spectral and timing properties of transient BHCs during an outburst with the variation of TCAF model fitted/derived physical flow parameters. Most importantly we require only four parameters (assuming mass and normalization are constant) to fit spectrum. It confirms our decade long conjecture that TCAF is the most accurate theoretical model or tool to understand physics of accretion processes around a BH.

We study the modulation of the observed radiation flux and the associated changes in the polarization degree and angle that are predicted by the orbiting spot model for flares from accreting black holes. The geometric shape of the emission region influences the resulting model lightcurves, namely, the emission region of a spiral shape can be distinguished from a simpler geometry of a small orbiting spot.

We further explore this scheme for the observed flares from the supermassive black hole in the context of Galactic center (Sgr A*). Our code simulates the lightcurves for a wide range of parameters. The energy dependence of the changing degree and angle of polarization should allow us to discriminate between the cases of a rotating and a non-rotating black hole.

*Keywords*: Gravitation; Black Holes; Galactic center

## 1. Introduction

Relativistic corrections to a signal from orbiting spots can lead to large rotation in the plane of observed X-ray polarization. When integrated over an extended surface of the source, this can diminish the observed degree of polarization. Such effects are potentially observable and can be used to distinguish among different models of the source geometry and the radiation mechanisms responsible for the origin of the polarized signal. The idea was originally proposed in the 1970s,[4,5,17] however, its observational confirmation and practical use in observations are still is a challenging task.

The geometrical effects of strong gravitational fields act on photons independently of their energy. The gravitational field is described by the metric of Kerr black hole[16]

$$ds^2 = -\frac{\Delta}{\Sigma}\Big(dt - a\sin^2\theta\, d\phi\Big)^2 + \frac{\Sigma}{\Delta}\, dr^2 + \Sigma\, d\theta^2 + \frac{\sin^2\theta}{\Sigma}\Big[a\, dt - \big(r^2+a^2\big)\, d\phi\Big]^2 \quad (1)$$

†New address: Center for Theoretical Physics, Polish Academy of Sciences, Warsaw, Poland

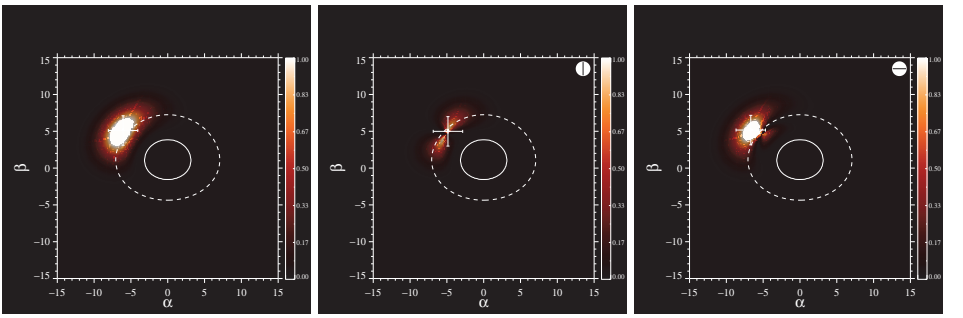

Fig. 1. An exemplary snapshot of a spot orbiting at constant radius just above the marginally stable orbit ($r = 1.1 r_{\rm ISCO}$). Left panel: the total intensity image shows the observer plane $(\alpha, \beta)$ near a non-rotating black hole, as observed at a moderate view angle ($\theta_{\rm o} = 45$ deg). The horizon radius (solid curve) and the ISCO (dashed curve) are indicated. Middle and right panels: The spot emission is assumed to be intrinsically polarized and recorded in two polarization channels, rotated by 90 degrees with respect to each other.[20,21]

in Boyer-Lindquist (spheroidal) coordinates $t$, $r$, $\theta$, $\phi$. The metric functions $\Delta(r)$ and $\Sigma(r, \theta)$ are known in an explicit form. The event horizon occurs at the roots of equation $\Delta(r) = 0$; the outer solution is found given by $r = R_+ = 1 + (1 - a^2)^{1/2}$.

Let us note that there are some similarities as well as differences between the expected manifestation of relativistic effects in polarization changes in X-rays and in other spectral bands (NIR). We show these interrelations in the associated poster and point out that the near-infrared polarization measurements of the radiation flares from the immediate vicinity of the horizon have been studied in detail from the Galactic Center (Sagittarius A*) supermassive black hole.[15,20,21]

## 2. Polarization from an Orbiting Spot

Within the scheme of the spot scenario the spots are considered to represent regions of enhanced emission on the disc surface rather than massive clumps that would decay due to shearing motion in the disc. The observed signal is modulated by relativistic effects. Doppler and gravitational lensing influence the observed radiation flux and this can be computed by GR ray-tracing. Such an approach has been developed to compute also strong gravity effects acting on polarization properties.[11]

Our code (KY) is publicly available.[7] The current version[a] allows the user to include the polarimetric resolution and to compute the observational consequences of strong-gravity effects from a Kerr black hole accretion disc. Within the XSPEC notation, this polarimetric resolution is encoded by a switch defining which of the four Stokes parameters is returned in the photon count array at the moment of the output from the model evaluation. This way one can test and combine various models, and pass the resulting signal through the response matrices of different

[a] http://stronggravity.eu/results/models-and-data/

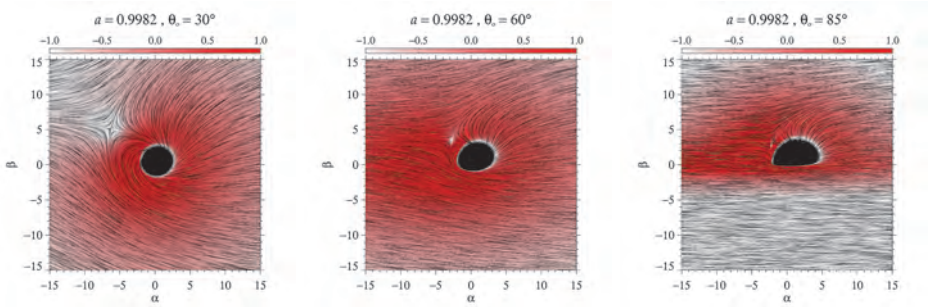

Fig. 2. A map of the distribution of the polarization angle (flow lines) and the intensity of the polarized light (colour coded in the logarithmic scale; arbitrary units are indicated by the colour bar), for a large value of spin $a$ of the Kerr black hole and different view angles of the observer, as indicated on top of the panels. This time the model has been computed for the case of thermal radiation of an equatorial accretion disk polarized via Comptonization; see Dovčiak et al. (2008).[8] A critical point is clearly seen in the flow-line structure through which then the orbiting spot circles.

instruments. As an illustration, figure 1 shows a single time-frame from a simulation of a spot rotating rigidly at constant radius.

The detected polarization degree is expected to decrease mainly in the part of the orbit where the spot moves close to the region where the photons are emitted perpendicularly to the disc and the polarization angle changes rapidly. The drop of the observed polarization degree occurs also in those parts of the orbit where the magnetic field points approximately along light ray (see fig. 2 for a map showing the distribution of the polarization effects within the disk plane of a rapidly rotating Kerr black hole). For the more realistic models the resulting polarization exhibits a very complex behaviour due to, e.g., Faraday rotation effects interfering with strong-gravity.[10] Among generic features is the peak in polarization degree for the spin parameter $a \to M$ and large inclinations, caused by the lensing effect at a particular position of the spot in the orbit. This effect disappears in the non-rotating $a = 0$ case.

To conclude, let us note that the above described modelling has recently gained new impetus in the context of forthcoming X-ray polarimetry satellite missions that have been under active consideration. The enhanced X-ray Timing and Polarimetry (eXTP) mission[9,22] is the concept of novel Chinese X-ray mission that has currently reached the extended phase A with a possible contribution from Europe and the anticipated launch date by 2025.

The Large Area Detector (LAD) aboard the new mission will be a suitable instrument for performing time-resolved spectroscopy with polarimetric resolution, large effective area, and moderate energy resolution to explore bright flares from accreting black holes, possibly in the connection with the processes of tidal disruption of stars and similarly violent events.[6,23–25]

Let us just remind the reader that the revealing role of X-ray polarimetry clearly extends to all scales far away from the central black hole. This has been widely discussed in the context of reflection nebulae surrounding Galactic center.[3,14] The combination of the polarization signal from the Sgr B and Sgr C complexes strengthens the need for an imaging detector with a fine spatial resolution to resolve the structures as small as the Bridge clouds. Therefore, the X-ray polarimetry is needed to explore variety of physical processes operating near supermassive black hole.

## 3. Conclusions

We explored the approach based on mapping the Kerr black hole equatorial plane onto the observer's plane at radial infinity. Orbiting spots are projected onto the disc plane (hence imposing the vertically averaged approximation) and then their image is transported towards a distant observer. The strong gravity effects can be seen as the predicted (time-dependent) direction of polarization is changed by light propagation through the curved spacetime. What can be foreseen in the near future is the tracking of the wobbling image centroid that a spot produces. With the polarimetric resolution, this wobbling can provide the evidence of orbiting features.

In conclusion, the rotating spots are a viable scenario capable to explain the occurrence about once per day of modulated flares from within a few milli-arcseconds of the Sagittarius A* supermassive black hole.[12,18] However, the astrophysically realistic scenarios have to account not only for the time-scales of gradual dispersion of the orbiting features by tidal effects[1,19] but also for the effects of plasma influencing the light propagation through a non-vacuum spacetime near the black hole.[2,13]

# New insights into the plasma region near black holes from hard X-ray observations

Piotr Lubiński

*Institute of Physics, University of Zielona Góra,*
*Licealna 9, PL-65-417 Zielona Góra, Poland*
**E-mail: P.Lubinski@if.uz.zgora.pl*

Two examples of the analysis of the hard X-ray/soft $\gamma$-ray emission from accreting black holes observed with the *INTEGRAL* satellite are presented. The first study is based on data covering 16 years of monitoring of the bright persistent Cyg X-1 system. This huge data set allowed us to get more insights into the geometry of the plasma region in different spectral states of the object. In particular, we identify two substates of the hard state and provide new information on the plasma behaviour during the jet emission. The second study is based on data taken during the 2015 outburst of transient black hole binary V404 Cygni. The results of detailed spectral analysis show that a single Componization component, purely thermal or hybrid, is not sufficient to explain the hard X-ray emission during a strong radio emission period.

*Keywords*: Accreting black holes; spectral states; hard X-rays; $\gamma$-rays.

## 1. Introduction

The properties of the plasma residing in the centre of the black hole (BH) accreting systems remain an open question despite several decades of observational and theoretical efforts[1]. Since the plasma is emitting mainly in the hard X-ray/soft $\gamma$-ray band, the INTEGRAL satellite[2] operating in that band is currently one of the best tools for a direct diagnosis of the plasma properties. In this talk a review of the results of two examples of such studies will be presented. The first study is related to the spectral states of the well-known persistent BH binary Cyg X-1. The second study involves the hard X-ray emission observed from the V404 Cygni transient source during its recent outburst in 2015.

## 2. Spectral states of Cyg X-1

Characterization of the spectral states of the BH systems is a common method to get deeper insights into to the nature of these systems[1]. In general, both transient and persistent systems evolve between two main states, hard and soft, with several intermediate state classes observed. The hard state corresponds to the emission from a hot plasma dominating in the X-ray band, well modeled with a thermal Comptonization of some seed photons. In the soft state the plasma emission appears weaker and rather non-thermal, and the soft band is dominated by a thermal emission from the accretion disk. Spectral states are usually classified through one or two parameters derived from the soft X-ray observations, i.e., in the band below $\approx$10 keV. In the case of X-ray monitors providing count rate in several energy bands the state is identified with the use of the count rate and ratio of count rates in two energy bands (hardness ratio). These quantities are commonly plotted in a form of so-called hardness-intensity diagram (HID) showing the spectral evolution

of the object. The HID data allow for a quite good separation of the states as demonstrated for example for Cyg X-1[4].

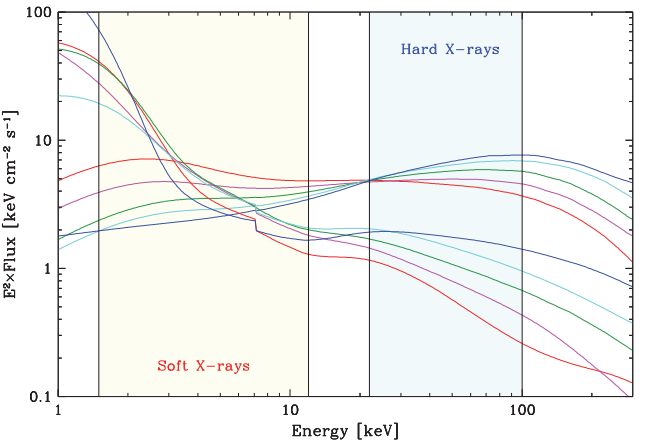

Fig. 1. Models fitted to twelve INTEGRAL's summed spectra of Cyg X-1, with data selected according to the hard X-ray flux and hardness. Yellow region shows typical energy range used to classify the spectral states. Cyan region is the hard X-ray band used in our study.

The soft X-ray band is a natural choice for spectral states studies because of a large number of photons emitted from the source and relatively low instrumental background. On the other hand, the X-ray/soft $\gamma$ spectra of accreting BHs are quite complex because besides the two dominating components, i.e., the disk and plasma emission, there are other processes involved, such as absorption or reprocessing in surrounding media, including Compton reflection and iron line emission. These additional components affect mostly the soft X-ray band, whereas for objects with a limited reflection the hard X-ray emission is mainly governed by the plasma. Therefore, the plasma properties can be studied in a quite unambiguous way using the emission above $\approx$ 20 keV, not affected by the disk emission and absorption.

In Fig. 1 we present models fitted to the Cyg X-1 spectra collected with the *INTEGRAL*'s IBIS and JEM-X telescopes. These spectra were summed over observations done in the 2002–2017 period, with a selection based on the count rates in the 22–40 and 40–100 keV bands. It can be clearly seen that the hard X-ray band enables a better separation of the hard and soft spectral states than the soft X-ray band. This motivated us to do a massive analysis of several spectral parameters obtained in that band with the ISGRI detector over 16 years of *INTEGRAL*'s observations of Cyg X-1. Since the ISGRI calibration evolved over so many years, the spectral fitting with responses taking into account that evolution was done to extract the photon index $\Gamma_{\rm H}$ and flux $F_{\rm H}$ for the 22–100 keV band. In total, we extracted the data for 7821 observations lasting 0.5–2.0 hours (so-called science windows). These results are presented in Fig. 2. The soft and hard state are separated by the flux level of about $75{\times}10^{-10}$ erg sm$^{-2}$ s$^{-1}$. In addition, for the hard state we

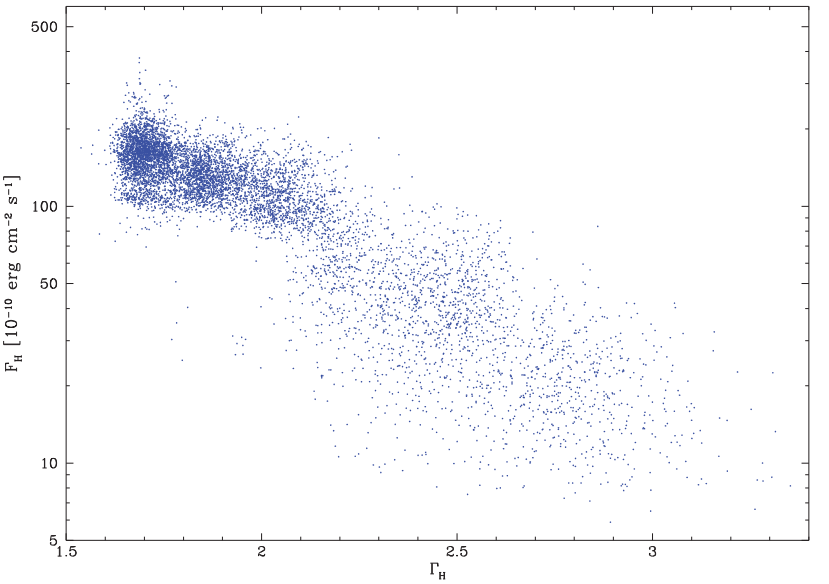

Fig. 2. Hard X-ray photon index $\Gamma_H$ - hard X-ray flux $F_H$ diagram. Both quantities were determined for the 22–100 keV band.

observe a clear clustering around $\Gamma_H$ equal to 1.68, 1.85 and 2.02. We called these substates pure hard, transitional hard and hard intermediate, respectively.

To characterize better these states we did a Spearman rank-order test for the $\Gamma_H$-$F_H$ data over each single *INTEGRAL* orbit (about 3 days), determining the correlation coefficient $r_S$ and null hypothesis probability $P_S$. As shown in Fig. 3 the flux - photon index correlation varies with increasing $\Gamma_H$. For pure hard state as well as for the softest data we do not observe correlation whereas it is quite strong for the transitional hard state and then slowly decreases when the spectra become softer. Such behavior implies that the pure hard state and softest state are physically different from the rest. Interpreted in terms of the Comptonization scenario a lack of correlation points toward self-synchrotron source of the seed photons instead of the disk photons.

Cyg X-1 was quite frequently observed during the studied period at the 15 GHz radio band by the Ryle telescope[5] and its successor, the AMI Array[10]. The radio flux $F_R$ plotted against the hard X-ray photon index determined for contemporary *INTEGRAL* spectra shows interesting features. For all three hard substates we observe a stratification of $F_R$, with the relatively low range seen for the pure hard state, then higher values for the transitional state and the highest radio emission during the hard intermediate state. For softer spectra the radio flux slowly decreases and vanishes for the softest state. Such an interdependence reinforces our findings for Cyg X-1: the hard X-ray data reveal several substates of the hard state in that object. In the forthcoming paper[3] we will present details of our analysis and a deeper interpretation of the results.

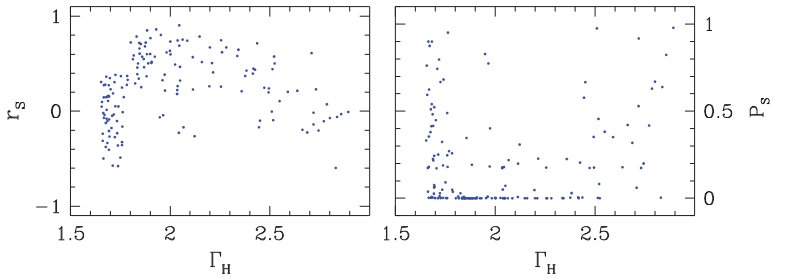

Fig. 3. Correlation between the hard X-ray photon index and flux in a function of the photon index. Left panel shows the Spearman correlation coefficient $r_S$, right panel corresponding null hypothesis probability $P_S$.

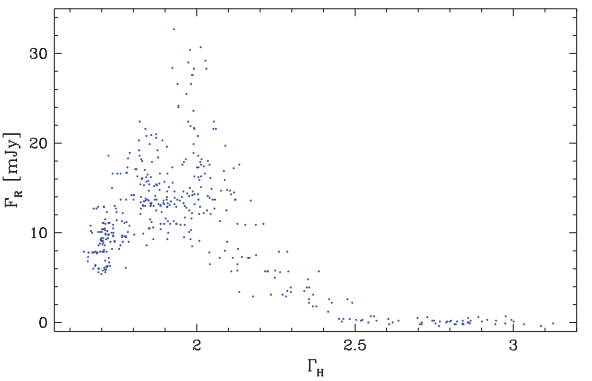

Fig. 4. Radio flux at 15 GHz measured by the Ryle and AMI observatories plotted against the hard X-ray photon index.

## 3. Evolution of V404 Cygni emission during the 2015 outburst

The transient BH system V404 Cygni enters an outburst phase every $\approx 30$ years, showing some properties specific to this object. The emission is highly variable and strongly absorbed when compared to the other transient systems[11]. Its recent outburst in 2015 was observed by many observatories[9], what resulted in dozens of papers presenting interesting results. Analysis of the hard X-ray spectra from *INTEGRAL* was already presented, however, the research was done in a rather limited band, without the soft X-rays[7,8]. Here we present preliminary results of a broad-band analysis of spectra from the JEM-X, ISGRI and PICsIT detectors, covering the 3–1000 keV band.

Figure 5 presents the hard X-ray and soft $\gamma$-ray light curves of the 2015 outburst. An interesting feature is that the emission was extremely variable during the satellite orbits 1554, 1554 and first part of 1556, whereas later the count rates varies rather smoothly, with a clear detection of emission above 250 keV. Taking into account the single science window spectra we have summed up the data for periods with similar overall spectral shape. The resulting 18 spectra were fitted with the complex

model including hybrid Comptonization, Compton reflection and several absorption components. Examples of these spectra together with the fitted model are shown in Fig. 6. The $\gamma$-ray emission during the bright phase of the 1557 orbit is detected up to almost 1 MeV, revealing a hard power-law like tail in addition to the hybrid plasma model.

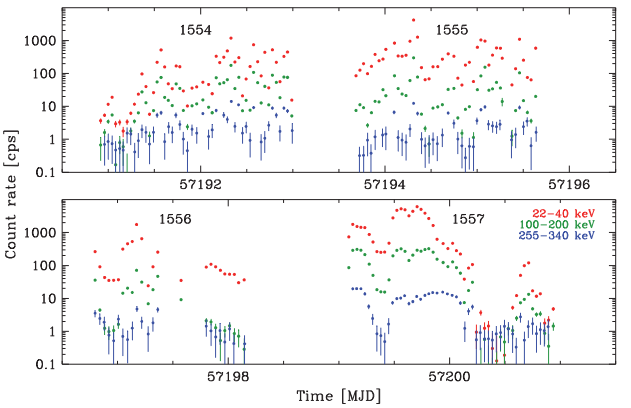

Fig. 5. Variability of the V404 Cygni hard X-ray/*gamma* emission during the 2015 outburst. The 22–40 keV and 100–200 keV count rates were measured by *INTEGRAL*/ISGRI and the 255–340 keV count rate by *INTEGRAL*/PICsIT.

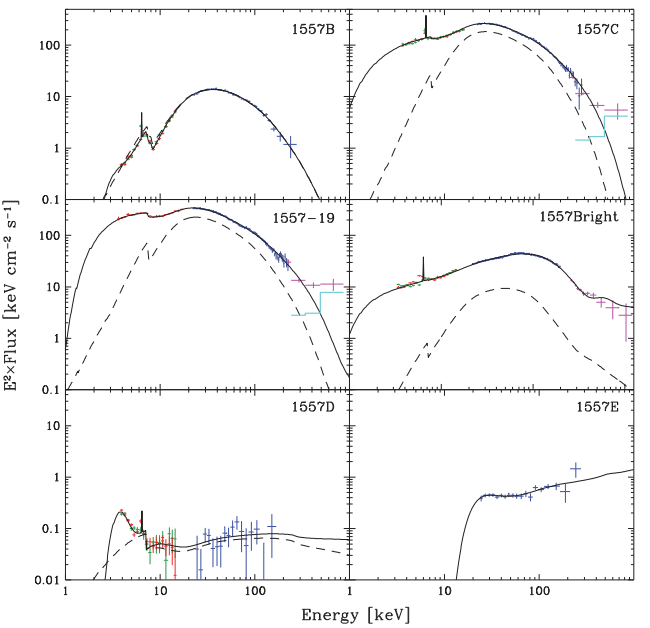

Fig. 6. Examples of V404 Cygni spectra collected by the *INTEGRAL* satellite in the 3–1000 keV band. Total fitted model is shown with a solid line and the reflection component with a dashed line. Cyan steps show the 3-$\sigma$ detection limits for the PICsIT detector data (magenta).

Besides the hard tail seen in several cases, all the spectra are well modeled with the Comptonization model, either thermal or hybrid with a non-thermal component. A presence of the additional tail component appears to be correlated with an enhanced radio emission[9], indicating its relation to the strong jet. Almost all spectra are dominated by the Compton reflection component. Its low ionization state points toward reprocessing in a dense and cold medium what seems to be puzzling taking into account the X-ray brightness of the object. We do not observe a correlation of the absorbing column density with the flux level, thus the strong variability seems to be driven by some phenomenon other than varying absorber. Further details of this research will be presented in a forthcoming paper[6].

Observational evidences show that during the outburst, black hole binaries move to different spectral states depending on accretion flow that feeds these objects. However proper physical picture is still unclear, what causes these states change and how the quasi periodic oscillation (QPO) in observed lightcurve is related with the disk properties? In a Two Component Advective Flow (TCAF) solution it is established that low angular momentum and low viscous sub-Keplerian flow produces hot corona, which up-scatters soft photons from the Keplerian disk. We analyze the outbursts data of black holes of different scales ranging from low mass to super massive observed by different satellites with TCAF and discuss the outburst features and their spectral states.

*Keywords*: X-Rays:binaries; Black Holes; shock waves; accretion; accretion disks; Radiation:dynamics

## 1. Introduction

Accreting black hole spectra consist different components, e.g. blackbody, power-law and an iron line at around 6.4 keV. These distinct components are mainly from the optically thick and thin components of the flow. It is well established that the spectra change their shape during the outburst from hard to soft through intermediate states. Several attempts were made to explain changes in the spectral shape and its variation (Remillard & McClintock 2006 for a review). It is believed that the changes in the accretion rate might be responsible for the changes in the spectral states (Maccarone & Coppi 2003). However, causes of the change in accretion rate on a progressive days, the origin of corona and its temperature, optical depth etc. were unclear.

The problems were satisfactorily resolved when proper usage of the solution of transonic flows in presence of cooling, heating and viscosity were used. In a Two Component Advective Flow (TCAF, Chakrabarti & Titarchuk 1995, hereafter CT95) solution, a Keplerian disk which arises out of higher viscosity is flanked by a hot sub-Keplerian flow of lower viscosity. This sub-Keplerian, low angular

momentum hot matter forms an axisymmetric shock due to the balance of the centrifugal force with gravity (Chakrabarti 1989). The subsonic region between the shock (centrifugal barrier) to the inner sonic point is hot and puffed up and behaves as the Compton cloud, which reprocesses intercepted soft photons from the standard disk. This region could be oscillatory when its cooling time scale roughly matches with the infall (compression) timescale inside CENBOL (Molteni et al. 1996). Recently, Chakrabarti et al. (2015) applied the resonance condition for H 1743-322 black hole candidate and showed that the low frequency quasi-periodic oscillations (LFQPOs) are produced when cooling time scale roughly matches with the heating time scale. Transonic solution by Mondal & Chakrabarti (2013; CT95) shows that cooling mechanism is also responsible for the change in spectral states during the outburst.

After the implementation of TCAF in XSPEC (Debnath et al. 2014) and fitting data of several black hole candidates (BHCs), one obtains physical parameters of the flow, such as the accretion rates of the disk and halo components, the shock location and the shock compression ratio. If the mass of the candidate is unknown, this will also be found out from the spectral fitting (e.g., Molla et al. 2016; 2017). A plot of photon count variation with accretion rate ratio (ARR = halo rate/disk rate) gives the so call ARR intensity diagram (ARRID, Mondal et al. 2014; Jana et al. 2016) and directly shows why the spectral state changes. The changes in accretion rates on a progressive days is due to changes in viscosity parameter ($\alpha$) of the flow during the outburst (Mondal et al. 2017). The presence of double horn Iron line is also observed from the TCAF (Mondal et al. 2016) during the fitting of high resolution NuSTAR data of GX 339-4 BHC, which helps to determine the spin parameter of the candidate. It should be noted that so far TCAF is implemented for low mass black hole binaries as an additive table model. However, very recently, the model is directly implemented in XSPEC as a local model to analyze the active galactic nuclei (AGNs, Nandi et al. 2019) data.

The *paper* is organized in the following way: in the next Section, briefly we discuss the observation and data analysis procedure for both Swift and NuSTAR satellites. In §3, we present our results of spectral fitting for both low mass and super massive BHs. We also discuss how viscosity is responsible for the change in spectral states. Finally we draw our concluding remarks.

## 2. Observation and data analysis

In the present manuscript, we analyze both Swift/XRT (Gehrel et al., 2004) and NuSTAR (Harrison et al. 2013) satellite observations of the BHC Swift J1357.2-0933 during its 2017 outburst. The Swift/XRT observation we analyzed 00031918066 (Windowed Timing mode, WT) with exposure time 0.7 ksec and NuSTAR observations with observation ID: 90301005002, with exposure time 45ksec. To fit the data with the TCAF model in XSPEC, we use a TCAF model generated *fits* file (Debnath et al. 2014). We use the absorption model *TBabs* with hydrogen column

density fixed at $1.3\times 10^{21}$ atoms cm$^{-2}$ throughout the analysis for the SwiftJ1357.2. We analyze *NuSTAR* data with exposure times longer than 5 ksec for NGC 4151 with observation date from November 11 to 14, 2012. The observation IDs are 60001111002, 60001111003 and 60001111005 respectively. For the spectral fitting of AGN data with TCAF, we run TCAF directly in XSPEC as a local model (see Nandi et al. 2019). The model was originally introduced by Chakrabarti in 1995 for AGN and a discussions of satisfactory fits of AGN spectra are present in the literature (Mandal & Chakrabarti 2008). For the data processing and analysis, we follow the standard tasks discussed in Mondal et al. (2016).

## 3. Results and Discussions

In this section we discuss about the model fitted results and the geometry of the flow on the basis of the fitted parameters. We consider Swift J1357.2-0933, a low mass candidate and NGC 4151, an AGN for our study.

### 3.1. *Swift J1357.2-0933*

The source was first detected in 2011 by the *Swift* Burst Alert Telescope (Krimm et al. 2011). We fit the observation of Swift J1357.2-0933 with TCAF solution based fits file which uses five physical parameters (if mass is unknown): The parameters are as follows (i) Mass of the black hole, (ii) disk accretion rate, (iii) halo accretion rate, (iv) location of the shock, and (v) shock compression ratio. All the parameters collectively give the electron density and temperature, photon spectrum and density, the fraction of soft photons intercepted by the Compton cloud from the Keplerian disk, as well as the reflection of hard photons from the Compton cloud by the disk. In Chakrabarti (1997) showed a detailed spectral variation with different model parameters. In Fig. 1 (left panel), we present the TCAF model fitted spectrum for this candidate which covers a broadband energy range from 0.5 - 70 keV. The data fits well for $M_{\odot} = 4.01$, $\dot{m}_d = 0.019$, $\dot{m}_h = 0.213$, $X_s = 36.7\ r_g$, R=2.0 with $\chi^2/dof$=473.1/446.

The model fitted parameters show that the halo rate is higher than the disk rate and the shock compression ratio is in the regime of strong mass loss (see Chakrabarti 1999). This is an indication of hard spectral state. If we follow the previous observed day and fit the data with model, it shows that, at some point in time after the first observation day, viscosity may have started to go up, and the Keplerian disk rate also started to increase (see Mondal & Chakrabarti 2019). However, this was not enough so as to change the spectral state (as a minimum viscosity is required for such changes (Mondal et al. 2017)). We also fit the data with power-law (PL) model. The PL model fitted photon index (=1.8) also indicates a hard spectral state. Following the above model understanding and the values of the model fitted parameters, we conclude that the source was in rising hard state of the outburst during the observations. We also estimate some physical parameters of the disk

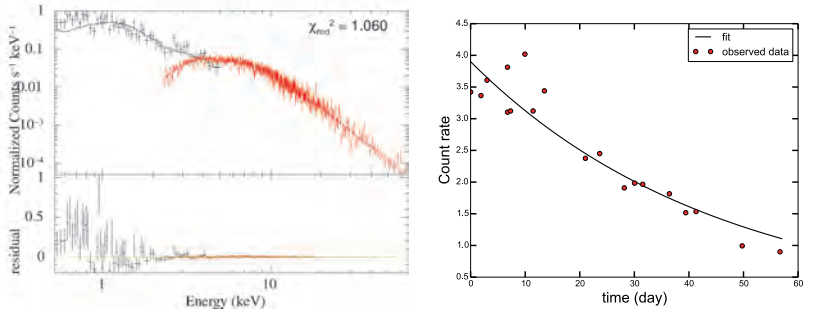

Fig. 1. Left panel: Swift/XRT and NuSTAR (focal plane module A, FPMA) data from 0.5-70.0 keV energy range are fitted with an absorbed TCAF model. Right panel: Variation of count rate with time (day). Black solid line shows the model fit and filled circles are observed count rates. Data are fitted with $H/R = 0.024$ (from above), $P = 2.8$ hrs, $q = 0.03$ and SS73 $\alpha = 0.25$. Data and figure are presented from MC19.

and check the stability of the disk to produce a sufficient viscosity to explain the observed lightcurve from the TCAF model fitted parameters. From the Kepler's law, one can derive a relation between orbital period ($P$) and orbital separation $a$. Outer disk radius ($r_{out}$) of the primary star is calculated from the Roche lobe radius of the primary following Eggleton (1983). In this work, we consider that the outer edge of the disk ($r_{out}$) is 70% of the Roche lobe radius. which appears to be $r_{out} = 0.68 \times 10^{11}$. The steps followed to fit the observed lightcurve are: (i) we have mass and disk accretion rate from the model fit, (ii) using (i) we estimate the temperature of the disk thus the sound speed, (iii) outer disk radius is estimated from orbital period and mass ratio from the literature, (iv) once (ii) and (iii) are known one can estimate height of the disk, Keplerian angular frequency, and disk kinematic viscosity to estimate the viscous time scale, and (v) finally, we extract SS73-$\alpha$ parameter ( Shakura & Sunyaev 1973) for which the derived and the fitted $\tau$ values are consistent. Here, $\alpha$ takes the value 0.25 to give a decay timescale ($\tau$) of $\sim$ 45 days. To fit the observed lightcurve using decay timescale, we use an exponential decay function, $f = A\ exp(-t/\tau)$, where $A$ is a normalization constant, which takes the value of $3.91 \pm 0.16$ with an exponential decay timescale ($\tau$) around $45.28 \pm 4.78$ *days*. The estimated SS73 disk viscosity parameter ($\alpha = 0.25$) satisfies the same order of magnitude obtained for other observed candidates (Mondal et al. 2017). In Fig. 1 (right panel), we show exponential decay function fitted with the observed lightcurve. As the halo rate is higher than the disk rate and the shock compression ratio is always greater than unity for this outburst, inverse-Comptonization process is dominant which cools down the system and the shock moves inward (Mondal & Chakrabarti 2013; CT95). The velocity of the shock movement is $\sim$ 0.15 m/s for this candidate which is similar to the shock velocity in other outbursts (Mondal et al. 2015 for H 1743-322 and references therein). This indicates that the outburst probably remained in the rising phase and no other

spectral state has been missed in between these $\sim 40$ *days*. Our model fitted disk rate is $\sim 2\%$ of $\dot{M}_{Edd}$. As the shock compression ratio is intermediate, the jets and outflows are expected to be strong with mass outflow/inflow rate ratio 3.4-4.2%.

### 3.2. *NGC 4151*

The Seyfert 1.5 galaxy NGC 4151 (z=0.00332, de Voucouleurs et al. 1991), sometimes considered as a Seyfert 1 type AGN, is one of the most popular sources for which many AGN phenomena were first characterized (for more details, see Ulrich 2000). Here we study spectral properties of NGC 4151 with TCAF using three *NuSTAR* observations during 2012. The outburst data considered in this work is fitted with TCAF in addition with a power-law (PL) model. In Fig. 2(a-c), we show the TCAF model fitted 3.0-70.0 keV spectra along with residual in the bottom panel for three observation IDs. In Fig. 2d, unabsorbed model spectra are shown which are used to fit the observed data.

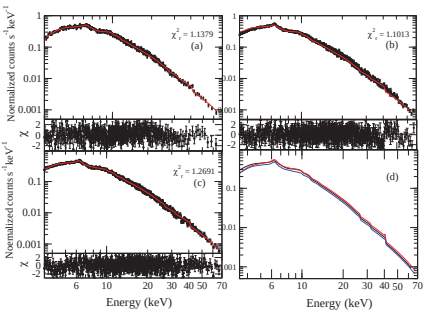

Fig. 2. TCAF model fitted 3.0 - 70 keV *NuSTAR* spectra with variation of $\chi^2$, for three IDs. (a) 60001111002, (b) 60001111003 and (c) 60001111005. In (d), unabsorbed TCAF+PL model generated spectra are shown, which are used to fit the observation. Figure is adopted from Nandi et al. (2019).

From the spectral fit we estimate the mass of the central black hole to be $3.03^{+0.26}_{-0.26} \times 10^7 M_\odot$ which appears to be in the same ball park as obtained by previous studies. Furthermore, unlike other models, we obtained the two accretion rates and found that the halo rate is much larger as compared to the disk accretion rate, consistent with the fact that the object was always in the hard state and the fact that AGN usually accretes low angular momentum matter, unless a part is also converted to Keplerian by a sufficient viscosity. Analysis also shows that in all these three observations, the $X_s$ (i.e. corona) was more or less constant $\sim 150\ r_s$. This is partly due to the fact that in a supermassive black hole system short term variabilities are rare. However to get the more detail understanding about the evolution of the accretion flow, we need to have a long term monitoring. The details about the model parameters variation can be seen in Nandi et al. (2019).

# ULXs as magnetized sub-Eddington advective accretion flows around stellar mass black holes

Banibrata Mukhopadhyay

*Department of Physics, Indian Institute of Science,*
*Bangalore 560012, India*
*E-mail: bm@iisc.ac.in*
*www.iisc.ac.in*

Ultra-luminous X-ray sources (ULXs) have been puzzling us with a debate whether they consist of an intermediate mass black hole or super-Eddington accretion by a stellar mass black hole. Here we suggest that in the presence of large scale strong magnetic fields and non-negligible vertical motion, the luminosity of ULXs, particularly in their hard states, can be explained with sub-Eddington accretion by stellar mass black holes. In this framework of 2.5D magnetized advective accretion flows, magnetic tension plays the role of transporting matter (equivalent to viscous shear via turbulent viscosity) and we neither require to invoke an intermediate mass black hole nor super-Eddington accretion. Our model explains the sources, like, NGC 1365 X1/X2, M82 X42.3+59, M99 X1 etc. which are in their hard power-law dominated states.

*Keywords*: accretion disks; ULXs; magnetic fields; black holes.

## 1. Introduction

While the existence of stellar mass black holes of mass $M \lesssim 80M_\odot$ and supermassive black holes of mass $M \gtrsim 10^6 M_\odot$ are confirmed, there is no direct evidence for black holes of mass in between. Scientists believing in the continuous mass distribution argue for the existence of such black holes, called intermediate mass black hole. However, many others argue that there is no such obvious expectation as the origins of stellar mass and intermediate mass black holes are completely different. Nevertheless, there are ultra-luminous X-ray sources (ULXs) observed in galaxies around, which apparently cannot be explained by the conventional idea of stellar mass black holes accreting at a sub-Eddington limit. Hence, the proposal is that the sources harbor an intermediate mass black hole, particularly when they reveal lower temperature in the underlying multicolor black hole spectra [1]. However, there is another idea behind ULXs that they are stellar mass black holes only but accreting at a super-Eddington rate: candidates for slim accretion disk [2].

Nevertheless, none of the above ideas is a conventional one. There are significant evidences that X-ray binaries are sub-Eddington accretors and there is no direct evidence yet of galactic black hole mass $M \gtrsim 100M_\odot$ (though the detection of gravitational wave argues for the black hole mass larger than that determined in X-ray astronomy). Here our story lines start. We show that ULXs in hard states can be explained by a stellar mass black hole accreting at a sub-Eddington rate with advection in the presence of large scale strong magnetic field. Hence, by the interplay between magnetic field and advection, X-ray binaries could be quite luminous in the hard state. For that we neither require an intermediate mass black hole nor super-Eddington accretion. Hence, while still the existence of intermediate

black hole, even appeared as ULX, is not ruled out, some ULXs in hard states, e.g. NGC 1365 X1/X2, M82 X42.3+59, M99 X1 etc., are suggested to be highly magnetized stellar mass black hole sources only.

We model a combined disk-outflow coupled system with the inclusion of vertical velocity and large scale magnetic stress explicitly. This is essentially a 2.5D magnetized advective accretion disk model. We show that energetics and luminosities of such a flow are in accordance with ULXs.

## 2. Magnetized disk-outflow coupled system

We consider a magnetized, viscous, advective disk-outflow/jet symbiotic system with cooling around black holes. We consider the large scale magnetic and turbulent viscous stresses both and depending on the field strength one of them may dominate over other. Here we assume a steady and axisymmetric flow and all the flow parameters: radial velocity ($v_r$), specific angular momentum ($\lambda$), outflow or vertical velocity ($v_z$), fluid pressure ($p$), mass density ($\rho$), radial ($B_r$), azimuthal ($B_\phi$), and vertical ($B_z$) components of magnetic field, are functions of both radial and vertical coordinates. Throughout we express length variables in units of $GM_{BH}/c^2$, where $G$ is the Newton's gravitational constant, $M_{BH}$ the mass of BH, and $c$ the speed of light. Accordingly, we also express other variables. Hence, the continuity and momentum balance equations are respectively

$$\nabla.(r\rho\mathbf{v}) = 0, \text{ and } (\mathbf{v}.\nabla)\mathbf{v} = \mathbf{F} - \frac{1}{\rho}\nabla\left(p + \frac{B^2}{8\pi}\right) + \frac{(\mathbf{B}.\nabla)\mathbf{B}}{4\pi\rho} + \frac{1}{\rho}\nabla.\mathbf{W}, \quad (1)$$

where $\mathbf{v}$ and $\mathbf{B}$ are velocity and magnetic field vectors respectively, $|\mathbf{F}|$ is the magnitude of the gravitational force for a BH in the pseudo-Newtonian framework[3]. The importance of generalized viscous shearing stress tensor ($\mathbf{W} = W_{ij}$) is taking care explicitly in this formalism. Various components of $W_{ij}$ are written in terms of $\alpha$-prescription[4] with appropriate modifications[5]. We also have to supplement the above equations with the equations for no magnetic monopole and induction, as respectively

$$\nabla.\mathbf{B} = 0 \text{ and } \nabla \times (\mathbf{v} \times \mathbf{B}) + \nu_m \nabla^2 \mathbf{B} = 0, \quad (2)$$

where $\nu_m$ is the magnetic diffusivity. We consider equation (2) in the very large magnetic Reynolds number ($\propto 1/\nu_m$) limit, which is the case for an accretion disk. We further have to supply the energy balance equations for ions and electrons by taking into account the detailed balance of heating, cooling and advection. The magnetized energy equations for ions and electrons read as

$$\Gamma_3' \left[ v_r \left\{ \frac{\partial p}{\partial r} - \Gamma_1 \frac{p}{\rho}\frac{\partial \rho}{\partial r} \right\} + v_z \left\{ \frac{\partial p}{\partial z} - \Gamma_1 \frac{p}{\rho}\frac{\partial \rho}{\partial z} \right\} \right] = Q^+ - Q^{ie}, \quad (3)$$

where

$$\Gamma_1 = \frac{32 - 24\beta - 3\beta^2 + \frac{2\beta(4-3\beta)}{3\beta_M}}{24 - 21\beta}, \text{ and } \Gamma_3' = \frac{24 - 21\beta}{2(4-3\beta)},$$

$$\Gamma_3' \left[ v_r \left\{ \frac{\partial p_e}{\partial r} - \Gamma_1 \frac{p_e}{\rho} \frac{\partial \rho}{\partial r} \right\} + v_z \left\{ \frac{\partial p_e}{\partial z} - \Gamma_1 \frac{p_e}{\rho} \frac{\partial \rho}{\partial z} \right\} \right] = Q^{ie} - Q^-, \tag{4}$$

where $Q^+$ represents the viscous and magnetic (Ohmic) heats generated in the flow, $Q^{ie}$ the Coulomb coupling estimating the amount of heat transferred from ions to electrons, and finally $Q^-$ the radiative cooling rate through electrons via different cooling processes including bremsstrahlung, synchrotron and inverse Comptonization of soft photons supplied from the Keplerian disk. Various cooling formalisms are adopted from past works[6–8]. In order to solve the equations semi-analytically, we make a reasonable hypothesis in the disk-outflow symbiotic region that the vertical variation of any dynamical variable (say, $A$) is much less than that with radial variation, that allows us to introduce $\partial A/\partial z \approx sA/z$, where $s$ is just the degree of scaling and is a small number.

## 3. Disk hydromagnetics and energetics

Figure 1 shows disk-outflow hydromagnetics revealing that large scale strong magnetic fields are able to transport angular momentum adequately rendering further significant $v_r$ and $v_z$ with decreasing $r$. The angular momentum profile turns out to be similar to that obtained based purely on $\alpha-$viscosity and hence $W_{ij}$ when the field is weak. However, the benefit with large scale magnetic stress is that it renders significant vertical outflow along with radial inflow. It is confirmed from Figs. 1d,e that close to the black hole magnetic field could be even $\sim 10^7$ G with an efficient magnetic shear compared to $\alpha-$viscosity induced viscous shear.

Now energetics can be estimated based on above hydromagnetism. The energy equation in conservative form under steady state condition is given by

$$\nabla.\mathcal{F} = 0 \text{ with } \mathcal{F}_i = \rho v_i \left( \frac{v^2}{2} + \frac{\Gamma_1}{\Gamma_1 - 1} \frac{p}{\rho} + \frac{B^2}{8\pi} + \Phi \right) + v_j M_{ij} - v_j W_{ij}, \tag{5}$$

where $i, j$ correspond to $r$ or $\phi$ or $z$, indicating radial or azimuthal or vertical component of the respective variables with $v^2 = v_r^2 + \lambda^2/r^2 + v_z^2$, $\Phi$ is the gravitational potential, and $M_{ij}$ is the magnetic stress tensor with standard definition, given by

$$M_{ij} = \frac{B^2}{8\pi}\delta_{ij} - \frac{B_i B_j}{4\pi}. \tag{6}$$

The outflow power extracted from the disk is computed at the disk-outflow surface region. It defines as[5]

$$P_j(r) = \int 4\pi r \left[ \rho v_z \left\{ \frac{v^2}{2} + \frac{\Gamma_1}{\Gamma_1 - 1} \frac{p}{\rho} + \Phi - \left( \frac{\lambda}{r} W_{\phi z} + v_r W_{rz} \right) \right\} + \frac{v_z}{4\pi} \left( B_r^2 + B_\phi^2 - \frac{v_r}{v_z} B_r B_z - \frac{\lambda}{r v_z} B_\phi B_z \right) \right]_h dr. \tag{7}$$

This accretion induced outflow power contains contributions from mechanical and enthalphy powers, and those of viscous and Poynting parts. Our model is restricted

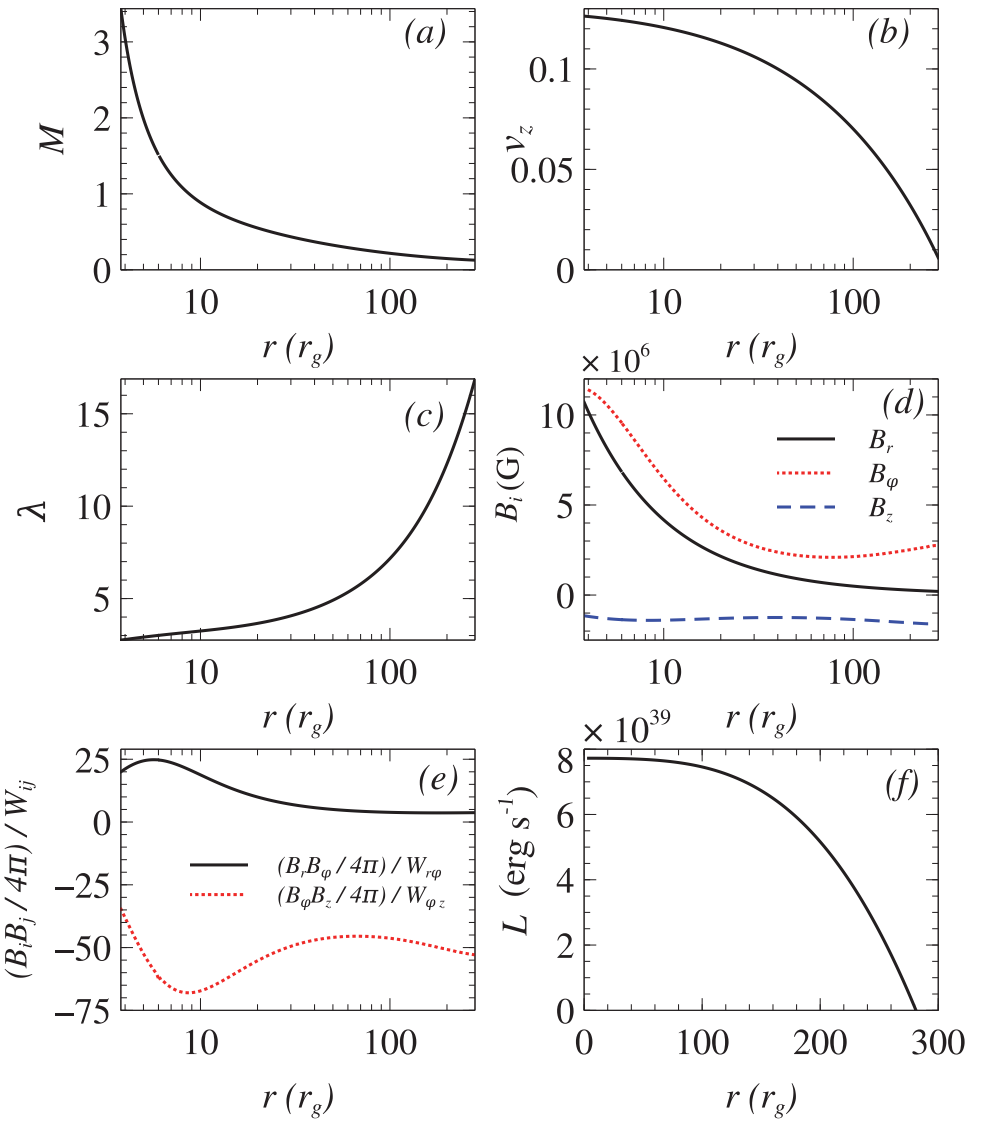

Fig. 1. Variation of (a) Mach number, (b) outflow speed, (c) specific angular momentum, (d) magnetic field components, (e) ratio of magnetic to viscous shearing stresses, and (f) luminosity, as functions of distance from the black hole. Other parameters are $M_{BH} = 20M_{\odot}$, $\dot{m} = 0.05$ Eddington rate.

vertically up to the disk-outflow coupled region, above which outflow may decouple and accelerate. Hence this computed power is basically the initial power of any astrophysical jets at the launching region. Also the disk luminosity can be computed from the cooling mechanisms and can be defined as

$$L = \int \left( \int_0^h Q^- 4\pi r \; dz \right) \; dr. \tag{8}$$

The variation of disk luminosity, whose magnitude is the most important observable in the present context, is shown in Fig. 1f. At an arbitrary $r$, the luminosity is obtained by integrating from the outer disk radius $r_{out}$ to that corresponding $r$. For the case of a stellar-mass black hole of mass $M_{BH} = 20\ M_\odot$ with total mass accretion rate $\dot{m} = 0.05$ Eddington rate, the maximum attainable luminosity, based on the integration over whole disk, is $L \sim 8 \times 10^{39}$ erg s$^{-1}$. This value is quite adequate to explain observed luminosities of ULXs in hard states. Table 1 enlists some ULXs with their respective power-law indices, indicating their harder nature. It is very interesting that the luminosity of the sources $L \sim 10^{40}$ erg s$^{-1}$, which can be explained by a stellar mass black hole accreting at a sub-Eddington rate in the presence of strong magnetic fields, as described in Fig. 1f.

Table 1: Some ULX sources in a hard power-law dominated state.

| Source | $\Gamma$ | $L_{0.3-10\ \mathrm{keV}}$ ($10^{40}$ erg s$^{-1}$) |
|---|---|---|
| M99 X1 [9] | $1.7^{+0.1}_{-0.1}$ | 1.9 |
| Antennae X-11 [10] | $1.76^{+0.05}_{-0.05}$ | 2.11 |
| Holmberg IX X-1 [11] | $1.9^{+0.1}_{-0.02}$ | 1.0 |
| NGC 1365 X1 [12] | $1.74^{+0.12}_{-0.11}$ | 2.8 |
| NGC 1365 X2 [12] | $1.23^{+0.25}_{-0.19}$ | 3.7 |
| M82 X42.3+59 [13] | $1.44^{+0.09}_{-0.09}$ | 1.13 |

## 4. Summary

ULXs and the question of plausible existence of intermediate mass black hole in the universe are both puzzling us for quite sometime. Some authors argue ULXs to be the sources of an intermediate mass black hole. Some others argue ULXs to be super-Eddington acrretors by a stellar mass black hole. The later group further argues that there is no need to expect a continuous mass distribution of black holes from stellar mass to supermassive scales. We suggest quite differently and uniquely. We show that at least some of ULXs are nothing but the highly magnetized accreting sources of stellar mass black holes accreting at a sub-Eddington rate only. The required field magnitude is of the order of $10^7$ G to explain ULXs in hard states, which is well below the underlying Eddington value. Therefore, at least some of

ULXs could just be stellar mass black holes. While this suggestion leaves the question for the existence of intermediate mass black hole wide open, it argues for the power of magnetically dominated/arrested accretion flows to explain enigmatic astrophysical sources.

We study the bound orbit conditions for equatorial and eccentric orbits around a Kerr black hole both in the parameter space ($E$, $L$, $a$) representing the energy, angular momentum of the test particle, and spin of the black hole, and also ($e$, $\mu$, $a$) space representing the eccentricity, inverse-latus rectum of the orbit, and spin. We apply these conditions and implement the relativistic precession (RP) model to M82X-1, which is an Intermediate-mass black hole (IMBH) system, where two high-frequency Quasi-Periodic Oscillations (HFQPOs) and a low-frequency QPO were simultaneously observed. Assuming that the QPO frequencies can also be generated by equatorial and eccentric trajectories, we calculate the probability distributions to infer $e$, $a$, and periastron distance, $r_p$, of the orbit giving rise to simultaneous QPOs. We find that an eccentric orbit solution is possible in the region between innermost stable circular orbit (ISCO) and the marginally bound circular orbit (MBCO) for $e = 0.2768^{+0.0657}_{-0.0451}$, $a = 0.2897 \pm 0.0087$, and $r_p = 4.6164^{+0.0694}_{-0.1259}$.

*Keywords*: Classical black holes; Relativity and Gravitation; Infall, accretion and accretion disks; Kerr black hole; QPOs.

## 1. Introduction

Black holes have been discovered as part of various systems in galaxies; as one of the components of the transient binary systems known as black hole X-ray binaries (BHXRB) with black hole mass in the range $5 - 30 M_\odot$, as intermediate mass black holes (IMBH) with mass range 300 to 600 $M_\odot$, and as galactic nuclei of mass $10^6 - 10^{10} M_\odot$ (Ref. 1). X-ray emission from such systems gives evidence of the presence of a compact object as X-rays originate very close to the black hole, and hence are important probes of the strong gravity regime. One of the important features discovered in the X-ray emission from these systems is quasi-periodic oscillations (QPOs), which are broad peaks in the Fourier power density spectrum. QPOs have been discovered with their frequencies ranging from mHz-kHz (Ref. 2), in BHXRB, mHz to a few Hz in IMBH (Ref. 3), and expected with the time scales of hours to days for AGN. The most interesting features among these are the high-frequency QPOs (HFQPOs) in the range 100-500Hz (Refs. 5, 6), detected in various BHXRB which may be used to calculate spin $a$ and mass $M_\bullet$ of the black hole when detected simultaneously. Some of these objects have also shown two simultaneous HFQPOs with their centroid frequencies having ratios ∼3:2 or 5:3 (Ref. 2), indicating a resonance. There are also some cases, for example, GROJ1655-40 (Ref. 7), and M82 X-1 (IMBH) (Ref. 3), which are known to show the detection of three simultaneous QPOs, two HFQPOs and one low-frequency QPO (LFQPO). There are various existing models that attempt to explain the origin of QPOs but perhaps the most

widely accepted is the relativistic precession (RP) model (Ref. 8), which interprets LFQPO as the nodal precession frequency given by ($\nu_\phi$-$\nu_\theta$), and the two HFQPOs as associated with the azimuthal frequency, $\nu_\phi$, and the periastron precession frequency ($\nu_\phi$-$\nu_r$) of a particle orbiting around a black hole. RP model has been previously applied to the cases of BHXRB (Ref. 7), assuming that the frequencies correspond to circular orbits of an equatorial system.

In this article, we first present the necessary bound orbit conditions both in the ($E$, $L$, $a$) and in the ($e$, $\mu$, $a$) space of the corresponding orbit for the equatorial bound orbits. Using these conditions, we classify various bound orbits in both spaces. Then, by applying the RP model to the case of an IMBH M82X-1, we find that an eccentric equatorial orbit can also originate three simultaneous QPOs. We also discuss the possible region around the black hole giving rise to these QPOs.

## 2. Bound orbit conditions for equatorial orbits

In this section, we write the bound orbit conditions in ($E$, $L$) and ($e$, $\mu$) space for a particle orbiting a Kerr black hole of a given spin, $a = J/M_\bullet$. Throughout this article, we have scaled $E$, $L$, and $a$ parameters by mass of the black hole $M_\bullet$, and have used geometrical units ($G = c = 1$).

### 2.1. *Dynamical parameter space* $\{E, L, a\}$

The equation defining radial motion of a particle (unit mass, $m_0 = 1$) in the equatorial plane of a Kerr black hole having spin $a$ is given by (Ref. 9)

$$\frac{\left(E^2-1\right)}{2} = \frac{1}{2}\left(\frac{\mathrm{d}r}{\mathrm{d}\tau}\right)^2 - \frac{1}{r} + \frac{L^2 - a^2\left(E^2-1\right)}{2r^2} - \frac{(L-aE)^2}{r^3}, \tag{1}$$

where $r$ is the radial distance from black hole and $\tau$ is the proper time. The radial kinetic energy vanishes at the turning points of the orbit, $\mathrm{d}r/\mathrm{d}\tau = 0$, which gives

$$\left(1-E^2\right)r^3 - 2r^2 + \left(L^2 - a^2\left(E^2-1\right)\right) r - 2(L-aE)^2 = 0. \tag{2}$$

We apply the Cardano's method (Ref. 10) to obtain real roots of Eq. (2) in terms of dynamical parameters $\{E, L, a\}$, which corresponds to the case when a bound orbit exists between the first two turning points. The three real roots of Eq. (2) can be expressed as (Ref. 14)

$$r_1 = r_a = \frac{2\left[1 + \left[4 - 3\left(1-E^2\right)\left(L^2 - a^2\left(E^2-1\right)\right)\right]^{1/2}\cos\left(\frac{\varphi}{3}\right)\right]}{3\left(1-E^2\right)}, \tag{3a}$$

$$r_2 = r_p = \frac{2\left[1 + \left[4 - 3\left(1-E^2\right)\left(L^2 - a^2\left(E^2-1\right)\right)\right]^{1/2}\cos\left(\frac{\varphi-2\pi}{3}\right)\right]}{3\left(1-E^2\right)}, \tag{3b}$$

$$r_3 = \frac{2\left[1 + \left[4 - 3\left(1-E^2\right)\left(L^2 - a^2\left(E^2-1\right)\right)\right]^{1/2}\cos\left(\frac{\varphi+2\pi}{3}\right)\right]}{3\left(1-E^2\right)}, \tag{3c}$$

where $\varphi$ is defined by

$$\cos\varphi = \frac{\left[8 - 9\left(1-E^2\right)\left(L^2 - a^2\left(E^2-1\right)\right) + 27\left(1-E^2\right)^2\left(L-aE\right)^2\right]}{\left[4 - 3\left(1-E^2\right)\left(L^2 - a^2\left(E^2-1\right)\right)\right]^{3/2}}; \quad (3d)$$

where $r_1 > r_2 > r_3$, $r_1$ and $r_2$ are the apastron and periastron points of the eccentric orbit respectively. It follows that

$$-1 < \cos\varphi < +1 \quad \text{holds for eccentric orbits.} \quad (3e)$$

As per the Cardano's method, the condition for three real roots is described by the discriminant of the cubic equation, which we obtain for Eq. (2), given by (Ref. 14)

$$\begin{aligned}\Delta = \; & 27\left(1-E^2\right)^2 x^4 - \left(L^2 - a^2\left(E^2-1\right)\right)^2 - 18x^2\left(1-E^2\right)\left(L^2 - a^2\left(E^2-1\right)\right) \\ & +16x^2 + \left(1-E^2\right)\left(L^2 - a^2\left(E^2-1\right)\right)^3, \end{aligned} \quad (4)$$

where $x = L - aE$. Hence, the condition on $\{E, L, a\}$ to get three real and distinct roots of $r$, which is possible only when the orbit is an eccentric bound orbit, is given by

$$\Delta < 0 \qquad \text{and} \qquad 0 < E < 1. \quad (5)$$

The case of two equal roots and one distinct real root is possible when $\Delta = 0$, which corresponds to the stable circular, and the separatrix orbit or the unstable circular orbit, which are classified using $\cos\varphi$ by the following conditions:

$$\text{Stable circular orbit when } \cos\varphi = -1 \;\Rightarrow\; r_1 = r_2 \text{ and } 0 < E < 1, \quad (6a)$$

$$\text{Separatrix orbit when } \cos\varphi = +1 \;\Rightarrow\; r_2 = r_3 \text{ and } 0 < E < 1, \quad (6b)$$

$$\text{Unstable circular orbit when } \cos\varphi = +1 \;\Rightarrow\; r_2 = r_3 \text{ and } E > 1. \quad (6c)$$

In this way, we are able to classify the various bound orbits in the $\{E, L, a\}$ space. Fig. 1(a) shows this classification as bound orbit region, we call it the $\Delta$ region, in the ($E$, $L$) plane which is bounded by the curves representing the stable circular orbits Eq. (6a), separatrix orbits Eq. (6b), and $E = 1$. The details of results presented in this section will be provided in paper in preparation (Ref. 14).

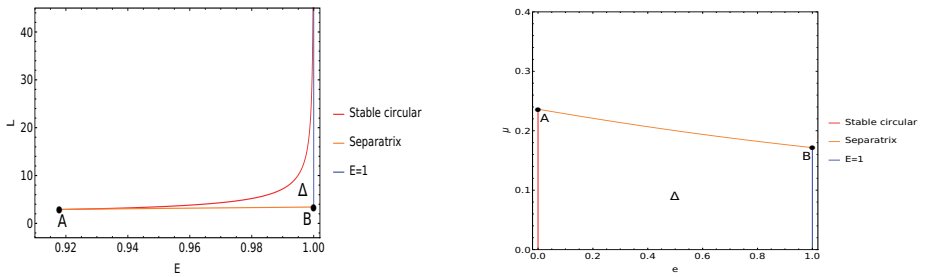
### 2.2. *Conic parameter space* $\{e, \mu, a\}$

Next, we extend and translate the bound orbit conditions to the conic parameter space which is useful for the geometric study of the bound trajectories. The eccentricity and inverse-latus rectum are defined as

$$e = \frac{r_a - r_p}{r_a + r_p}, \quad \mu = \frac{r_a + r_p}{2 r_a r_p}. \quad (7)$$

Using the transformation relations between ($E$, $L$) and ($e$, $\mu$) (Refs. 11, 12), we can express $\Delta$, Eq. (4), in terms of $\{e, \mu, a\}$ as (Ref. 14)

$$\Delta = \frac{-e^2}{\mu^2}\left[1 - x^2\mu^2\left(1+e\right)\left(3-e\right)\right]^2\left[1 - x^2\mu^2\left(1-e\right)\left(3+e\right)\right]^2 = \frac{-e^2}{\mu^2}\Delta_1^2\Delta_2^2. \quad (8)$$



(a) (b)

Fig. 1. The bound orbit condition, $\Delta \leq 0$, is shown as the $\Delta$ region (a) bounded by stable circular Eq. (6a), separatrix orbits Eq. (6b), and $E = 1$ in the ($E$, $L$) plane, and (b) bounded by stable circular Eq. (9a), separatrix orbits Eq. (9b), and $e = 1$ in the ($e$, $\mu$) plane for $a = 0.5$, where points A and B represents the innermost stable circular orbit (ISCO) and marginally bound circular orbit (MBCO) respectively.

It is seen that $\Delta \leq 0$ is valid for all the real values of $x$, and $\Delta = 0$ if any one of the following conditions is satisfied:

$$e = 0, \tag{9a}$$

$$\Delta_1 = 0 \Rightarrow \mu^2 x^2 (3 - e)(1 + e) = 1, \tag{9b}$$

$$\Delta_2 = 0 \Rightarrow \mu^2 x^2 (3 + e)(1 - e) = 1, \tag{9c}$$

where Eq. (9a) corresponds to the stable circular orbits, Eq. (9b) corresponds to the separatrix orbits and they together with $e = 1$ define the boundaries of the $\Delta$ region in the ($e$, $\mu$) plane; see Fig. 1(b). Hence, the condition in $\{e, \mu, a\}$ space for an eccentric bound orbit is given by $r_3 < r_p$, which corresponds to (Ref. 14)

$$\mu^2 x^2 (3 - e)(1 + e) \leq 1, \tag{10}$$

and is the operative condition for eccentric bound orbits representing the ordering of roots, $r_1 > r_2 > r_3$. The expression of $\cos\varphi$, Eq. (3d), in the $\{e, \mu, a\}$ space is given by (Ref. 14)

$$\cos\varphi = \frac{\left[1 - 3x^2\mu^2\left(1 - e^2\right)\right] \cdot \left[-1 + 3e + 3x^2\mu^2\left(1 - e - e^2 + e^3\right)\right] \cdot \left[1 + 3e - 3x^2\mu^2\left(1 + e - e^2 - e^3\right)\right]}{\left\{4 - 3\left(1 - e^2\right)\left[1 - x^2\mu^2\left(1 - e^2\right)\right]\left[1 + \mu^2 x^2\left(3 + e^2\right)\right]\right\}^{3/2}}. \tag{11}$$

## 3. Parameter estimation from RP model for QPOs

Now, we take a more generalized approach to the RP model by considering $e \neq 0$. We consider that three simultaneous QPOs can also be originated by a self-emitting blob orbiting in an equatorial eccentric trajectory around a Kerr black hole. Then, we calculate the parameters ($e$, $r_p$) of the orbit and spin $a$ of the black hole using the fundamental frequency formulae for equatorial orbits derived in Refs. (11, 12), and presented in Table 1. We search for the parameters in the allowed $\Delta$ region

Table 1. Fundamental frequencies of equatorial eccentrc orbits, Refs. 11, 12, 13.

| Constants | $m^2=\dfrac{4\mu^2ex^2}{\left[1-\mu^2x^2\left(3-e^2-2e\right)\right]}$, ${p_1}^2=\dfrac{2e}{1-e}$, ${p_2}^2=\dfrac{2ea^2\mu}{\left(a^2\mu-a^2\mu e-r_+\right)}$, ${p_3}^2=\dfrac{2ea^2\mu}{\left(a^2\mu-a^2\mu e-r_-\right)}$, ${z_+}^2=\dfrac{\left[a^2\left(1-E^2\right)+L^2\right]}{a^2\left(1-E^2\right)}$,<br>$a_1=\dfrac{\mu^{1/2}\left[La^2-2xr_+\right]}{\sqrt{1-a^2}\left(a^2\mu-a^2\mu e-r_+\right)\sqrt{1-\mu^2x^2\left(3-e^2-2e\right)}}$, $b_1=\dfrac{\mu^{1/2}\left[-La^2+2xr_-\right]}{\sqrt{1-a^2}\left(a^2\mu-a^2\mu e-r_-\right)\sqrt{1-\mu^2x^2\left(3-e^2-2e\right)}}$,<br>$a_2=\dfrac{2E}{\mu^{3/2}\left(1-e\right)^2\sqrt{1-\mu^2x^2\left(3-e^2-2e\right)}}$, $b_2=\dfrac{4E}{\mu^{1/2}\left(1-e\right)\sqrt{1-\mu^2x^2\left(3-e^2-2e\right)}}$,<br>$c_2=\dfrac{2a^2\mu^{1/2}\left(-La+2Er_-\right)}{r_-\sqrt{\left[1-\mu^2x^2\left(3-e^2-2e\right)\right]}\sqrt{1-a^2}\left(a^2\mu-a^2\mu e-r_+\right)}$, $d_2=\dfrac{2a\mu^{1/2}\left(-2Lr_-\sqrt{1-a^2}-2Er_-a+La^2\right)}{r_-\sqrt{\left[1-\mu^2x^2\left(3-e^2-2e\right)\right]}\sqrt{1-a^2}\left(a^2\mu-a^2\mu e-r_-\right)}$. |

(shown in Fig. 1) and defined by the bound orbit condition, Eq. (10). We apply this method to the case of an IMBH M82X-1, which has shown three simultaneous QPOs at $\nu_1 = 5.07 \pm 0.06$Hz, $\nu_2 = 3.32 \pm 0.06$Hz, and $\nu_3$ =204.8±6.3mHz (Ref. 3, 4) to find $\{e, r_p, a\}$. We fix the mass of black hole to be $M_\bullet = 428 M_\odot$ given in Ref. 3, and simultaneously solve the equations $\nu_\phi = \nu_1$, $\nu_\phi - \nu_r = \nu_2$, and $\nu_\phi - \nu_\theta = \nu_3$ to find the exact solutions for the RP model given by $\{e_0, r_{p_0}, a_0\}$. We assume the QPO frequencies as Gaussian distributed with their mean values at $\nu_1$, $\nu_2$ and $\nu_3$. We estimate the $1\sigma$ errors in the solution $\{e_0, r_{p_0}, a_0\}$ using the Jacobian of the transformation to $\{\nu_1, \nu_2, \nu_3\}$ space whose formulae are given in Table 1, and find the corresponding normalized joint probability density distribution in the ($e$, $r_p$, $a$) space. As the probability density $P\,(e, r_p, a)$ is three dimensional, we collapse the profile of the probability density in two dimensions and fit a Gaussian function to find the mean values, $\{e_0, r_{p0}, a_0\}$, and variances, $\{\sigma_e, \sigma_{r_p}, \sigma_a\}$ in other dimension.

Using this procedure, we found the exact solution at $e = 0.2768^{+0.0657}_{-0.0451}$, $a = 0.2897 \pm 0.0087$, and $r_p = 4.6164^{+0.0694}_{-0.1259}$ for M82X-1. We see that the probability density naturally peaks at non-zero eccentricity suggesting that the most probable solution might not be restricted to circular orbits as was previously assumed in Ref. 7. Fig. 2 shows this solution in the ($r_p$, $a$) plane suggesting an eccentric orbit having its periastron point in the region between ISCO and MBCO is the most probable orbit for the generation of three simultaneous QPOs. We have implemented a similar approach to various BHXRB to include non-equatorial and eccentric trajectories in our paper in preparation (Ref. 13).

## 4. Summary and discussion

We discussed the bound orbit conditions for the eccentric equatorial orbits in the $\{E, L, a\}$, and $\{e, \mu, a\}$ spaces. We applied it to the specific case of M82X-1, where three simultaneous QPOs were discovered (Ref. 3, 4), to find the parameters $e = 0.2768^{+0.0657}_{-0.0451}$, $a = 0.2897 \pm 0.0087$, and $r_p = 4.6164^{+0.0694}_{-0.1259}$ for the orbit generating these QPOs using the RP model. We find that the eccentric orbit solutions are possible in the region between ISCO and MBCO, as shown in Fig. 2. Hence, by assuming that the accretion disk ends near ISCO, we conclude that the blobs that originate near ISCO and follow equatorial and eccentric trajectories in this region that produce HFQPOs. In a paper in preparation (Ref. 13), we also discuss the non-equatorial eccentric trajectories as possible solutions for QPOs assuming the RP model.

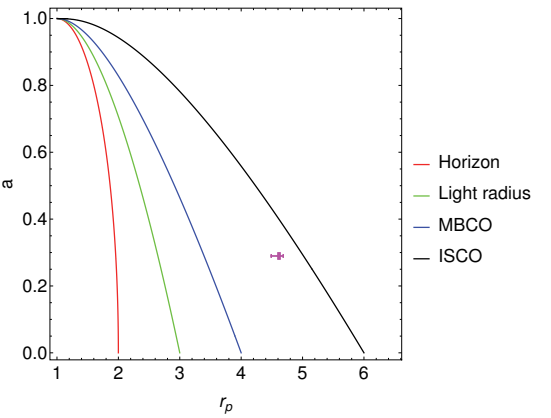

Fig. 2. An equatorial eccentric orbit solution (the point in magenta color) shown in the $(r_p,\ a)$ plane for the simultaneous QPOs discovered in M82X-1. The solution exists in the region between ISCO and MBCO.

# Polarization of emission from black hole accretion disks: including returning radiation

Roberto Taverna,*; Michal Bursa, Michal Dovčiak, Vladimir Karas, Frédéric Marin, Giorgio Matt, Romana Mikušincová and Wenda Zhang

*Department of Mathematics and Physics, University of Roma Tre, Rome, Italy 00146
*E-mail: taverna@fis.uniroma3.it*
*www.matfis.uniroma3.it*

Accretion disks around stellar-mass black holes (BHs) are observed to emit radiation peaking in the soft X-rays (at about 1 keV) when the source is in the thermal state. This emission is expected to be polarized, because of electron scattering in the disk. However, photons will experience a rotation of the polarization plane due to General Relativity effects. X-ray polarization measurements can then be crucial in assessing strong gravity effects around accreting stellar-mass BHs, providing independent constraints on their spin. In this work, we present the simulated polarization spectra (obtained according to the model by Dovčiak et al.[1]) for the X-ray, thermal radiation emitted by the accretion disk, as expected to be measured by IXPE, an X-ray polarimeter which will be launched in 2021. We also illustrate the code, currently under development, incorporate the contribution of returning radiation and account for absorption effects by the disk material.

*Keywords*: polarization – relativity – instrumentation: polarimeters – X-rays: binaries.

## 1. Introduction

Stellar-mass black holes (BHs) are believed to be born mainly in the gravitational core-collapse of very massive stars (with $M \gtrsim 25$–$30\,M_\odot$), while supermassive black holes ($M \approx 10^6$–$10^9 M_\odot$) are hosted in the center of most galaxies (including our own). Despite the fact that even light cannot escape from their event horizon, BHs have been observed so far as X-ray sources, through the electromagnetic radiation emitted from accretion disks in their surroundings, as well as, in the case of supermassive BHs, by studying the orbits of nearby stars influenced by the presence of their gravitational field. Very recently, BHs have been in the spotlight thanks to the results achieved by the LIGO/VIRGO collaboration, which detected for the first time the gravitational waves emitted in BH-BH merging events.[2] Nevertheless, electromagnetic observations still play a key role in understanding the physics of BHs. Moreover, the recent developments in X-ray polarimetry techniques gave new impetus to this field of research.[3]

In this work we revisit the issue of modeling the spectral and polarization properties of radiation emitted from the accretion disk around a stellar mass BH, where general relativistic effects play a crucial role. Theoretical models to investigate spectra and polarization from these sources have been developed by many authors in the past (see e.g. Ref. 4 for a more comprehensive list of references). We revisit in particular the work by Dovčiak et al.,[1] which addressed the contribution of photons

that reach the observer without interacting anymore with the disk since their emission (the so-called "direct radiation"). As already discussed in Ref. 5 the "returning radiation" (i.e. the emitted photons which are forced by the strong gravity effects to return to the disk, where they may be scattered to eventually arrive at infinity) may provide an important contribution, and therefore we decided to include it in the KYN code. However, contrary to Schnittman & Krolik, we use an observer-to-emitter approach, and we also aim to explore non-trivial prescriptions for the disk albedo. The predictions we will obtain for the polarization observables can be promptly tested by the new-generation X-ray polarimeter IXPE,[6] that will be launched in 2021.

In section 2 we briefly set out the theoretical model and present our main assumptions. An overview of the numerical implementation is described in section 3, while some preliminary plots are discussed in section 4. Finally, conclusions are presented in section 5.

## 2. Basic theoretical model

Accretion disks around stellar-mass BHs are observed to emit radiation peaking in the soft X-rays (at about 1 keV) when the source is in its thermal state. Photons propagating in the space-time around a BH (which is described by the Kerr metric, for different values of the dimensionless angular momentum per unit mass $a$) will experience general relativistic effects. More in detail, photons emitted close to a BH are redshifted due to the strong gravitational field, and their trajectory follows null geodesics, deviating from straight lines. As a consequence, the paths of photons emitted from regions of the disk closer to the central BH can be bent by its gravitational field. These photons may still reach the observer at infinity (direct radiation), but part of them can return towards the disk surface and scatter before to eventually arrive at infinity (returning radiation), depending on the emission point on the disk and on the emission direction.

Disk radiation is also expected to be linearly polarized, because of Thomson scatterings that occur onto the electrons which are present in the atmospheric layer assumed to cover the disk (see e.g. Ref. 7). For symmetry reasons, the polarization vector of photons must be either parallel or perpendicular to the disk symmetry axis projected in the plane of the sky. In particular, if no absorption is assumed in the atmosphere, polarization will be parallel to this axis for lower values of the atmospheric optical depth ($\tau \lesssim 1$) and perpendicular for higher ones. As for the photon energy and trajectory, strong gravity can also influence the polarization state of radiation.[8–10] In fact, the photon polarization plane should be parallely transported along the curved trajectory, and this results in a rotation of the polarization vector with respect to the direction assumed at the emission. Moreover, if the photon propagates around a rotating BH, it can be shown that the polarization vector undergoes a further rotation (also called the Gravitational Faraday rotation, see Ref. 11), the amount of which depends on $a$.

For these reasons, the expected polarization fraction $P_{\rm o}$ and polarization angle $\chi_{\rm o}$ will be strongly influenced by the general relativistic effects associated to the central BH gravitational field. In particular, the change $\Psi$ in polarization angle for a photon propagating along a null geodesic is given by

$$\tan\Psi = \frac{Y}{X}\,, \tag{1}$$

where, in the case of a Petrov type D space-time, the quantities $Y$ and $X$ can be expressed in terms of the components $\kappa_1$ and $\kappa_2$ of the Walker-Penrose constant,[12] which is a constant of motion along a null geodesic, as

$$\begin{aligned} X &= -(\alpha - a\sin\theta_{\rm o})\kappa_1 - \beta\kappa_2 \\ Y &= (\alpha - a\sin\theta_{\rm o})\kappa_2 - \beta\kappa_1\,. \end{aligned} \tag{2}$$

In equation (2), $\alpha$ and $\beta$ are the impact parameters which identify the $x$- and $y$-axes, respectively, of the observer's sky reference frame in the plane perpendicular to the line-of-sight, and $\theta_{\rm o}$ is the observer inclination.[1]

## 3. Numerical implementation

Calculations are performed for a standard disk[13,14] focussing, for the sake of simplicity, on the case in which the emitted radiation follows locally a simple blackbody distribution. Photons are assumed to be scattered by the electrons of a geometrically-thin atmospheric layer above the disk surface, which polarizes the emitted radiation. In particular, the intrinsic polarization properties in the diffusion limit ($\tau \gg 1$) are extracted from Chandrasekhar's analytical expressions[7] for a geometrically thin and optically thick atmosphere with infinite optical depth. It can be shown that this is a good approximation as long as $\tau \gtrsim 5$.[1] On the other hand, for lower values of $\tau$ the intrinsic polarization pattern is numerically evaluated using the Monte Carlo code STOKES, firstly developed by Goosmann & Gaskell[15] (see also Refs. 16 and references therein for subsequent updates).

### 3.1. *Direct radiation*

KYN[1] is a ray-tracing code based on an observer-to-emitter approach, contrary to the Monte Carlo code developed in Ref. 5. The observer-to-emitter method has the advantage of a much less computational load, even if, on the other hand, the inverse approach may prove to be more useful when electron scattering in the disk is considered.[4]

In its original version, KYN takes into account only the contribution of direct radiation. The code starts with calculating the local specific Stokes parameters $\boldsymbol{s}_{\rm l} = [i_{\rm l}, q_{\rm l}, u_{\rm l}]$ according to the formulae by Ref. 7, for photons emitted from different points on the disk surface, each characterized by the distance $r$ from the central BH and the azimuth $\phi$. Then, once selected the polar angles $\theta_{\rm e}$ and $\varphi_{\rm e}$ that the photon

emission direction makes with the disk normal, the code computes the integrated Stokes parameters at the observer,[1]

$$\begin{aligned}\Delta i_{\rm o} &= \int {\rm d}S \int {\rm d}E_{\rm l}\, i_{\rm l} G \\ \Delta q_{\rm o} &= \int {\rm d}S \int {\rm d}E_{\rm l}\, [q_{\rm l}\cos(2\Psi) - u_{\rm l}\sin(2\Psi)] G \\ \Delta u_{\rm o} &= \int {\rm d}S \int {\rm d}E_{\rm l}\, [u_{\rm l}\cos(2\Psi) + q_{\rm l}\sin(2\Psi)] G\,,\end{aligned} \tag{3}$$

where $\Psi$ and $G$ are the change in polarization angle (see equation 1) and the transfer function,[1,17] respectively, which account for the general relativistic effects that photons experience moving along the geodesic which connects the observer to the emission point, while $E_{\rm l}$ is the local photon energy.

### 3.2. *Returning radiation*

What is new in this work with respect to Ref. 1 is the addition of a specific module for including in the KYN code the contribution of returning radiation, motivated by the fact that in previous works[5] it turned out to be important. Calculations are performed using the C++ code SELFIRR:

- for each point on the disk surface (at the distance $\bar{r}_{\rm i}$ from the central BH), all the possible directions along which photons can return on the disk are sampled on a discrete $(\bar{\theta}_{\rm i}, \bar{\varphi}_{\rm i})$ angular mesh, with $\bar{\theta}_{\rm i}$ and $\bar{\varphi}_{\rm i}$ the polar angles with respect to the disk normal;
- then, for each point of the $(\bar{r}_{\rm i}, \bar{\theta}_{\rm i}, \bar{\varphi}_{\rm i})$ grid, the code computes the null geodesics, if any, that arrive to the disk at the selected distance $\bar{r}_{\rm i}$ with incidence direction given by $(\bar{\theta}_{\rm i}, \bar{\varphi}_{\rm i})$ from another point of the disk surface[a];
- finally, the values of the emission radius $\bar{r}_{\rm e}$, angles of emission $\bar{\theta}_{\rm e}$ and $\bar{\varphi}_{\rm e}$ (with respect to the disk normal), transfer function $\bar{G}$ and change in polarization angle $\bar{\Psi}$ which characterize each of the computed geodesics are stored in an external file, to be read by KYN.

The specific Stokes parameters of the photons originally emitted from the disk are still given according to a Novikov-Thorne profile[14] and using the formulae by Ref. 7 as in the case of direct radiation (Sec. 3.1). At the incidence point, the contributions of the different geodesics are summed together, in order to obtain the specific Stokes parameters due to returning radiation in each point of the disk surface.

Once returned to the disk, photons are considered to be reflected; for the sake of simplicity, in this preliminary version of the code we used a 100% albedo prescription, i.e. photons which return to the disk are all reflected towards infinity. For calculating the Stokes parameters of reflected photons we used the Chandrasekhar's

[a] We stress that SELFIRR naturally accounts for photons that, due to lensing, can travel along more than one geodesic between two points on the disk also with the same direction of incidence.

formulae for diffuse reflection (see Ref. 7 for more details). The integrated Stokes parameters at the observer are eventually obtained as mentioned in section 3.1 (see equations 3). The code provides in output the values of the Stokes parameters as functions of the photon energy at the observer, as well as the energy-dependent polarization degree and angle. Besides the outputs for the separate contributions of direct and returning radiation, the code is set to return also the "total" spectra and polarization observable behaviors, obtained by summing together the Stokes parameters of the two components.

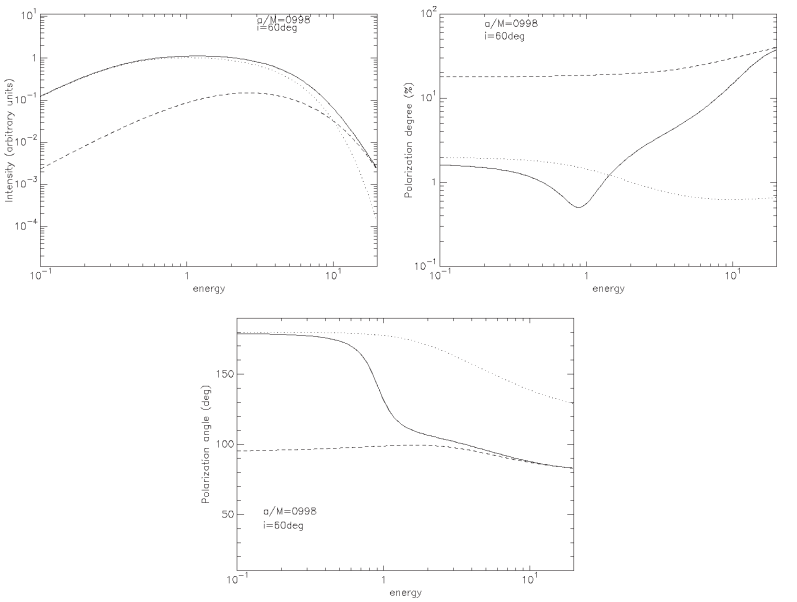

Fig. 1. Spectrum (top-left), linear polarization fraction (top-right) and polarization angle (bottom) produced by a KYN run for a maximally rotating ($a = 0.998$), stellar-mass BH ($M = 10\,M_{\odot}$, $\dot{M} = 3.5 \times 10^{17}$ g/s) with inclination angle $i = 60°$ (solid lines). Dotted and dashed lines represent the separate contributions of direct and returning radiation, respectively.

## 4. Preliminary results

The simplifying assumption of 100% albedo at the disk surface allowed us to compare directly our preliminary results with those obtained in Ref. 5. However, we aim to relax this assumption in future applications, using non-trivial (although still simple) prescriptions for the disk albedo and considering the mutual interplay between the strong gravity effects and those of the disk vertical structure on the returning radiation. As an example, we show in Figure 1 a typical output of our code in the case of a $10\,M_{\odot}$, maximally rotating BH (spin $a = 0.998$), for a value of the accretion rate $\dot{M} = 3.5 \times 10^{17}$ g/s, which roughly corresponds to a disk luminosity of order 10% of the Eddington limit (see Refs. 5, 18). Chandrasekhar's formulae

for a geometrically thin, optically thick disk are used to derive the polarization properties at the emission (see Sec. 3).

The plots show the spectrum, polarization fraction and polarization angle[b] as functions of the photon energy at infinity for an inclination angle of 60° (solid lines), together with the separate contributions of direct (dotted lines) and returning (dashed line) radiation. As a direct comparison with Figure 6 in Ref. 5 suggests, the results obtained from our code are compatible with those originally discussed by Schnittman & Krolik. In particular, the addition of the returning radiation component to the direct one modifies dramatically the polarization pattern expected when only direct radiation is considered. At high photon energies, where the collected photons come from the inner part of the disk and returning radiation effects are indeed more important, the polarization fraction can also exceed 10% and photons are predominantly polarized perpendicularly to the disk surface. On the other hand, polarization properties of low-energy photons, which come from the outermost regions of the disk, tend to follow more closely the Chandrasekhar's prescription.[7] In between these two regimes a transition occurs, where the contributions of direct and returning radiation are equivalent. Here the polarization direction turns out to rotate from parallel to perpendicular and correspondingly the polarization fraction attains a minimum, below 1%.

## 5. Conclusions and future prospects

We presented a numerical method to simulate the spectral and polarization properties of the X-ray radiation emitted by accreting stellar-mass BHs, including the effects of returning radiation alongside those of direct radiation. The preliminary plots shown in Figure 1 and obtained in the simplified 100% albedo prescription turn out to be in good agreement with the results already discussed in literature (see e.g. Ref. 5), although an inverse (observer-to-emitter) approach with respect to previous investigations has been used. Future improvements of our work will then consist in producing more complete simulations, in which the albedo is calculated by using more realistic, self-consistent disk models.

The first results obtained using the basic model illustrated in sections 2 and 3 strengthen the view that X-ray polarization measurements can be actually crucial in assessing strong gravity effects around accreting stellar-mass BHs. Whilst some pioneering efforts in measuring X-ray polarization from stellar-mass BHs were made with the OSO-8 satellite,[19] the poor sensitivity and quasi mono-energetic approach of past instrumentation did not allow to achieve conclusive results. On the other hand, the new techniques available with new-generation polarimeters like IXPE promise to strongly increase the sensitivity of polarization measurements in the 2–8 keV energy range. Numerical simulations, which exploit the IXPE effective

[b]In Figure 1 (as in the plots shown in Ref. 5) a polarization angle of 90° corresponds to photons polarized perpendicularly to the disk surface.

area and modulation factor, have been already performed[20] to test the feasibility of such polarization measurements for radiation emitted by stellar-mass BH accretion disks. These simulations have confirmed the capability of the instrument in constraining the physics of BHs, showing how polarization measurements may be used to determine the BH spin parameter $a$.

The Rossby-Wave Instability (RWI) has been proposed to be at the origin of the high-frequency QPOs observed in black-hole systems. Here we are presenting the first full GR simulations of the instability around a Kerr black-hole which allow us to explore the impact of the spin on the instability. Those simulations, coupled with a full GR ray-tracing, allow us to directly compare our simulation with the observables we get through X-ray observations.

*Keywords*: black hole binaries; MG15 Proceedings; HFQPOs

## 1. Introduction: NOVAs as a tool for theoretician and observer alike

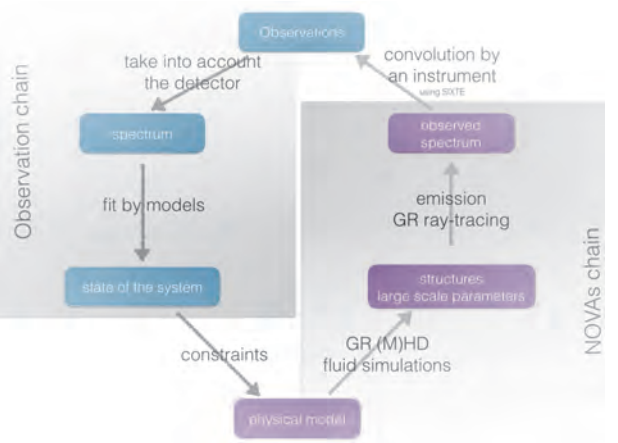

Fig. 1. How the 'standard' observation chain compare with the `NOVAs` chain.

By combining smoothly two GR codes, one providing a full hydrodynamical solution [1, 2][a] and one providing the ray-tracing of the emission[8][b], we now have a fully functional numerical observatory which allows us to obtain spectrums and lightcurves of theoretical models with limited hypotheses. Further linking the output of NOVAs with SIXTE allows us to also test the capacity of new instruments to distinguish between models and explore new possibilities.

Using this tool, we can explore the observables coming from different models. In particular we are interested in the fast variability of microquasars for which there has been a long string of efforts to understand their origin. This is especially true for the origin of the rather elusive High-Frequency Quasi-Periodic Oscillation (HFQPO) in systems containing (or thought to contain) a black hole (BH).

## 2. The RWI in the full Kerr metric

Here we focus on the model based on the Rossby-Wave Instability[3–5] which is predicted to occur when the inner edge of the disk is close to the last orbit. It has been previously proposed to explain several phenomena occurring in the vicinity of black holes[1,2,9] but its existence in an extreme Kerr environment had never been fully demonstrated until recently.

Indeed, using `NOVAs` we performed the first simulations of the RWI in the Kerr metric up to high spin of $a = 0.99$ proving its existence as well as confirming the conditions necessary for it to arise in black-hole disks. From this first set of simulations following the RWI from a Keplerian setup to a near extreme Kerr black-hole, we were able to study in more detail how the location of the RWI influences its physics and what changes, if any, we should be looking for in observations.

Fig. 2. summarizes our findings by showing, for multiple spins, the evolution of the growth rate, saturation level and time to reach saturation of the instability as function of its position with respect to the black hole. On the top part of Fig. 2. we see that the time to reach saturation, while relatively constant at larger $r_b$, the small differences coming mostly from the differences in the setup we used, increased rapidly when the RWI develops inside $\sim 4r_g$. This rise shows the impact of the lapse on the propagation of the instability. While the change is about 40% of the period, the actual numerical value is extremely small as those objects are very fast. It is not possible to detect such differences in observations.

At the bottom of Fig. 2. we see that the growth rate of the instability goes through a maximum for $r_b \sim 5r_g$. This, once again is too small of a change to have any detectable effect as one needs too long of an observation to detect HFQPOs, so we cannot follow the 'instantaneous' evolution of its rms.

[a] Freely available at `https://github.com/amrvac/amrvac`
[b] Freely available at `http://gyoto.obspm.fr`

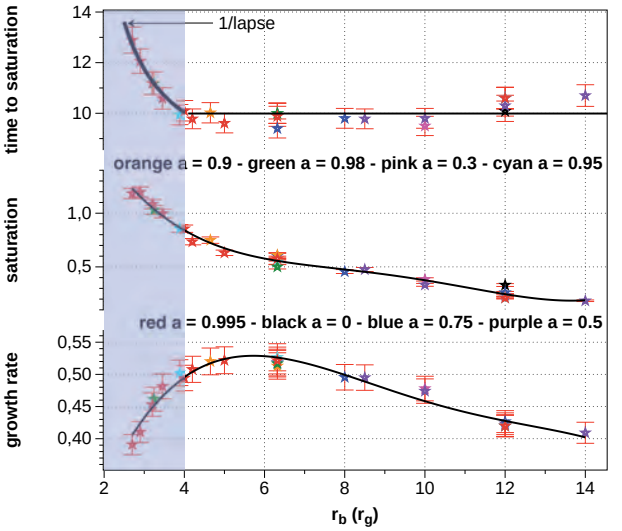

Fig. 2. Evolution of the growth rate of the instability, its saturation level and the time to reach saturation for different spins and positions of the instability ($r_b$).

More interestingly, we see on the middle plot, that the closer to $1r_g$ the RWI develops, the higher its saturation is. This quantity is related to the maximum strength a QPO can attain, hence to how much modulation there is in the observed flux. While we cannot directly test that with observations, indeed, the limitation being the very low number of spin determination for HFQPO sources, this is something we will be exploring, especially with NICER.

## 3. Potential Link with observations

Using `NOVAs`, we look into more detail at ways to compare the RWI with 'standard' observations. Indeed, while a direct comparison of the numerical simulation with observations is impossible, using the NOVAs framework we can produce lightcurves and spectrums that we can then compare with observables.

### 3.1. *What is at the origin of the different HFQPO pairs/ peak selection in the PDS*

The RWI has been proposed to explain the high-frequency QPOs, partially because of its ability to have multiple modes present at the same time. A question that can easily be answered using `NOVAs` is what causes the different modes to be detected. To achieve that we performed numerical simulations having slightly different setups and then produced the associated PDS to see when we get a certain type of pair.

Depending on the setup we get different modes of the RWI and in turn those create different patterns in the PDS depending on which modes dominate and this translates in different peak distributions in the PDS as seen on the left of Fig. 3.

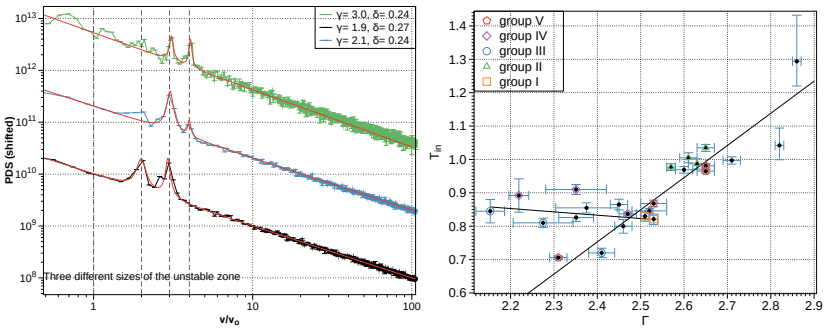

Fig. 3. Left: three PDSs obtained for the same black-hole spin but different local conditions. Right: scatter plot of the power-law slope, Γ, versus the temperature at the inner edge of the disk, $T_{in}$, for all the HFQPO observations in XTE J1550-564[7].

From those simulations we did not yet get a clear criteria for the different peak distributions but we were able to reproduce all the observed peak distributions[7] while having the parameters of the system change by about 30%. Using all the observations of XTE J1550-564 with a published HFQPO we looked at how much variation exists in the system parameters. We see on the right of Fig. 3. that the observed changes in the system parameters are compatible with the kind of changes needed by the RWI to explain the observed PDSs.

### 3.2. *Evolution of HFQPOs with spin/ rms amplitude of the modulation as function of spin*

One of the first things we looked at is the growth of the RWI in the case of different black-hole spins. As you can see on the left of Fig. 4. we get higher saturation levels, and hence detectabilities, as the spin increases. While this is not a direct observable, we can still look at how the maximum rms amplitude of the observed HFQPOs behaves as function of spin. The right graph of Fig. 4. compiled all the HFQPOs' rmses published for black-holes with known spins. Even if this is a limited sample, we see a similar trend as the one we have in our simulations, namely that high spin systems have higher rmses. We will be continuing to look for new HFQPO/spin couples to add to that plot as soon as new data become available.

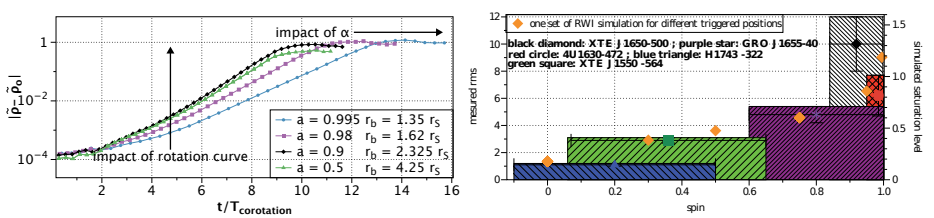

Fig. 4. Left: growth of the RWI as function of the time for different spins. Right: distribution of the rms amplitude of HFQPOs as function of spin for all the known couples.

## 4. Conclusion

Using our new `NOVAs` framework we are able to show that the RWI does indeed develop at the inner edge of a disk at its last stable orbit when full GR is taken into account.

We then explored several observables related to the RWI as a model for HFQPOs and compared them with actual data. We first look at the number and relation between the dominant peaks in Fourier space, showing that they are dependent on the local disk conditions where the RWI is developing. On top of that, we were able to reproduce all of the observed HFQPOs' distributions as of today and showed that the required changes in the local disk is compatible with the observed values.

Also, when computing the RWI for the full range of spins we saw that, under similar conditions, the higher spins will have a higher saturation level. While we do not have observations of different systems under the same conditions, we looked at the maximum rms observed as function of spin and showed that higher spin systems tend to get HFQPOs with higher rms.

All in all, using `NOVAs` allowed us to strengthen the RWI as a possible explanation for the HFQPO.

With NICER up and running and the ATHENA mission in preparation there is need to study in more detail what is the influence, if any, of the spin on the observed spectrum. Using the newly developed NOVAs framework which is comprised of a GR code, GRAMRVAC, coupled with the ray-tracing GR code, gyoto, we computed a series of simulated disk spectrums for a variety of black-hole spins. Using standard models from xspec we fitted those spectrums and looked at how they performed to give us the parameters of the simulated spectrums. Here we report on our findings and how we could improve the existing models to get better insights into the physical large scale disk parameters.

*Keywords*: black hole binaries; MG15 Proceedings; energy spectrum

`NOVAs`, our Numerical Observatory of Violent Accreting systems[a], can have a lot of uses, such as preparing observations, thanks to being easily coupled to `SIXTE`, but also trying to understand the origin of some observed features. Here we show a few examples of what `NOVAs` can do in particular related to the energy spectrum of accretion disks around black-holes.

## 1. Computing a simulated disk spectrum using `NOVAs`

### 1.1. *Introduction: Forming the Inner edge of the disk*

The first step to compute the energy spectrum of an accretion disk around a black-hole is to obtain the shape of the disk. Using `NOVAs`, in particular the `GRAMRVAC`

[a]See other proceedings by the same author in this volume.

step, we ran a series of simulations following the formation of a stable accretion disk reaching its last stable orbit. We focused on the shape of the temperature profile as function of the spin, needed to compute the emission, and also on the position of the inner edge.

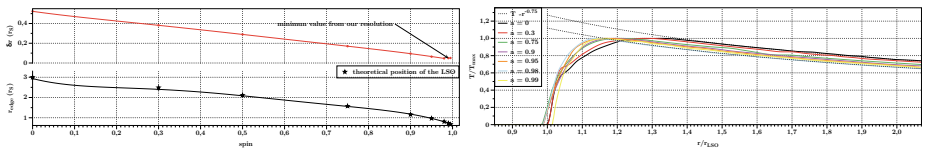

Fig. 1. Left: position and shape of the inner edge of the simulated disk forms as compared to the predicted last stable orbit. We see that, as the spin increases, the inner edge of the disk gets sharper and thinner. Right: temperature profile as function of the radius in the disk (normalized to the last stable orbit) for increasing spins. We see that a higher spin means a sharper and thinner edge.

As expected, we recover the position of the last stable orbit very precisely (left Fig.1) but the curvature of the temperature profile depends on the spin with lower spins having a larger turnover zone (right Fig.1). This means that higher spins imply a sharper and thinner inner edge of the disk.

### 1.2. *simulated disk spectrum*

Once we obtain the temperature in every point of our disk we can compute its blackbody emission and ray-trace it back to the observer using the `gyoto` step of `NOVAs`. One of the advantages of `NOVAs` is that we can turn on/off certain aspects of the process in order to test its impact.

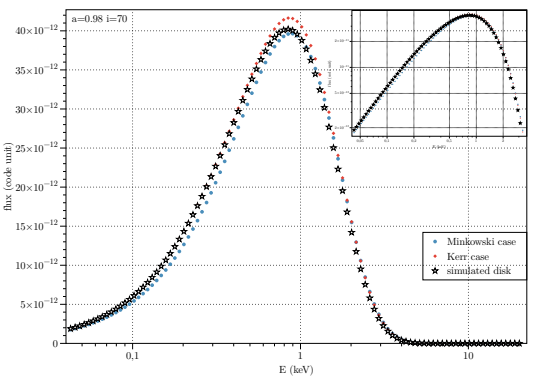

Fig. 2. Comparison between the full GR simulated spectrum (star) with the cases of a Shakura&Sunyaev equivalent disk with either a Minkowski ray-tracing (diskbb equivalent) or Kerr. The corner plot is the same plot in log-log.

The first test was to see which aspect of the full GR treatment was necessary and when. To that respect we compared in Fig.2 the cases with full GR simulation (stars), GR only for the fluid dynamical part but Minkowski space for the ray-tracing back to the observer (Minkowski case) and with the cases of a Shakura&Sunyaev equivalent disk with either a Minkowski ray-tracing (diskbb equivalent) or Kerr.

As expected from the temperature profile which becomes closer to the equivalent Shakura&Sunyaev case at higher spin (sharper) we see in Fig.2 (in log-lin and log-log), that for high spins, the simulated disk spectrum is close to both the SS-Kerr and SS-Minkowski cases, which is an acceptable approximation of the full GR simulation in particular if we are looking for a fast fit of the overall disk parameters.

### 1.3. *Impact of inclination*

Another advantage of a numerical observatory is that we can look at the same system under different conditions such as for example the inclination. This allows us to test the impact of parameters related to the position of the system with respect to the observer.

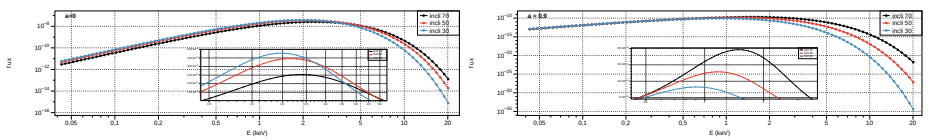

Fig. 3. Energy spectrum of the simulated disk for different inclinations of the system for the case of zero spin (left) and a higher spin of $a = 0.9$ (right).

Fig.3 shows the impact of inclination on the shape of the spectrum in the case of no spin (a=0) and a higher spin (a=0.9). The most noticeable effect is on the energy of the maximum, especially for high inclination systems where the Doppler effect is the strongest.

## 2. From numerical simulation to spectral fitting

A great advantage of a numerical observatory is that we know the 'correct' value from the simulation and therefore we can evaluate the error made on the parameters determination coming from each spectral fitting method applied on our 'observations'. As the output of `NOVAs` is compatible with `xspec` we can use the standard fitting procedure on our numerical observations and assess how close the fitted parameters are to those input in the simulation.

### 2.1. *Error on the disk parameters*

Often the main results from the spectral fitting are the overall disk parameters such as the position of the inner edge of the disk and its temperature. Here we

are using energy spectrums coming from our simulations and then use `xspec` to fit them with `diskbb, ezdiskbb, diskpbb` to see how well each of those performs when compared with the value input in the simulation.

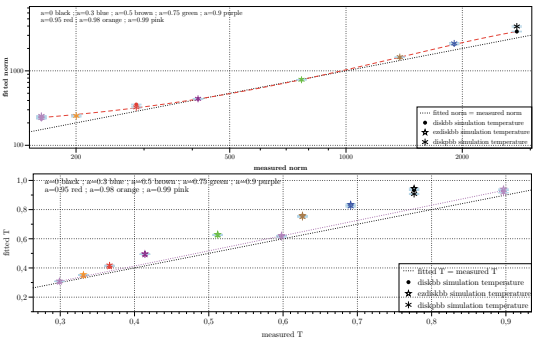

Fig. 4. Comparison of the fitted parameters of the disk, namely the norm and inner temperature, compared to the measured value in the simulations for different spins values.

We see on Fig.4 that for all those cases the norm was reasonably recovered for all spins especially for mid-level spins, while the temperature was much better recovered for high spins, with an error close to 25% at low spin. This can be related to the difference in shape of the temperature profile which is much closer to the diskbb model at higher spin than it is at lower spin.

## 2.2. *Testing the efficiency of the spin determination*

Using the simulation of an accretion disk formed around different spin black-holes we created the 'observations' to plug into `xspec` and used the `kerrbb` model to fit the spin value from the energy spectrum. To simplify the test we input the exact value of inclination, mass and distance of the `NOVAs` observation, leaving only the spin to be fitted.

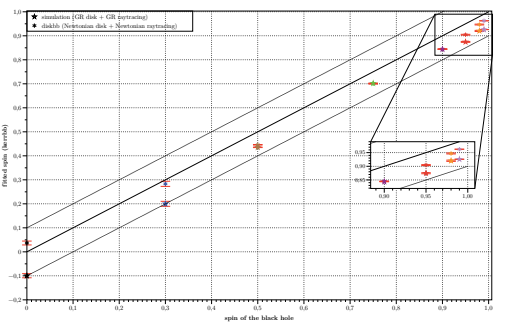

Fig. 5. Comparison between the spin of the numerical observation and its fitted value with `kerrbb`.

The resulting fitted spins are represented in Fig.5 with respect to the spin of the numerical observation. For all the spins the fitted value is within 0.1 of the actual spin of the numerical observation and the quality of the fitted value improves as the spin increases. It is interesting to note that, for all of the cases explored here, the fitted value was always lower than the actual spin of the object. This is a preliminary study and more cases need to be explored but it shows a good efficiency of the spin fitting method if we know well the system's parameters.

### 2.3. *Understanding the origin of some observed features*

Another possible application of the `NOVAs` framework is to look for the cause of some observed features. Here we are looking at what could be the reason behind the fact that it is harder to obtain good $\chi^2$ for the spectral fit of high-spin systems, and that for every state.

In order to explore the difference between high and low spin we look at the shape of the spectrum, or more precisely at how the shape of the spectrum compares with the `diskbb` spectrum which is often used to fit spectral data.

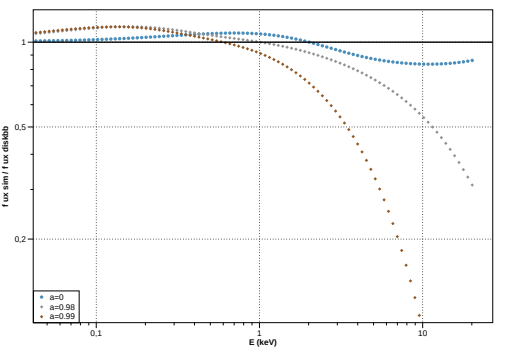

Fig. 6. Evolution as function of energy of the simulated flux over the `diskbb` flux for the same system.

Fig.6 shows that for low spin (blue points) the full GR simulated flux is relatively close to the `diskbb` flux that it is fitted against but as soon as we go to high spins the overall shape of the spectrum starts to diverge. This would then lead to a worse $\chi^2$ for higher spins than can be achieve for lower spins.

## 3. Conclusion

Here we focus on a few cases where `NOVAs`, our Numerical Observatory of Violent Accreting systems[b], have helped us understand observations. Indeed, using `NOVAs` we can now explore the influence of hard-to-measure parameters, such as the spin

[b]See other proceedings by the same author in this volume.

of the black-hole or the inclination of the system, in the hope of finding some observational constraints.

Among the numerous applications we first looked at how well some commonly-used `xspec` models performed to retrieve the information from our simulated spectrums and found that most models have similar pitfalls but give adequate results. We also explore how well the `kerrbb` model constrains the spin and found that for our range of spin and accretion rates the `kerrbb` model was able to get the spin within 0.1 of its actual value.

Finally, we propose the relativistic effects on the disk emission to be responsible for the difficulty to get good $\chi^2$ for high spin sources. This emphasizes the need to improve our disk modelisation in `xspec` for newer missions.

Here we are presenting NOVAs, a Numerical Observatory of Violent Accreting systems, which couples a GR AMR MPI fluid dynamics code (GRAMRVAC) able to follow accretion around a Kerr Black-hole with the ray-tracing code GYOTO. Together, they allow us to test different models by running the simulation and obtaining spectral energy distributions and power-density spectrums from which we can extract the same observables as for 'real' observations, hence making it a Numerical Observatory.

*Keywords*: black hole binaries; MG15 Proceedings; HFQPOs

## 1. Introduction: why a numerical observatory?

While there are a lot of observational data and theoretical models trying to explain black-hole system, it is hard to bridge the gap between observables, such as the energy spectrum for example, and an analytical or numerical model. This is especially true when looking at highly relativistic systems such as the inner region of an accreting black-hole.

The idea behind NOVAs is to create consistently, from numerical GR-(M)HD simulations the same outputs as we have from observations, *i.e.* lightcurve, energy spectrum and Power-Density Spectrum, in a compatible format to be analyzed by software like `xspec`. It makes use of several existing or in development codes which are:

`GRAMRVAC` All the general relativistic (GR) fluid dynamics are done with the general relativistic version of MPI-AMRVAC[a]. In most of the simulations presented here we used a Harten, Lax and van Leer (HLL) solver linked to a Koren slope limiter. See [1, 2] for the full code description and some applications.

`GYOTO` For all the GR ray-tracing computations, we use the open-source[b] GYOTO code. Photons are traced by integrating the geodesic equation using a

[a]Freely available at `https://github.com/amrvac/amrvac`
[b]Freely available at `http://gyoto.obspm.fr`

Runge-Kutta-Fehlberg adaptive-step integrator at order 7/8 (meaning that the method is 8th order, with an error estimation at 7th order). From such maps of specific intensity, the light curve (flux as a function of time) is derived by summing all pixels weighted by the element of the solid angle, which is subtended by each pixel. See [7] for the code presentation.

`SIXTE` In order to add instrumental effects we use the SIXTE[c] package for X-Ray telescope observation simulations. It allows us to undertake instrument performance analyses and to produce simulated event files for mission- and analysis studies.

On top of developping the GR formalism for `GRAMRVAC` we have added to the codes, when needed, new outputs and formats so that one can smoothly go from the fluid simulation to the spectrum observed by an instrument.

## 2. How does NOVAs works

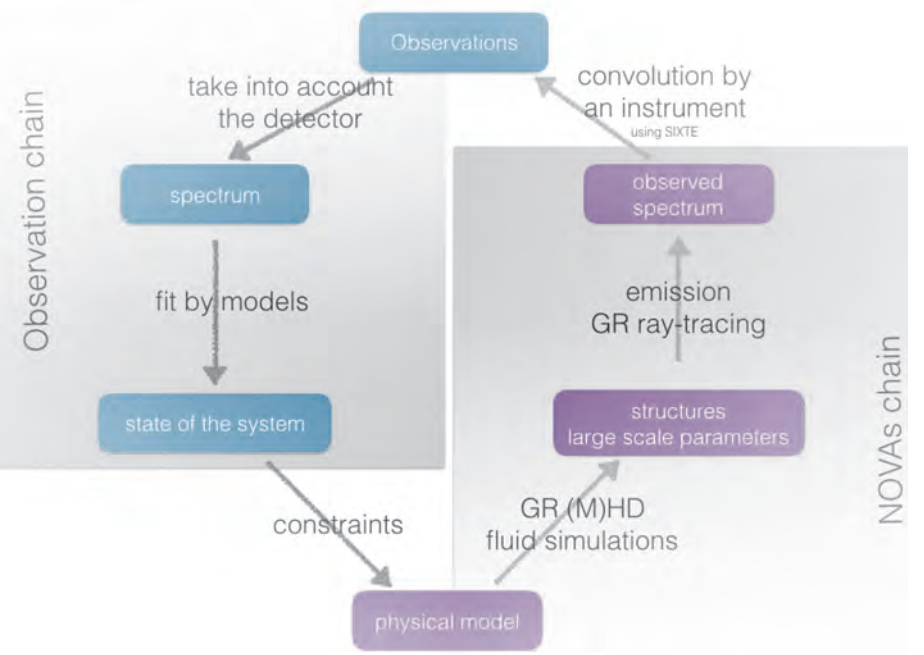

Fig. 1. How the 'standard' observation chain compares with the `NOVAs` chain.

Fig. 1 shows how the numerical observatory of `NOVAs` works when compared with 'standard' observations. This emphasizes how a numerical observatory is complementary to 'standard' observations.

[c]Freely available at `https://www.sternwarte.uni-erlangen.de/research/sixte/index.php`

To explain in more detail how the NOVAs chain works, lets look at the case of an accretion disk orbiting around a Kerr black hole, of spin a, mass M:

– The NOVAs chain starts from a physical model. In our example below we have matter orbiting around a Kerr black hole of spin a, mass M. The first step is to use `GRAMRVAC` to evolve the system in order to obtain a self consistent disk. Here we are particularly interested in the shape of the inner edge formed, left of Fig. 2, as it will first impact the direct emission of the disk but also as it can lead to disk instabilities such as the Rossby-Wave Instability [3, 4, 5, 8].

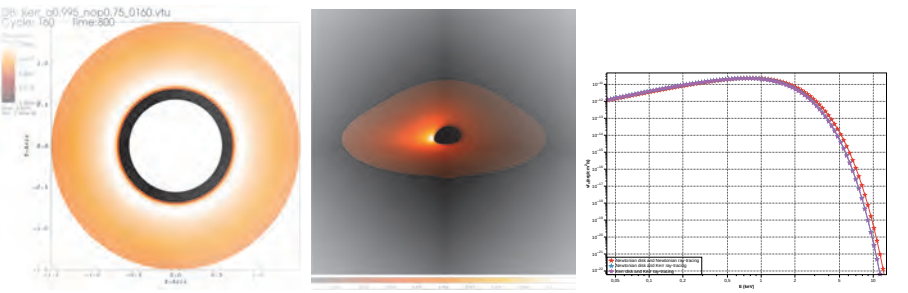

Fig. 2. Left: snapshot from the GR-HD simulation leading to the creation of a disk. Middle: the emission ray-traced back to the observed for a perfect instrument. Right: energy spectrum of the same snapshot.

– Once we have the overall structure of the system from the fluid simulation and the large scale parameters of the system, such as its distance and inclination, we use `GYOTO` to ray-trace back to the observer the emitted flux as a function of energy. A zoom in on the inner portion of the disk is shown in the middle figure of Fig. 2.

– Lastly, those can in turn can be translated into a lightcurve and an energy spectrum for the source (directly or going through a non-perfect instrument using `SIXTE`) as shown on the right of Fig. 2. Then those can be reduced through the standard analysis process to access observables.

There are numerous applications to that numerical observatory, among those we can make predictions from models, test how certain observed features can be explained, test the impact of parameters that are hard to pinpoint such as the inclination, and also test the detectability of certain features with new instruments using `SIXTE`.

## 3. First Applications

Our first application of this Observatory is to study the ability of the Rossby-Wave Instability to reproduce the High Frequency Quasi-Periodic Oscillations detected as peaks in the Power-density spectrum of some black-hole binaries. This is the first

time a full GR study of the RWI has been done with an extreme Kerr black-hole and the associated PDS is computed.

### 3.1. *The RWI around an extreme Kerr black-hole*

While the RWI has been demonstrated to exist in a variety of setups this has only been done in Newtonian and Pseudo-Newtonian approaches until recently. For that reason, the 'first light' of NOVAs was to confirm that the RWI develops as expected in the Kerr metrics, even for high spins.

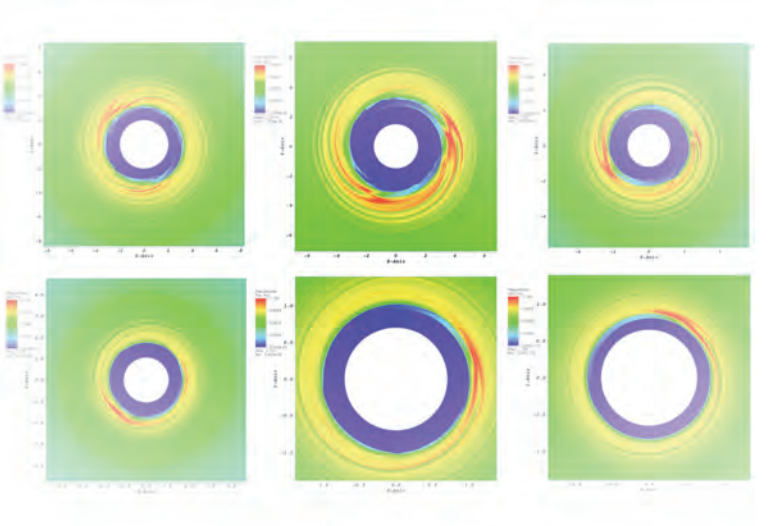

Fig. 3. Snapshots from the GR-HD simulation with the RWI active at the inner edge of a disk orbiting a black hole of spin a={0, 0.3, 0.5, 0.75, 0.95, 0.98}.The x-axis is scaled in $r_S$.

As we can see on Fig. 3., in every simulation the RWI develops close to the last stable orbit,as expected from linear study [3]. The exact position depending on the density profile at the inner edge of the disk, hence on the spin of the black hole. The full impact of the spin on the instability has been explored in [1, 2].

### 3.2. *HFQPOs created from the RWI*

Thanks to `NOVAs` having a full observatory capability we can go one step further and make the lightcurve associated with those simulations as it would be observed with an X-ray satellite and then use standard reduction tools to obtain the power-density spectrum. This allows us to use the most direct way to check if the RWI can indeed produce the High-Frequency Quasi-Periodic Oscillations it has been proposed to explain. Indeed those HFQPOs are detected in the form of peaks in the PDS and, thanks to `NOVAs`, we can produce the PDS associated with our simulations.

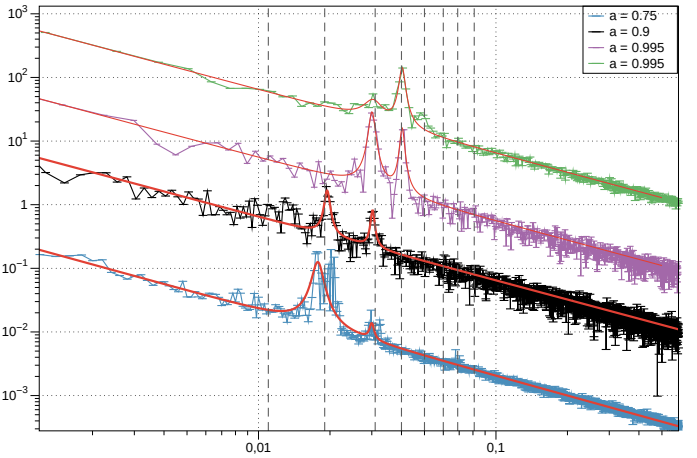

Fig. 4. a small selection of PDSs from our simulations showcasing similar peak ratios as is observed in microquasars.

We see in Fig. 4 that the RWI does not only produces peaks in the PDS and therefore confirm itself as a candidate for the HFQPOs, but it also sometimes exhibits 3:2 and 4:3 ratios for the peaks similar to what is observed in sources such as XTE J1550-564 [6]. In the context of the RWI what fixes the strength of each peak is the local conditions. Indeed, the two upper curves of Fig. 4 are for the same black hole spin but different local disk conditions, leading to different ratios of the strength between the peaks.

## 4. Conclusion

By combining smoothly two GR codes, one providing a full fluid dynamical solution and one providing the ray-tracing of the emission back to the observer, we now have a fully functional numerical observatory, `NOVAs`, which allows us to obtain spectrums and lightcurves of theoretical models with limited hypotheses. Further linking the output of `NOVAs` with SIXTE allows us to also test the capacity of new instruments to distinguish between models and explore new theoretical features.

Among the numerous applications we first looked at the RWI to demonstrate that it will be trigged near the last stable orbit of any spin black-hole as it was linearly predicted. We then computed the lightcurves and associated PDSs and proved the ability of the RWI to produce peaks in the PDS similar to what is observed in microquasars.

A solution of the Boltzmann equation is obtained for a magnetized plasma with strongly degenerate electrons and nondegenerate nuclei. The components of the diffusion, thermal diffusion, and diffusion thermoeffect tensors in a nonquantizing magnetic field are calculated in the Lorentz approximation without allowance for electron-electron collisions, which is asymptotically accurate for plasma with strongly degenerate electrons. Asymptotically accurate analytical expressions for the electron diffusion, thermal diffusion, and diffusion thermoeffect tensors in the presence of a magnetic field are obtained. The expressions reveal a considerably more complicated dependence on magnetic field than analogous dependences derived in the previous publications on this subject.

*Keywords*: neutron stars; dense matter; kinetics.

## 1. Introduction

The kinetic coefficients in the crusts of neutron stars and the cores of white dwarfs play an important role in the evolution of these stars. The heat fluxes and current densities are determined by heat conduction, diffusion, thermal diffusion, and the diffusion thermoeffect. To calculate these coefficients, it is necessary to know the transport properties of a dense stellar matter, in which electrons are strongly degenerate and form a nearly ideal Fermi gas, while ions are nondegenerate and form either a Coulomb liquid or a Coulomb crystal. Under such conditions, electrons are the main carriers of charge and heat, and the kinetic coefficients are mainly determined by electron scattering from ions. Knowing the distributions of heat and current, one can calculate the magnetothermal evolution of a neutron star with the crust that forms a Coulomb crystal [1]. The kinetic coefficients of degenerate electrons in neutron stars and white dwarfs in a magnetic field were analyzed in [2,3]. The ratio between the electric conductivities along and perpendicular to the magnetic field was phenomenologically obtained in [2]. It is given by

$$\frac{\sigma_\perp}{\sigma_\parallel} = \frac{1}{1+(\omega\tau)^2} \tag{1}$$

and was used in [3] to calculate the thermal and electroconductivity coefficients of a degenerate electron gas in the crusts of neutron stars. Here, $\omega = eB/(m_e c)$ is the cyclotron electron frequency, $\tau$ is the time between electron collisions, e is the

electron charge, $m_e$ is the electron mass, B is the magnetic field strength, and c is the speed of light. The influence of the magnetic field on the electron thermal conductivity and electric conductivity in form (1) was used in many subsequent papers.

The electron thermal conductivity tensor in a dense magnetized matter was calculated in [4] by solving the Boltzmann equation by the Chapman-Enskog method for nondegenerate electrons and in the Lorentz approximation for strongly degenerate non-relativistic electrons. Similar calculations had been done in [5] for tensors of diffusion, thermal diffusion and diffusion thermoeffect.

In the present contribution, we briefly present results of [5]. The expressions reveal a substantially more complicated dependence on magnetic field than those obtained in earlier publications on this subject. The use of the kinetic coefficients calculated in this paper makes it possible to take into account the processes occurring in the crust of a neutron star more accurately. The obtained expressions can also be used to describe the transport coefficients in other magnetized objects containing free degenerate electrons.

## 2. Boltzmann equations and transfer equations

We use a Boltzmann equation for electrons, in a magnetic field, with an allowance of arbitrary degeneracy, and assuming them as non-relativistic. We consider the electron gas in a crystal lattice of heavy nuclei, and take into account the interaction of the electrons with a nondegenerate nuclei and with one another. If the mass of the nucleus $m_N$ is much greater, than the electron mass $m_e$, then to the terms $\sim m_e/m_N$ the details of the distribution function $f_{N0}$ are unimportant, and the calculations can be made for arbitrary $f_{N0}$.

Boltzmann equation, which describes the time variation of the electron distribution function $f$ in presence of the electric and magnetic fields is written as[6,7]

$$\frac{\partial f}{\partial t} + c_i \frac{\partial f}{\partial r_i} - \frac{e}{m_e}(E_i + \frac{1}{c}\varepsilon_{ikl} c_k B_l)\frac{\partial f}{\partial c_i} + J = 0. \tag{2}$$

Here $(-e), m_e$ are the charge (negative) and the mass of the electron, $E_i, B_i$ are the strength of the electric field, and magnetic induction, $\varepsilon_{ikl}$ is the totally antisymmetric Levi-Civita tensor, $c$ is the speed of the light. The collision integral $J$ for arbitrary degenerate electrons, from[8,9], is written in the form,

$$J = J_{ee} + J_{eN} = R \int [f^{'} f_1^{'}(1-f)(1-f_1) - f f_1 (1-f^{'})(1-f_1^{'})] \times g_{ee} b\, db\, d\varepsilon dc_{1i}$$
$$+ \int [f^{'} f_N^{'}(1-f) - f f_N (1-f^{'})] \times g_{eN} b\, db\, d\varepsilon dc_{Ni}. \tag{3}$$

Here, the impact parameter $b$, and $\varepsilon$ are geometrical parameters of particle collisions with relative velocities $g_{ee}, g_{eN}, R = \frac{2m_e^3}{h^3}$. The integration in electron part of the

collision integral in (3) is performed over the phase space of the incoming particles ($dc_{1i}$), and the physical space of their arrival ($b\,db\,d\varepsilon$)[8]. The velocity functions after collision are marked with touches.

The Boltzmann equation for electrons with a binary collision integral (3) may be applied in conditions, when the electron gas can be considered as ideal, meaning that the kinetic energy of the electrons is much larger than the energy of electrostatic interactions. It is applicable for plasma at small density. In the neutron stars and white dwarfs we have an opposite conditions of plasma at very large density, when it is important to take into account the electrons degeneracy. It is known from the statistical physics, that a gas of strongly degenerate electrons becomes ideal, because large Fermi energy substitutes here the thermal energy[10]. The calculations in this paper are applied to the high density plasma with degenerate electrons.

The collision integral similar to $J_{ee}$ from (3) for strongly degenerate neutrons in nuclear matter had been found analitically in[9], see also[11]. It was found that that in the presence of non-degenerate heavy nuclei and strongly degenerate neutron, the input of collisions between them in the heat transfer and diffusion coefficients is negligibly small, in comparison with neutron-nuclei collisions. The same situation we have for the strongly degenerate electrons. Therefore for strongly degenerate electrons the Lorentz approximation, with account of collisions between light and heavy particles only, is asymptotically exact. So for our consideration we can neglect $J_{ee}$ in comparison with $J_{eN}$, and we can equate $J = J_{eN}$ in the (3).

Lets introduce the thermal velocity of electrons, $v_i = c_i - c_{0i}$, where $c_{0i}$ is the mass-average velocity. So we can write the Boltzmann equation with respect to the thermal velocity in the form[7]

$$\frac{df}{dt} + v_i \frac{\partial f}{\partial r_i} - \left[ \frac{e}{m_e}(E_i + \frac{1}{c}\varepsilon_{ikl} v_k B_l) + \frac{dc_{0i}}{dt} \right] \frac{\partial f}{\partial v_i} - \frac{e}{m_e c}\varepsilon_{ikl} v_k B_l \frac{\partial f}{\partial v_i} - \frac{\partial f}{\partial v_i} v_k \frac{\partial c_{0i}}{\partial r_k} + J = 0. \tag{4}$$

The transfer equations for the electron concentration, total momentum, and electron energy, in the two-component mixture of electrons and nuclei, can be obtained in a usual manner from the Boltzmann equation in a quasi-neutral plasma [6–8,12].

## 3. Kinetic coefficients of strongly degenerate electrons in magnetic field

We solve the Boltzmann equation by Chapman-Enskog successive approximation method[8]. In the zero-order approximation, the electron distribution function $f_0$ in thermodynamic equilibrium is determined by the Fermi-Dirac function. In the first order approximation, we seek the distribution function $f$ in the form: $f = f_0[1 + \chi(1 - f_0)]$, where $\chi$ is a small correction.

The function $\chi$ allows representing the solution in the form[4]

$$\chi = -A_i \frac{\partial \ln T}{\partial r_i} - n_e D_i d_i \frac{G_{5/2}}{G_{3/2}}, \tag{5}$$

$$d_i = \frac{\rho_N}{\rho}\frac{\partial \ln P_e}{\partial r_i} - \frac{\rho_e}{P_e}\frac{1}{\rho}\frac{\partial P_N}{\partial r_i} + \frac{en_e}{P_e}(E_i + \frac{1}{c}\varepsilon_{ikl}c_{0k}B_l) - \frac{m_e}{kT}F_i. \tag{6}$$

The functions $A_i$ and $D_i$ describe the heat flux and particle diffusion, respectively. It was demonstrated in[6,7] that polar vectors $A_i$ and $D_i$ in the presence of a magnetic field with an axial vector $B_i$ can be sought for in the form:

$$\begin{aligned} A_i &= A^{(1)}v_i + A^{(2)}\varepsilon_{ijk}v_jB_k + A^{(3)}B_i(v_jB_j), \\ D &= D^{(1)}v_i + D^{(2)}\varepsilon_{ijk}v_jB_k + D^{(3)}B_i(v_jB_j), \end{aligned} \tag{7}$$

Introducing functions

$$\xi_A = A^{(1)} + iBA^{(2)}, \quad \xi_D = D^{(1)} + iBD^{(2)}, \tag{8}$$

and dimentionless velocity $u_i = v_i\sqrt{m_e/2kT}$, we obtain from the (4) the equations for $\xi_A$ and $\xi_D$

$$\begin{aligned} f_0(1-f_0)(u^2 - \frac{5G_{5/2}}{2G_{3/2}})u_i &= -iBf_0(1-f_0)\frac{e\xi_A}{m_ec}u_i + I_{eN}(\xi_A u_{Ni}), \\ f_0(1-f_0)u_i &= -iBf_0(1-f_0)\frac{e\xi_D}{m_ec}u_i + I_{eN}(\xi_D u_{Ni}), \end{aligned} \tag{9}$$

where

$$I_{eN}(\xi u_{Ni}) = \int f_0 f_{N0}(1-f_0^{'})(\xi u_i - \xi^{'}u_i^{'})g_{eN}bdbd\varepsilon dc_{Ni}. \tag{10}$$

Detailed description of (9) solving can be obtained from the [4] and[5]. Here we introduce computed kinetic coefficients for three tensors and show the comparison of our results with those, obtained in the subsequent papers.

General expressions for the heat flux $q_i$, and the average directional (diffusion) electron velocity $\langle v_i \rangle$ are given by

$$\begin{aligned} q_i &= -\lambda_{ij}\frac{\partial T}{\partial x_j} - n_e\frac{G_{5/2}}{G_{3/2}}\nu_{ij}d_j = q_i^{(A)} + q_i^{(D)} \\ \langle v_i \rangle &= -\mu_{ij}\frac{\partial T}{\partial x_j} - n_e\frac{G_{5/2}}{G_{3/2}}\eta_{ij}d_j = \langle v_i^{(A)} \rangle + \langle v_i^{(D)} \rangle, \end{aligned} \tag{11}$$

The indices (A) and (D) correspond to the heat flux and diffusion velocity of electrons determined by the temperature gradient $\partial T/\partial x$ and diffusion vector $d_j$.

$$\begin{aligned} q_i = q_i^{(A)} + q_i^{(D)} = &-\left(\lambda^{(1)}\delta_{ij} + \lambda^{(2)}\varepsilon_{ijk}B_k + \lambda^{(3)}B_iB_j\right)\frac{\partial T}{\partial x_j} \\ &-n_e\frac{G_{5/2}}{G_{3/2}}\left(\nu^{(1)}\delta_{ij} + \nu^{(2)}\varepsilon_{ijk}B_k + \nu^{(3)}B_iB_j\right)d_j, \end{aligned} \tag{12}$$

$$\langle v_i \rangle = \langle v_i^{(A)} \rangle + \langle v_i^{(D)} \rangle = -n_e \frac{G_{5/2}}{G_{3/2}} \left( \eta^{(1)} \delta_{ij} + \eta^{(2)} \varepsilon_{ijk} B_k + \eta^{(3)} B_i B_j \right) d_j - \left( \mu^{(1)} \delta_{ij} + \mu^{(2)} \varepsilon_{ijk} B_k + \mu^{(3)} B_i B_j \right) \frac{\partial T}{\partial x_j}. \quad (13)$$

where $\lambda_{ij}$ $\nu_{ij}$ are tensors for heat conductivity and diffusion thermoeffect, respectively, while $\mu_{ij}$ and $\eta_{ij}$ are the thermal diffusion and diffusion tensors.[11,13].

The frequency of electron-ion collisions $\nu_{ei}$ was expressed in[14] and in the limiting case for degenerate matter can be expressed as

$$\nu_{ei} = \frac{32\pi^2}{3} m_e \frac{Z^2 \mathrm{e}^4 \Lambda n_N}{h^3 n_\mathrm{e}} \qquad (D) \qquad \tau_d = 1/\nu_d. \quad (14)$$

Using expression for $\tau_d$, the components for thermal diffusion tensor, diffusion tensor and diffusion thermoeffect tensor can be written in this form:

$$\mu^{(1)} = \frac{4\pi^3 k^2 T (3n_e)^{1/3} \tau_d}{3 n_e h^2 \pi^{1/3}} \left[ \frac{1}{1+\omega^2\tau_d^2} - 2\frac{\omega^2\tau_d^2}{(1+\omega^2\tau_d^2)^2} - \frac{\pi^2}{6} \left( \frac{1}{1+\omega^2\tau_d^2 \frac{y^3}{x_0^3}} \right)'' |_{y=x_0} \right] \quad (15)$$

$$\mu^{(2)} = -\frac{4\pi^3 k^2 T (3n_e)^{1/3}}{3 n_e h^2 \pi^{1/3}} \frac{\omega\tau_d^2}{B} \left[ \frac{2}{1+\omega^2\tau_d^2} - 2\frac{\omega^2\tau_d^2}{(1+\omega^2\tau_d^2)^2} - \frac{\pi^2}{6} \left( \frac{1}{1+\omega^2\tau_d^2 \frac{y^3}{x_0^3}} \right)'' |_{y=x_0} \right] \quad (16)$$

$$B^2 \mu^{(3)} = \mu^{(1)}(B=0) - \mu^{(1)}. \quad (17)$$

$$\eta^{(1)} = \frac{kT}{n_e m_e} \tau_d \left( \frac{1}{1+\omega^2\tau_d^2} + \frac{\pi^2}{6} \left( \frac{1}{1+\omega^2\tau_d^2 (y^3/x_0^3)} \right)'' |_{x=x_0} \right), \quad (18)$$

$$\eta^{(2)} = -\frac{kT}{n_e m_e} \frac{\omega\tau_d^2}{B} \left( \frac{1}{1+\omega^2\tau_d^2} + \frac{\pi^2}{6} \left( \frac{1}{1+\omega^2\tau_d^2 (y^3/x_0^3)} \right)'' |_{x=x_0} \right), \quad (19)$$

$$B^2 \eta^{(3)} = \eta^{(1)}(B=0) - \eta^{(1)}. \quad (20)$$

$$\nu^{(1)} = \frac{kTh^2}{8m_e^2} \left( \frac{3n_e}{\pi} \right)^{2/3} \tau_d \left( \frac{1}{1+\omega^2\tau_d^2} + \frac{\pi^2}{6} \left( \frac{1}{1+\omega^2\tau_d^2 (y^3/x_0^3)} \right)'' |_{x=x_0} \right), \quad (21)$$

$$\nu^{(2)} = -\frac{kTh^2}{8m_e^2} \left( \frac{3n_e}{\pi} \right)^{2/3} \frac{\omega\tau_d^2}{B} \left( \frac{1}{1+\omega^2\tau_d^2} + \frac{\pi^2}{6} \left( \frac{1}{1+\omega^2\tau_d^2 (y^3/x_0^3)} \right)'' |_{x=x_0} \right), \quad (22)$$

$$B^2\nu^{(3)} = \nu^{(1)}(B=0) - \nu^{(1)}. \tag{23}$$

Here $x_0 = \mu/kT$ is rate of degeneracy, $\mu$ is the chemical potential of electrons , and $y = u^2$ is squared dimentionless velocity.

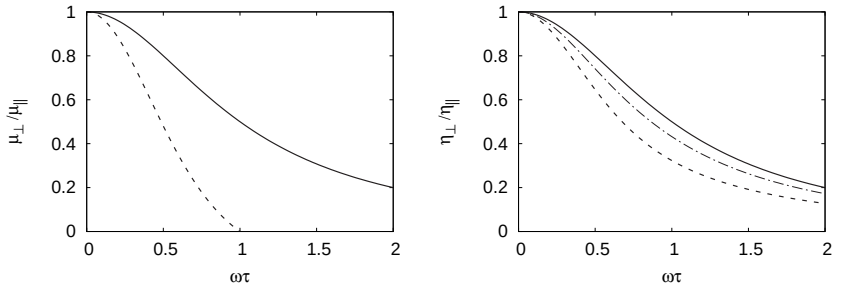

Fig. 1. The left figure is the ratio $\mu_\perp/\mu_\parallel$ as a function of $\omega\tau$. For comparison, the curves representing the phenomenologically determined thermal diffusion coefficient (solid curve) and that obtained from the asymptotic solution to the Boltzmann equation (dashed curve) are shown. The right figure is the ratio $\eta_\perp/\eta_\parallel$ as a function of $\omega\tau$. For diffusion, the phenomenologically obtained solid curve coincides with the curve obtained by solving the Boltzmann equation in the case of strong degeneracy. If terms on the order of smanless of $1/x_0^2$ are retained in the exact solution, then the solution obtained from the Boltzmann equation differs from the phenomenological one given by (1). The dash-dotted and dashed curves correspond to the solutions obtained with the allowance for small terms at $kT = 0.11E_f \quad (x_0 = 9)$ and $kT = 0.2E_f \quad (x_0 = 5)$ respectively.

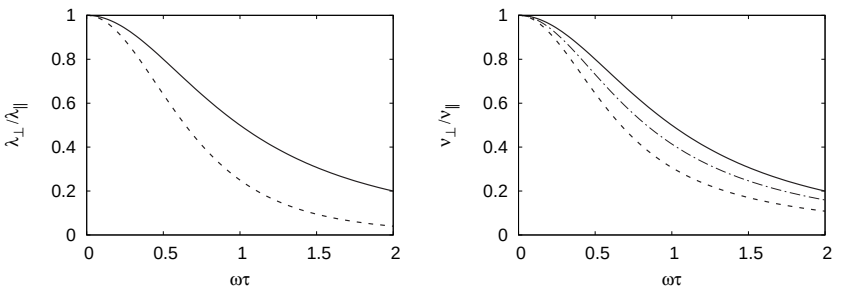

Fig. 2. The left figure is ratio $\lambda_\perp/\lambda_\parallel$ as a function of $\omega\tau$. For comparison, the curves representing the phenomenologically determined thermal conductivity (solid curve) and the asymptotic thermal conductivity obtained by solving the Boltzmann equation (dashed curve) are shown. The right figure is ratio $\nu_\perp/\nu_\parallel$ as a function of $\omega\tau$. Similar to diffusion, the phenomenologically obtained solid curve coinsides with the asymptotic solution for the diffusion thermoeffect. If terms on the order of smalness of $1/x_0^2$ are retained in the solution obtained from the Boltzmann equation, then the plot of $\nu_\perp/\nu_\parallel$ differs from the phenomenological curve. The dash-dotted and dashed curves correspond to the solutions obtained at $kT = 0.11E_f \quad (x_0 = 9)$ and $kT = 0.2E_f \quad (x_0 = 5)$, respectively.

Components for heat conductivity tensor $\lambda_{ij}$ were obtained in the work [4], and the left plot at Fig.2 of $\lambda_\perp/\lambda_\parallel$ is given here for completeness.

## 4. Discussion

In this contribution tensors of diffusion, thermal diffusion and diffusion thermoeffect are presented for strongly degenerate electrons in presence of a non-quantizing magnetic field. The kinetic coefficients are obtained asymptotically exactly in Lorentz approximation, when the electron-electron collision may be neglected in comparison with electron-nuclei collisions at nondegenerate nuclei. In most works considering kinetic coefficients in astrophysical objects, in the neutron stars in particular, following Flowers and Itoh[2], the influence of the magnetic field on the heat flux and on the average directional electron velocity was taken into account phenomenologically, using the coefficient $1/(1+\omega^2\tau^2)$, which decreases the heat flux and the diffusion in the direction perpendicular to the direction of a magnetic field. Our results, obtained by the solution of Boltzmann equation show, that the influence of the magnetic field on the coefficients of heat conductivity is stronger, and has a more complicated character. The new coefficients can be used for calculation of heat fluxes and electric current in white dwarfs, on the surface and in the crust of magnetized neutron star, as well as in the magnetized matter accreting to the magnetized neutron star.

# Hexagonal close pack mesh for fluid dynamics

Atsushi Miyauchi

*Research Organization for Information Science and Technology (RIST),*
*1-5-2 Minatojima-minami, Kobe 650-0047, Japan*
*E-mail: miyauchi@rist.or.jp*

Although regular orthogonal mesh is usually used in numerical relativity, isotropic mesh is preferable for complex fluid motions from the points of numerical accuracy and stability. Hexagonal close pack(HCP) mesh is thought to be an ideal for those purposes. However, HCP has not been used widely so far since it is difficult to implement HCP with data structures existing programming language such as C/C++ or Python provides. In this paper, I propose novel coordinate system suitable to realize HCP with usual array data. In addition, Voronoi tessellation and mesh refinement of HCP is described briefly.

*Keywords*: Hexagonal Close Pack; Coordinate System; Mesh Refinement; Voronoi tessellation; Finite Volume Method.

## 1. Twisted Cartesian Coordinate

In case of HCP mesh, three principal axes of unit cell strongly skew. If we employ unit cell as building block of three-dimensional array, the region defined by the array spans oblong too much. As a result, it wastes large margins to contain a cubic object. Indirect access using list vectors is a typical solution. However, indirect access is poorly efficient in performance for modern processors. Then I have proposed twisted Cartesian coordinate to make HCP implemented easily and efficiently with three-dimensional arrays[1]. Keep in mind, hereafter I treat tri-layered type (i.e. Face-Centered Cubic) of HCP which is better in symmetry than dual-layered type. I found the way to make my algorithm simpler recently. Figure 1 shows a improved allocation algorithm of nearest neighbors using regular three dimensional array indexed by (i,j,k).

Definition of Greek-symbols in the figure follows. Percent symbols mean remainder after division.

$$\xi \equiv \lfloor (k\%3)/2 \rfloor = \begin{cases} 1 & \textit{if } k\%3 = 2 \\ 0 & \textit{otherwise} \end{cases} \qquad \alpha \equiv j\%2 = \begin{cases} 1 & \textit{if } j\%2 = 1 \\ 0 & \textit{otherwise} \end{cases}$$

$$\eta \equiv \lfloor ((k+1)\%3)/2 \rfloor = \begin{cases} 1 & \textit{if } k\%3 = 1 \\ 0 & \textit{otherwise} \end{cases} \qquad \beta \equiv (j+1)\%2 = \begin{cases} 1 & \textit{if } j\%2 = 0 \\ 0 & \textit{otherwise} \end{cases}$$

$$\zeta \equiv \lfloor ((k+2)\%3)/2 \rfloor = \begin{cases} 1 & \textit{if } k\%3 = 0 \\ 0 & \textit{otherwise}. \end{cases} \tag{A.1}$$

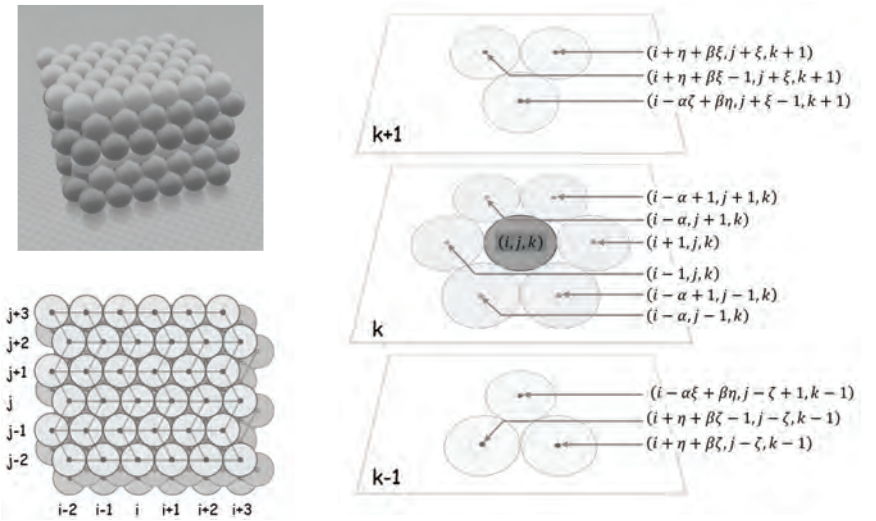

Fig. 1. Stereographic configuration (top-left), arrangement of grid points in a horizontal plane (bottom-left) and a stencil of nearest neighbors surrounding a grid point $(i, j, k)$ (right).

## 2. Voronoi Tessellation

In computational fluid dynamics, finite volume method is frequently used to calculate flow fields over complicated geometry[2]. It calculates a change of quantity in a volume by summing up flux across surrounding surfaces. Accordingly, to employ FCC for finite volume method, a partition of space without any opening is required. After straightforward but tedious calculations of Voronoi tessellation, we can find Rhombic dodecahedron serves as a such partitioned volume. You can also consult Wikipedia to be informed[3]. Although it is not a platonic solid, rhombic dodecahedron has fairly good symmetry since its surface is comprised of twelve identical rhomboids. In addition, it is noteworthy that surface-to-volume ratio is 3.67/d which is nearly half of cube, where d stands for edge length. Empirically, small surface ratio is preferable from the point of numerical stability.

## 3. Mesh Refinement

Recursive mesh refinement of HCP is possible through the steps in what follows. First, make all voxels shrunk half in length around its center, then fill generated space between voxels in each layer with additional voxels. Finally, insert reciprocal layers to fit void between existing layers. Although not shown here, current version of interpolation procedure of data from parents to children still remains partly asymmetric and left room to be improved. However, agglomeration procedure of children to parents is straightforward and symmetric.

## 4. Conclusion

A concise and easy way of identifying nearest neighbors in HCP (FCC actually) is presented which thought to be promising for precise simulation of gravitational waves through finite volume method. However, mesh refinement algorithm still needs improvement.

# Magnetized 1.5-dimensional advective accretion flows around black holes

Tushar Mondal* and Banibrata Mukhopadhyay†

*Department of Physics, Indian Institute of Science, Bengaluru 560012, India*
**E-mail: mtushar@iisc.ac.in*
†*E-mail: bm@iisc.ac.in*

We address the role of large scale magnetic stress in the angular momentum transport, as well as the formation of different kinds of magnetic barrier in geometrically thick, optically thin, vertically averaged 1.5-dimensional advective accretion flows around black holes. The externally generated magnetic fields are captured by the accretion process from the environment, say, companion stars or interstellar medium. This field becomes dynamically dominant near the event horizon of a black hole due to continuous advection of the magnetic flux. In such magnetically dominated accretion flows, the accreting matter either decelerates or faces magnetic barrier in vicinity of the black hole depending on the magnetic field geometry. We find that the accumulated strong poloidal fields along with certain toroidal field geometry help in the formation of magnetic barrier which may knock the matter to infinity. When matter is trying to go back to infinity after getting knocked out by the barrier, in some cases it is prevented being escaped due to cumulative action of strong magnetic tension and gravity, and hence another magnetic barrier. We suggest, this kind of flow may be responsible for the formation of episodic jets in which magnetic field can lock the matter in between these two barriers. We also find that for the toroidally dominated disc, the accreting matter rotates very fast and decelerates towards the central black hole.

## 1. Introduction

In 1972, Bekenstein proposed an idealized engine, namely Geroch-Bekenstein engine[1], that makes use of the extreme gravitational potential of a black hole (BH) to convert mass to energy with almost perfect efficiency. However, the practical realization of this engine is very difficult in astrophysical systems. Generally astrophysical BHs do convert mass to energy via accretion process with modest efficiencies. Later the idea came to address the importance of large scale dipole magnetic field in an accretion flow[2]. Following this idea, it was suggested and also verified numerically[3] that this efficient conversion is practically possible in the presence of large scale poloidal magnetic field. Such an efficient accretion phenomenon is named as Magnetically Arrested Disc (MAD)[4].

The origin of strong magnetic field near the event horizon of a BH is as follows. For the case of advective accretion flow, the magnetic fields are captured from accreting medium or companion star. These fields are dragged inward with continuous accretion process and become dynamically dominant through flux freezing in vicinity of a BH. Theoretical models suggest the importance of large-scale magnetic field in accretion and in the formation of strong outflows/jets, as well as high-energy radiation[5–7]. Observations of all well-known jetted sources also indicate

the presence of dynamically important magnetic field at the jet-footprint[8]. In this proceeding, we explore the underlying role of such large-scale strong magnetic fields on the disc flow behaviours for optically thin, geometrically thick, advective accretion flows around BHs. Unlike MAD, here the advection of both poloidal and toroidal magnetic fields are considered. We address the possible origin of different kinds of magnetic barriers depending on field geometry.

## 2. Model equations

We address magnetized, optically thin, advective, axisymmetric, vertically averaged, steady-state accretion flow around BHs in the pseudo-Newtonian framework with Mukhopadhyay potential[9]. The flow parameters, namely, radial velocity ($v$), specific angular momentum ($\lambda$), fluid pressure ($p$), mass density ($\rho$), the radial ($B_r$) and toroidal ($B_\phi$) components of magnetic fields, are solved simultaneously as functions of radial coordinate $r$. Throughout in our computation, we express the radial coordinate in units of $r_g = GM_{BH}/c^2$, where $G$ is Newton's gravitational constant, $M_{BH}$ is the mass of the black hole, and $c$ is speed of light. We also express $\lambda$ in units of $GM_{BH}/c$ and velocity in units of $c$, and the other variables accordingly to make all the variables dimensionless. Hence, the continuity equation, the components for momentum balance equation, and the energy equation can read as, respectively,

$$\frac{d}{dr}\left(r\rho h v\right) = 0, \tag{1}$$

$$v\frac{dv}{dr} - \frac{\lambda^2}{r^3} + \frac{1}{\rho h}\frac{d(hp)}{dr} + F = -\frac{\sqrt{h}B_\phi}{4\pi\rho h r}\frac{d}{dr}\left(r\sqrt{h}B_\phi\right), \tag{2}$$

$$v\frac{d\lambda}{dr} = \frac{1}{r\rho h}\frac{d}{dr}\left(r^2 W_{r\phi} h\right) + \frac{\sqrt{h}B_r}{4\pi\rho h}\frac{d}{dr}\left(r\sqrt{h}B_\phi\right), \tag{3}$$

$$\frac{hv}{\Gamma_3 - 1}\left(\frac{dp}{dr} - \frac{\Gamma_1 p}{\rho}\frac{d\rho}{dr}\right) = Q^+ - Q^- = f_m Q^+ = f_m(Q^+_{vis} + Q^+_{mag}), \tag{4}$$

where $F$ is the magnitude of the gravitational force corresponding to the pseudo-Newtonian potential. $W_{r\phi}$ is the viscous shearing stress, which can be expressed using Shakura-Sunayev[10] $\alpha$-viscosity prescription with appropriate modifications[11] due to advection as given by $W_{r\phi} = \alpha(p + \rho v^2)$. Following the vertical momentum balance equation, the disc half-thickness can be written as

$$h = r^{1/2}F^{-1/2}\sqrt{\left(p + \frac{B^2}{8\pi}\right)/\rho}. \tag{5}$$

The energy equation is written by taking care of the proper balance of heating, cooling and advection. $Q^+$ is the energy generated per unit area due to magnetic ($Q^+_{mag}$) and viscous dissipation ($Q^+_{vis}$), whereas $Q^-$ infers the energy radiated out per unit area through different cooling mechanisms[7]. However for the present purpose, we do not incorporate cooling processes explicitly. The factor $f_m$ measures the degree of cooling and it varies from 0 to 1 for two extreme cases of efficient cooling and no cooling respectively. The details of dissipation terms are followed

from the Ref. 12. Note that in the energy equation, we do not include the heat generated and absorbed due to nuclear reactions[13].

The presence of magnetic field provides two other fundamental equations, namely, the equation for no magnetic monopole and the induction equation. These are respectively

$$\nabla.\mathbf{B} = 0, \text{ and } \nabla \times (\mathbf{v} \times \mathbf{B}) + \nu_m \nabla^2 \mathbf{B} = 0, \tag{6}$$

where $\mathbf{v}$ and $\mathbf{B}$ are the velocity and magnetic field vectors respectively and $\nu_m$ is the magnetic diffusivity. For this accretion disc solution, we consider the induction equation in the limit of very large magnetic Reynolds number ($\propto 1/\nu_m$).

## 3. Solution procedure

The set of six coupled differential equations $(1) - (6)$ for six flow variables $v$, $\lambda$, $p$, $\rho$, $B_r$, and $B_\phi$ are solved simultaneously to obtain the solutions as functions of the independent variable $r$. The appropriate boundary conditions are as follows. Very far away from the BH, matter is sub-sonic and the transition radius between the Keplerian to sub-Keplerian flow is the outer boundary of our solutions. Very near the BH, matter is super-sonic and the event horizon where matter velocity reaches speed of light is the inner boundary. In between these two boundaries, matter becomes tran-sonic where matter velocity is equal to (or similar to) medium sound speed and this location is called as sonic/critical point. We use this point as one of the boundary. Different types of sonic/critical points, say, saddle, nodal, and spiral, are described in the Ref. 12.

## 4. Results

The angular momentum transport in accretion physics had been a long standing issue until Balbuas & Hawley[14] described the importance of magnetorotational instability (MRI), particularly in an ionized medium in the presence of weak magnetic fields. Later Mukhopadhyay & Chatterjee[15] showed that the efficient transport of angular momentum is also possible by large-scale magnetic field in geometrically thick, advective accretion flow, even in the complete absence of $\alpha$-viscosity. Here, we address the importance of large-scale strong magnetic field in accretion geometry. When the magnetic field is strong enough, presumably that corresponds to the upper limit to the amount of magnetic flux which a disc around a BH can sustain, it disrupts the accretion flow. Then the force associated with the magnetic stress becomes comparable to the strong gravitational force of the BH. As a consequence, the magnetic field arrests the infalling matter in vicinity of the BH. Here we plan to understand such magnetic activity depending on different kinds of field geometry.

In Figure 1 we show three different natures of accretion depending on different magnetic field geometries. The left column indicates the Mach number ($M$), defined as the ratio of the radial velocity to the medium sound speed, whereas the right

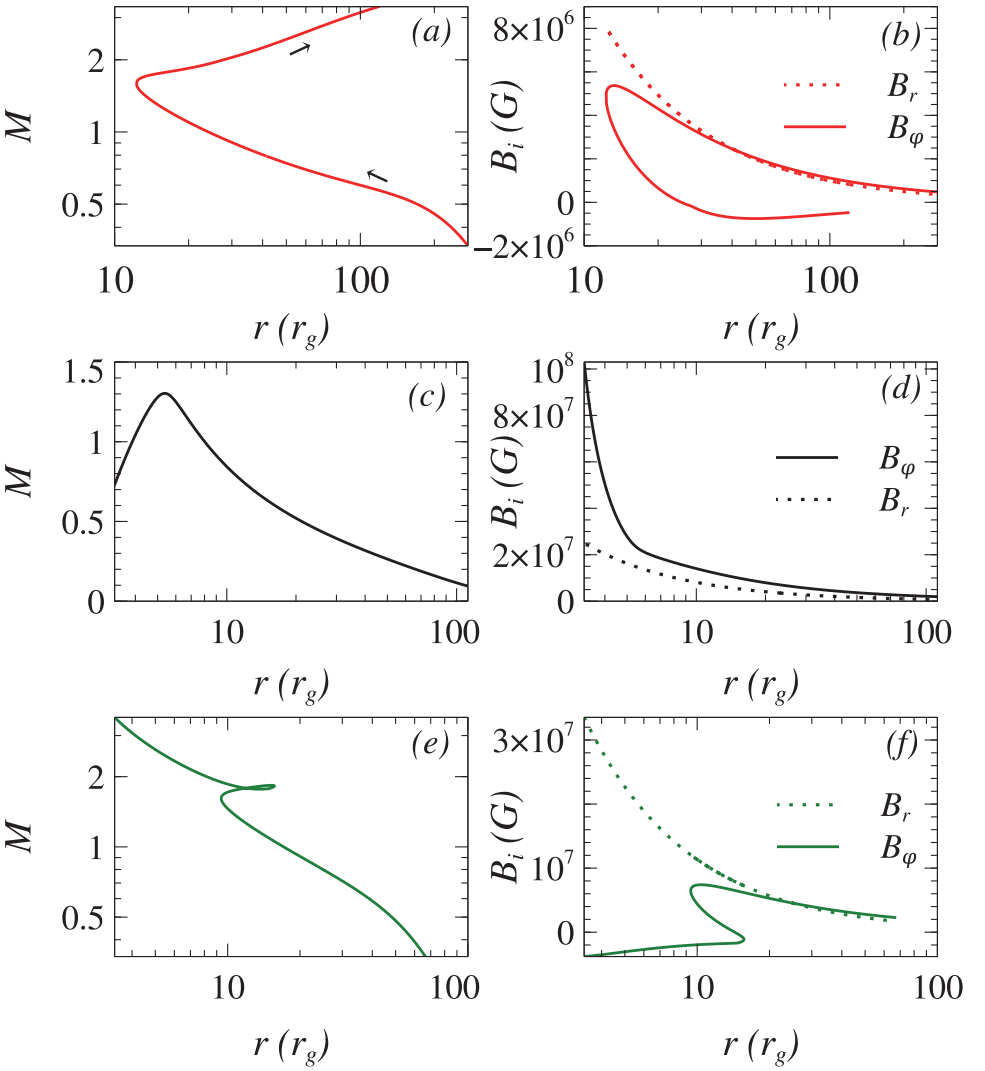

Fig. 1. Variation of Mach number ($M$) and the corresponding magnetic field components ($B_i$) for different relative field strengths in the disc. The model parameters are $M_{\rm BH} = 10M_\odot$, $\dot{M} = 0.01\dot{M}_{\rm Edd}$ and $f_m = 0.5$.

column represents the corresponding magnetic field components ($B_i$). In Figure 1 ($a$), the Mach number increases monotonically towards the central BH until it faces magnetic barrier at $r \simeq 12$. After facing such a barrier, matter goes back to infinity. To explain the origin of such barrier, we focus on the underlying role of magnetic force along with strong gravity, centrifugal force, and force due to gas pressure. When matter falls towards central BH, the forces supporting gravity may suppress by the forces acting outward. In such circumstances, following radial momentum

balance equation, the condition for which barrier appears as

$$-\frac{1}{4\pi\rho h}\left(\sqrt{h}B_\phi\frac{d(\sqrt{h}B_\phi)}{dr}\right)-\frac{1}{\rho h}\frac{d(hp)}{dr}+\frac{\lambda^2}{r^3}>F+\frac{1}{4\pi\rho h}\frac{(\sqrt{h}B_\phi)^2}{r}, \qquad (7)$$

where the first term appears from magnetic pressure and the last term from magnetic tension. Simply it suggests the essential condition to appear magnetic barrier is $\frac{d}{dr}(\sqrt{h}B_\phi)\ll-\frac{\sqrt{h}B_\phi}{r}$. On the other hand, the equation for no magnetic monopole leads to $\frac{d}{dr}(\sqrt{h}B_r)=-\frac{\sqrt{h}B_r}{r}$. These combine conditions suggest that the matter faces magnetic barrier only when the field strength is strong enough to satisfy equation (7) and the disc is poloidal magnetic field dominated. Figure 1($b$) infers such field conditions.

In Figure 1($c$), the Mach number initially increases monotonically and finally slows down to the central BH. In this case, the disc is toroidal magnetic field dominated as shown in Figure 1($d$). In this situation matter is rotating very fast compared to the inward dragging. In Figure 1($e$), the Mach number increases up to $r\simeq 9.5$, where the magnetic barrier appears due to dominant poloidal magnetic field. After knocking out by such a barrier, matter tries to go away from the BH, but faces another barrier at $r\simeq 15.6$. This is because of the cumulative action of the inward strong gravity force and the inward force due to magnetic tensions along the field lines. In between these two barriers matter faces spiral-type critical point and again falls back to the central BH. The corresponding field components are shown in Figure 1($f$). Note that the magnetic field strength within plunging region is few factor times $10^7$ G for $10M_\odot$ BH for all the cases mentioned above.

## 5. Discussions

Accretion disc can carry small as well as large-scale strong magnetic fields. Small-scale field may generate, locally, through some physical scenario, Biermann batery mechanism, dynamo process etc. However, the origin of large-scale strong magnetic fields is still not well understood. It was suggested that the externally generated magnetic field either from companion star or from interstellar medium may capture and drag inward through continuous accretion process. This field becomes dynamically dominant in vicinity of a BH due to flux freezing. In such circumstances, strong magnetic fields arrest the infalling matter and disrupt the conventional accretion flow properties.

In this proceeding, we address three different types of accretion flow properties depending on field geometry in the presence of large scale strong magnetic fields. First, when the disc is poloidal field dominated, the infalling matter faces magnetic barrier and tries to go back to infinity. On its way away from the BH, matter may completely lose its angular momentum and at the same time the combined effects of inward strong gravity and the magnetic tension along field lines can prevent the matter being escaped. In this particular case, matter again falls back to the BH by facing second magnetic barrier. The important application of such a flow

behaviour is the formation of episodic jets in which magnetic field can lock the infalling matter in between these two magnetic barriers. Second, for such a poloidal field dominated case, matter can completely go back to infinity after knocked out by the first magnetic barrier. Magnetic tension is not strong enough to prevent the matter being escaped in this case. This type of flows is the building block to produce unbound matter and hence strong continuous outflows/jets. Third, when the disc is toroidal field dominated, the infalling matter rotates very fast rather than being dragged inward in vicinity of the BH. In such case, matter falls slowly into the BH. For all these scenarios the maximum magnetic field strength near the stellar mass BH is few factor times $10^7$ G, which is well below the Eddington magnetic field limit[6] and hence perfectly viable. The other important aspect of this quasi-spherical advective flow is the angular momentum transport. The outward transport of angular momentum occurs through large-scale magnetic stress. The specific angular momentum is quite below the local Keplerian value.

In the other proceedings of this volume, we discuss more general disc-outflow symbiotic model[16] and its observational implication to ultra-luminous X-ray sources[17].

We represent results of simulation protostellar molecular clouds(MC) collision process. The interaction of the MC with each other leads to the emergence of extremely dense, gravitationally bounded regions, which can be sources of the formation of new stars and star systems. Computer modeling was carried out on high-resolution grids up to $2048 \times 1024 \times 1024$. Oscillations of the MC surface, which are caused by the formation of a dense lenticular structure at the interface of the colliding clouds in the process of collision, are found.

*Keywords*: Molecular clouds collision; Numerical simulation; Kelvin-Helmholtz instability.

## 1. Introduction

Collisions of molecular clouds and their interaction with shock waves play a large role in the chain of events leading to the formation of stars.

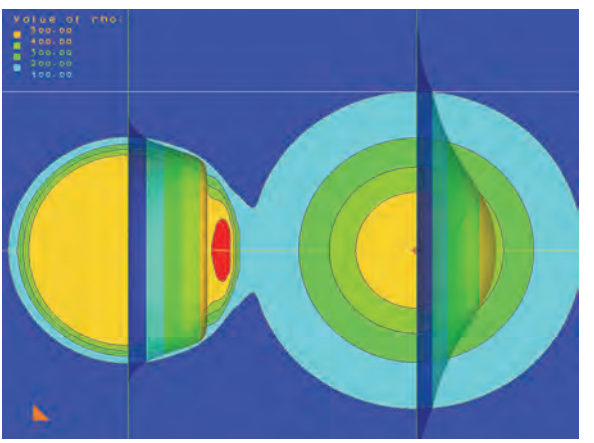

Fig. 1. Density dictribution in the collision of two MC

When molecular clouds collide or when shock waves pass through them, the gas density in MC increases by many orders of magnitude. This can lead to fragmentation and restructuring of clouds. As a result of such processes, a system of dense filaments and proto-cores is formed. At relatively small scales (about 1 parsec), star

formation processes occur in numerous dense nuclei in the filaments. The resulting turbulent motions become the dominant factor in the formation of high-density gas regions, some of which may become protostar. In Fig. 1 shows an example of the collision of two molecular clouds, which is a trigger for the formation of new stars.[1].

This article presents the results of numerical modeling of the processes of collision MO. Turbulent motions that occur during a collision are the dominant cause of the formation of areas with high density, some of which can become a protostar.

## 2. Formulation of the problem

Modeling is carried out with using high-resolution difference schemes, on sufficiently detailed grids. The paper presents the processes of formation, evolution and interaction between each other filament structures, the emergence of supersonic turbulence, etc.As known[2,3] molecular clouds are often gravitationally bound objects. The appearance of the Jeans instability and the formation of dense proto-cores is often the result of such a gravitational coupling. Further gravitational contraction of the proto-core can lead to the emergence of new stars.

The interstellar medium(ISM) consists of a relatively warm substance $\sim 10^4 K$. The ISM contains molecular clouds whose densities are much higher than the density of the ISM. The temperature in the molecular cloud is less than the ISM $T_{cloud} \sim 10^2 K$ temperature. The shock wave formed after the supernova explosion hits a molecular cloud that is in the interstellar medium. Fig. 1 schematically shows the geometry of the computational domain. The cross-section of the three-dimensional computational domain by a plane perpendicular to the axis OZ is shown. In Fig. 1 shows the initial (t = 0) position of two molecular clouds in a central collision. In the sections shown, the initial density distribution in the clouds is shown.

The computational domain is a parallelepiped with sizes ranging from $2048 \times 1024 \times 1024$ to $1024 \times 512 \times 512$ cells along the axes $X$, $Y$ and $Z$, respectively. In the above calculations, the cell size along the axes $\triangle\, x, \triangle\, y, \triangle\, z$ was assumed to be the same: $\triangle\, x = \triangle\, y = \triangle\, z$. Thus, each environment has its own sound speed equal to $a_i = \sqrt{\gamma_i \frac{p_i}{rho_i}}$, $i = 0.1$, ($i = 0$ for ISM, $i = 1$ for MC)

Mach numbers $M_i = u_i/a_i$ are also different for these media. However,[5,6] showed that it is possible to ignore these differences and use the same value of $\gamma = 5/3$ for the entire computational domain.

For modeling, a system of laws of conservation of mass, momentum and energy in a three-dimensional Cartesian coordinate system is used.

When modeling the process of collision of two molecular clouds or the interaction of a strong shock wave with a molecular cloud, we will use the equation of state in the form:

$$p = \rho(\gamma - 1)\Big[e - \frac{1}{2}(u^2 + v^2 + w^2)\Big], \tag{1}$$

here $\gamma$ is the adiabatic index, $\rho$ density, $\mathbf{v} = \{u, v, w\}$ velocity vector and $p$ pressure[4].

Initially, the cloud is in dynamic equilibrium with the background gas. Thermal conductivity and radiation losses in the interaction can be neglected. In the work $\gamma = 5/3$. The density of the interstellar medium is assumed to be $rho_a = 2.15 * 10^{-25}\ g/sm^3$, the temperature is $T_a = 10^4 K, u_a = 0.0$. The cloud density is $\rho_c = 1.075 * 10^{-22} g/sm^3$, temperature is $T_c = 100K$, $u_c = 0.0$. The parameters of the gas behind the shock wave are determined from the Rankin Hugoniot equations.

One of the most important parameters of the process of interaction of the shock wave with the MC is the ratio of the density of MC to the ISM density:

$$\chi = \frac{\rho_{mc}}{\rho_{ism}} \tag{2}$$

Here $\rho_{mc}$ is the density of the molecular cloud, $\rho_{ism}$ is the density of the interstellar medium, respectively. We assume that the shock wave does not undergo radiation cooling and the Mach number of the shock wave is sufficiently large.

## 3. Results

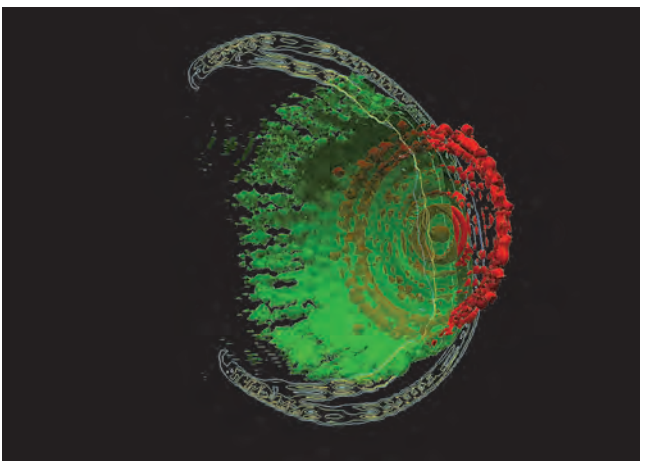

Fig. 2. The stage of passage by the cloud of MC1 zone at the exit from the area opposite to the MC2. Given the distribution of fragmented condensation of gas, with a contrast of 8000.

The results of the central collision of two MOs at a speed of 0.5 to 15 km/s are given. Under such conditions, there is a significant fragmentation of clouds, the spread of gas from the center to the periphery, the formation of dense areas in the area of impact. Depending on the initial density and speed of impact, areas of increased density appear in the contact zone and are constantly increasing, which over time can become gravitationally bound objects. In Fig. 2 shows the results of molecular collision calculations at a mutual velocity of 5 km/s. The moments of

dimensionless time are given, at which a smaller MC penetrated into large one more than about half the radius of a small cloud (right fragment). The center shows the contact area, which quickly changes in shape and mass.

This process is presented in more detail in Fig. 3. The development in time of the field of a rapidly changing density gradient in the core (red) and in the shell (green) is given. The maximum density contrast, when colliding at relatively low speeds, increases by two orders of magnitude compared to the initial contrast $\chi = 500$. A change in the density, shape, and position of the contact surface leads to the appearance of oscillations that occur on the midsections (equators) of the MO and the appearance of oscillations in the interstellar medium. With further interaction, the MC of a shock-compressed, lens-like layer forms superdense regions (clumps) in which ring waves propagate.

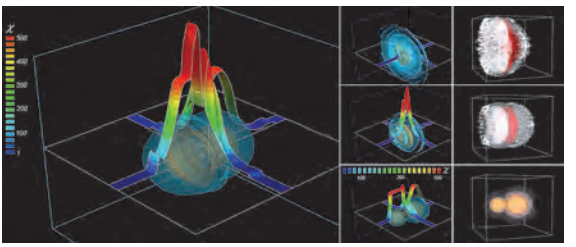

Fig. 3. On the left is a plot of the density distribution in the collision of two MOs, on the right - successive stages of the collision process (bottom-up)

In Fig. 3 shows the graphs of the density distribution at different stages of a collision (left). The density distribution in the lens-like contact area is shown in the center. On the right - the destruction of the shells of the MO and the formation of filaments at successive time moments.

## 4. Conclusions

Numerical simulation of collisions of initially spherical clouds in a hot interstellar medium (MS) revealed significant details of the increase in density in the boundary regions between the molecular clouds and the MC substance. This process is accompanied by the Kelvin-Helmholtz instability and disturbance of the gas density above the disturbed surface layers of the clouds. Oscillations caused by extremely strong density changes at the contact boundary of the MC become clearly observable. It is very likely that this process is generated through the exchange of energy in high-gradient outer layers and deformation of the lens-like surface at the contact boundary. The nonlinear instability of thin shells in the gas phase can play a crucial role in the launch of this process. The Kelvin-Helmholtz instability apparently, lead to the formation of surface oscillations and deformation of the MC.

This work was supported by the Program of the Presidium of the Academy of Sciences of Russia, No. 26.

We model the propagation of pulsars through the inhomogeneous ISM using non-relativistic axisymmetric magneto-hydrodynamic (MHD) simulations. We take into account the wind from the star, which carries predominantly azimuthal magnetic field, and investigate the PWN at different levels of magnetization (the ratio of magnetic to matter energy-densities) in the wind. We consider the interaction of PWN with large-scale and small-scale imhomogeneities in the ISM at different values of magnetization. We conclude that the inhomogeneities in the ISM can change the shapes of the bow shocks and magnetotails at different values of the magnetization.

*Keywords*: neutron stars; magnetic field; PWN; ISM; MHD.

## 1. Introduction

Pulsars emit winds of relativistic particles and magnetic fields, and are often surrounded by the PWN. Many pulsars have high velocities and propagate supersonically through the ISM, and their PWN interact with the ISM, forming bow shocks and magnetotails. The bow shocks are often observed in the $H_\alpha$ spectral line[3]. Many interesting structures (bow shocks, very long tails, and jet-like features) are observed in the X-ray[6] and radio[9] wavebands.

One remarkable PWN is the Guitar Nebula, which is powered by the pulsar PSR B2224+65 that travels at a high velocity of about 1600 km/sec. The high-resolution observations in the $H_\alpha$ line show that the shape of the Nebula's head becomes wider with time. The variation in shape may be connected with the variation in the density of the ISM[5]. Figure 1 shows another interesting example of PWN, the $H_\alpha$ pulsar bow shock connected with the pulsar PSR J0742-2822[3]. This PWN shows multiple irregularities in its shape, which suggests that the pulsar may be travelling through small-scale fluctuations in the ISM.

In the X-ray band, many of the PWN show irregularities in their shapes, as well as very long tails (see review by Kargaltsev at al.[8]). Even longer tails are observed in the radio band[9]. Figure 2 shows two examples of PWN, observed in the X-ray and radio bands: the PWN associated with the pulsar PSR J1509-5850 and the Mouse Nebula, powered by the pulsar PSR J1747-2958[7]. One can see that both PWN have long tails in the X-ray band (red colour), and even longer tails in the radio band (blue colour).

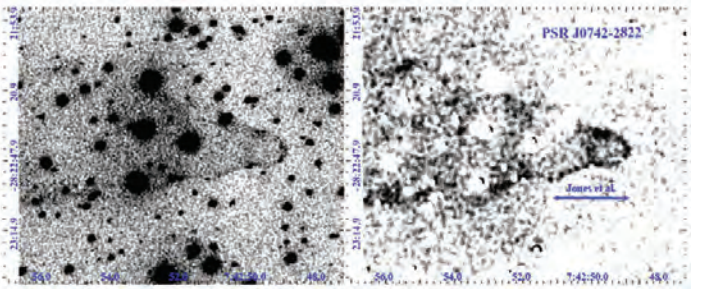

Fig. 1. PWN of the pulsar PSR J0742-2822, observed in the $H_\alpha$ line by (image taken by Brownberger & Romani[3]. *Left panel:* A median-filtered 3 x 600 W012 SOI image of PSR J0742.2822, smoothed with a 0.45" Gaussian. *Right panel:* Same image, but with the scaled continuum image subtracted and a 0.9" top-hat smoothing. The arrow indicates the extent of the previous nebula detection.

If a pulsar propagates supersonically through the ISM, then the PWN interacts with the ISM, forming a bow shock and magnetotails. In the bow shock, the energy of accelerated particles may dominate over magnetic energy-density. However, in the magnetotails, the magnetic energy-density may be comparable to or larger than the energy-density of the particles. Long, magnetically-dominated magnetotails are expected to form in the PWN. They may be visible, if the accelerated particles propagate into the magnetotails, or invisible otherwise. In modelling the supersonic PWN, it is important to take into account both, the matter and the magnetic field components of the PWN.

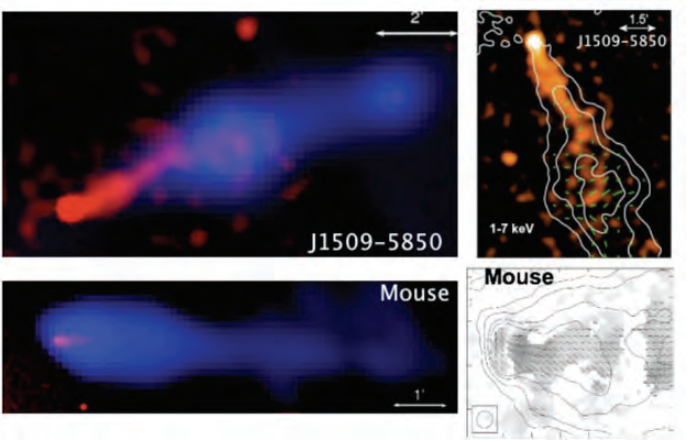

Fig. 2. X-ray and radio images of the very long pulsar tails, by Kargaltsev and Pavlov[7]. Right panels show the radio contours and the direction of the magnetic field. The red and blue colours in the left panels correspond to X-ray and radio, respectively.

Supersonic propagation of pulsars through the ISM has been studied in a number of axisymmetric non-relativistic and relativistic hydrodynamic simulations (e.g., Bucciantini[4], Barkov[2]). Many of the above simulations of the bow shocks propagating through an inhomogeneous ISM medium were performed in hydrodynamic approximation. Our goal is to study this problem in axisymmetric MHD simulations at different magnetization values of the pulsar wind.

## 2. Numerical Model

We performed MHD simulations to investigated the supersonic propagation of magnetized neutron star through the non-uniform ISM. We used an axisymmetric, resistive MHD code. The code incorporates the methods of local iterations and flux-corrected-transport[12]. The flow is described by the resistive MHD equations:

$$\frac{\partial \rho}{\partial t} + \nabla\cdot(\rho\ \mathbf{v}) = 0\ ,$$

$$\rho\frac{\partial \mathbf{v}}{\partial t} + \rho(\mathbf{v}\cdot\nabla)\mathbf{v} = -\nabla p + \frac{1}{c}\mathbf{J}\times\mathbf{B} + \mathbf{F}^g\ ,$$

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla\times(\mathbf{v}\times\mathbf{B}) + \frac{c^2}{4\pi\sigma}\nabla^2\mathbf{B}\ ,$$

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \nabla\cdot(\rho\varepsilon\mathbf{v}) = -p\nabla\cdot\mathbf{v} + \frac{\mathbf{J}^2}{\sigma}\ . \qquad (1)$$

We assume axisymmetry ($\partial/\partial\phi = 0$), but calculate all three components of $\mathbf{v}$ and $\mathbf{B}$. The equation of state for an ideal gas, $p = (\gamma-1)\rho\varepsilon$, where $\gamma = 5/3$ is the specific heat ratio and $\varepsilon$ is the specific internal energy of the gas. The equations incorporate Ohm's law $\mathbf{J} = \sigma(\mathbf{E}+\mathbf{v}\times\mathbf{B}/c)$, where $\sigma$ is the electric conductivity. The associated magnetic diffusivity, $\eta_{\rm m} \equiv c^2/(4\pi\sigma)$, is assumed to be a constant. The gravitational force, $\mathbf{F}^g = -GM\rho\mathbf{R}/R^3$, is due to the star because the self-gravity of the accreting gas is negligible.

We use a cylindrical, inertial coordinate system $(r,\phi,z)$ with the $z-$axis parallel to the star's dipole moment $\mu$ and rotation axis $\mathbf{\Omega}$. The vector potential $\mathbf{A}$ is calculated so that automatically $\nabla\cdot\mathbf{B} = 0$ at all times. The intrinsic magnetic field of the star is taken to be an aligned dipole, with vector potential $\mathbf{A} = \mu\times\mathbf{R}/R^3$. A detailed description of numerical model can be found in[10],[11].

We measure length in units of the Bondi radius $R_B \equiv GM/c_s^2$, with $c_s$ the sound speed at infinity, density in units of the density of the interstellar medium $\rho$, and magnetic field strength in units of $B_0$ which is the field at the pole of the numerical star. We measure time in units of $t_0 = (Z_{max} - Z_{min})/v_\infty$, which is the crossing time of the computational region with the star's velocity, $v_\infty$.

## 3. Propagation of PWN through the non-uniform ISM

We investigate the propagation of a PWN through an ISM with an inhomogeneous matter distribution. Observations point to large and small-scale inhomogeneities, and therefore we consider two types of imhomogeneities: (1) large-scale clouds, which are much larger than the size of the bow shock, (2) small-scale clouds, whose size is comparable with the width of the bow shock.

### 3.1. *Large-scale cloud*

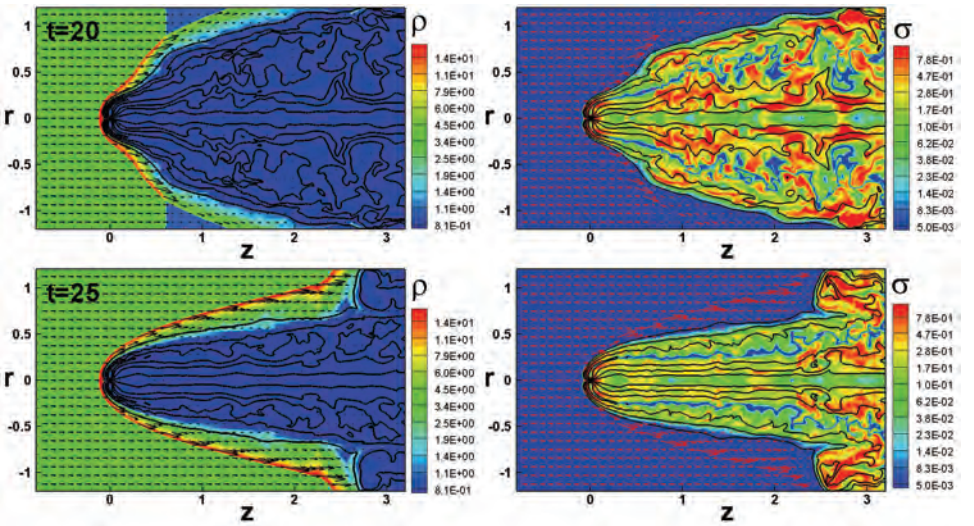

Fig. 3. *Left panels:* Propagation of a PWN of moderate magnetization through a large cloud of density $\rho_{\rm cloud} = 3\rho_0$ at two moments in time. The background represents the logarithm of density. The solid lines are magnetic field lines. *Right panels:* Same, but the background shows magnetization $\sigma$.

Fig. 3 shows an example of propagation of a large cloud of density $\rho_{\rm cloud} = 3\rho_0$ through the PWN in the model with a moderate magnetization. The left panels show that the cloud compresses the bow shock and the bow shock has a smaller opening angle (the Mach cone). The cloud is in pressure balance with the rest of the ISM, so that the sound speed in the cloud is three times lower than in the rest of the ISM. Therefore, the Mach number of the star inside the cloud is $M_{\rm new} = v_p/c_s = 3M_{\rm old} = 60$. This is why we observe a smaller opening angle of the Mach cone. The bottom left panel shows that after entering the cloud, the KH instability develops in the region of CD. This is an expected result: at larger Mach number, there is a larger difference between velocities of matter from two sides of the contact discontinuity. The right panels of Fig. 3 show that the region of high magnetization becomes more narrow after the passage of the cloud. Also,

the region of high magnetization becomes less homogeneous (more patchy) due to the action of the KH instability. These simulations demonstrate that propagation through a large-scale cloud leads to a reconstruction of the magnetic field in space and to change in the value of the magnetic field. The tangled magnetic field may reconnect and the magnetic energy can be converted to the energy of accelerated particles and radiate. This may be a possible reason for the re-brightening of PWN magnetotails observed in X-ray [8].

#### 3.1.1. *Small-scale inhomogeneities*

Our simulations show that the KH instability frequently forms at the CD and produces some wavy structure of the bow shock. However, a wavy structure could also result from the interaction of the bow shock with the small-scale inhomogeneities in the ISM. To model the interaction of the small-scale inhomogeneities with the bow shock, we took models where the KH instability is weak and does not modify the shape of the bow shock.

We model small-scale inhomogeneities as a set of small clouds with Gaussian density distribution, with the maximum density of $\rho_{\max}$ and half-width of $\Delta r = 0.2$. To keep the pressure balance between the clouds and the rest of the ISM, we take the temperature in the cloud to be $T_{\rm cloud} = T_{\rm ISM} * \rho_0/\rho_{\rm cloud}$. We experimented with clouds of different densities, and found that the shape of the bow shock varies significantly if the density in the cloud is $\rho_{\rm cloud} \gtrsim 2\rho_0$. At $\rho_{\rm cloud} = 2\rho_0$, a wavy structure starts to become visible, while at $\rho_{\rm cloud} = 3\rho_0$, the bow shock changes its local shape significantly.

Fig. 4 shows a wavy variation of density in the bow shocks that appears after the propagation of clouds of density $\rho_{\rm cloud} = 3\rho_0$ in the models with low and moderate magnetizations. Such an interaction with small-scale inhomogeneities may explain the wiggles in the shape of the bow shock observed in PSR J0742-2822 (see Fig. 1). In PSR J0742-2822, the estimated stand-off distance is $R_{\rm sd} \approx 4.2 \times 10^{16} d/2{\rm kpc}$ cm. The size of clouds in our model $R_{\rm cl} \approx (2-4)R_{\rm sd} \approx (0.8-1.6) \times 10^{17} d/2{\rm kpc}$ cm. It may correspond to one of scales in turbulent ISM matter. We should note that an alternative explanation of these small-scale features in bow shocks can be connected with the KH instability. Currently, we cannot distinguish between these two mechanisms.

## 4. Conclusions

We performed MHD simulations of the bow shock PWN propagating through a uniform and non-uniform ISM at different levels of magnetization. Our main findings are the following:

**1.** The interaction of the bow shock with a large-scale, dense cloud leads to the compression of the bow shock and the formation of a new bow shock with a smaller opening angle. The level of compression (the ratio between the original

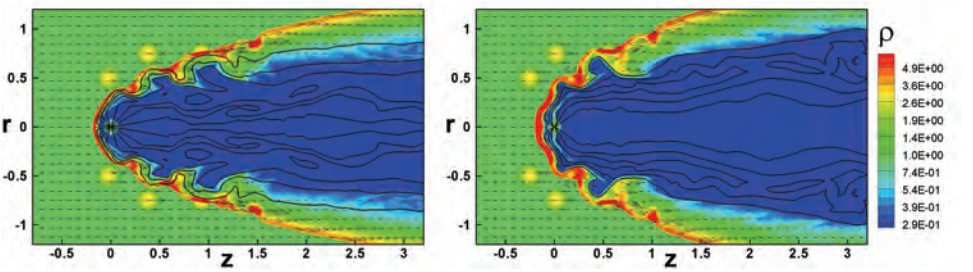

Fig. 4. Interaction of the bow shock with small-scale clouds of maximum density $\rho_{\rm cloud} = 3\rho_0$ in the model with low $\sigma$ (left panel) and in the model with medium $\sigma$ (right panel). The background represents the logarithm of density. The solid lines are magnetic field lines.

and final widths of the bow shock) is approximately the same for PWN of different magnetization.

**2.** The interaction of the bow shock with the small-scale inhomogeneities in the ISM leads to a wavy structure in the bow shock. The amplitude of the "waves" increases with the ratio $\rho_{\rm cloud}/\rho_0$. For example, variation in the shape of the bow shock of pulsar PSR J0742-2822 can be explained by the propagation through a series of clouds with a density ratio of $\rho_{\rm cloud}/\rho_0 \approx 3$. Small-scale clouds produce wavy shapes of the bow shocks in PWN of different magnetization.

# MHD simulation of magnetized laboratory jets

Olga D. Toropina, Gennadiy S. Bisnovatyi-Kogan and Sergey G. Moiseenko

*Space Research Institute, Russian Academy of Sciences*
*Profsoyuznaya 84/32, Moscow 117997, Russia*
** E-mail: toropina@iki.rssi.ru*

We present the results of MHD simulation of the laboratory experiment for creating plasma jets. In the experiment on a NEODIM laser installation the plasma jet is formed as a result of the action of a powerful laser on the target. We simulated plasma flow, we chose a numerical method, boundary and initial conditions. We investigated the picture of the flow and compared it with the experiment.

*Keywords*: MHD; plasma; laboratory jets.

## 1. Introduction

Astrophysical jets are observed at various astronomical scales and are found in active galactic nuclei, quasars, compact objects in binary systems and young stellar objects. The emergence of jets is possible with the explosion of collapsing supernovae. The processes of formation and evolution of astrophysical jets are one of the most interesting problems of astrophysics[1].

The study of astrophysical jets is conducted in two ways: observations in the optical, X-ray and radio bands and multidimensional numerical MHD modeling. A simulation must take into account the entire complex nature of relativistic jets, including the gravitational field and the magnetic field of the central object. Recently, methods of laboratory astrophysics were added to the methods of investigating relativistic jets. They allow to create of plasma jets by the laser and to investigate the structure, evolution, and features of jets in the laboratory conditions.

The equations of magnetic hydrodynamics describing the formation and evolution of jets are nonlinear even in the one-dimensional case. For the theoretical description of the processes occurring in jets, it is necessary to apply methods of multidimensional numerical simulation. Multidimensional numerical calculations make it possible to obtain a detailed picture of the flow of matter in the jet and the shock-wave structure of the flow. Numerical simulation allows calculations to be performed both for initial data corresponding to astrophysical jets, and for a set of parameters from a laboratory experiment.

Laboratory research is conducted by several groups of scientists. Fua, Liang, Tzeferacos and Lamb work on the creation of a magnetized supersonic laboratory jet. They perform numerical simulation of the experiment using the two-dimensional FLASH code[2]. Experiments on laboratory jets were carried out at the Kurchatov Institute on the installation of the plasma focus PF-3 by Krauz at al.[3]. Pikuz at al.[4] presented the results of a laboratory laser experiment and the numerical simulation of a magnetized jet expiring from a young stellar object. The collimated jet in these calculations is obtained due to the presence of a poloidal magnetic field.

## 2. Experiment

The purpose of the study is numerical modeling and analysis of the results of a laboratory experiment simulating the formation of cosmic relativistic plasma jets on the 10 TW picosecond NEODIM laser installation (TsNIIMASH, Korolev, Russia)[7].

The laser unit has the following parameters of the laser pulse: energy up to 10 J, wavelength 1.055 mkm, duration 1.5 ps, laser radiation contrast about $10^7$. The focusing system based on an off-axis parabolic mirror with a focal length of 20 cm provides a concentration of at least 40% of the energy of the laser beam into a 15 $\mu m$ spot and, correspondingly, a peak intensity of $2 \times 10^{18} W/cm^2$.

The laboratory experiment consists of the following: a cylindrical chamber is placed as a target a foil of $Cu$ or $Ta$ with a thickness of 30 $\mu m$ and 50 $\mu m$. On the opposite side are track detectors CR-39. The energy $10\,J = 6.24 \times 10^{19}$ eV is uniformly and instantaneously applied to the central region of the target with a diameter of 10 m. As a result of heating the target, two directional plasma ejections appear in the form of symmetrical jets. In our numerical simulation, only one of them is considered.

In the experiment, clearly distinct ring structures formed on track detectors by protons with energies in the range of $0.8 \div 1.7$ MeV are observed. An example of images of proton beams is shown in Figure 1.

The scale of physical processes in astrophysical jets is very different from those in jets that occur when a laser pulse is applied to a target. However, the application of similarity criteria makes it possible to obtain a correspondence between a number of characteristics of an astrophysical and laboratory jet. The use of such similarity criteria is convenient both for direct comparison of laboratory and observational data, and for multidimensional numerical simulation. As a result of scaling, we get a satisfactory similarity of a number of jets parameters expiring from the young stars and the jet obtained on the NEODIM laser installation. A detailed description of the similarity criteria and scaling can be found in our recent papers[5,6].

## 3. Numerical model

We did not consider the processes of laser heating, melting, and evaporation of the target material in detail during the simulation. A considerable amount of work has been devoted to the study of laser ablation processes, for example, Mazhukin et al.[8] We believe that the ablation process has already happened, the substance has evaporated from the surface of the target and is taken into account in determining the initial and boundary conditions. For numerical simulation of the experiment, the system of magnetohydrodynamics equations[9] was used. In the future, to more accurately describe the processes occurring with the target material as a result of high-power laser irradiation, it seems necessary to combine MHD and the kinetic approach. But at the initial stage of modeling, we can confine ourselves to the system of MHD equations.

We take into account an external poloidal magnetic field directed along the normal to the plate. Simulations were carried out for different values of the magnetic field. The emission from the plasma target was simulated under the influence of laser radiation. A single-component plasma flow was studied - the region and shape of the flow at various distances from the target and at different times, the distribution of plasma density, energy, and the magnetic field. The analysis of the experiment showed that the formation of the jet is associated with the heating of the plate, and the geometry of the incident laser beam is irrelevant. The model of jet formation in the experiment can be constructed in axisymmetric approximation, assuming that the spot heated by the laser has the form of a circle. An inertial cylindrical coordinate system $(r, \phi, z)$ is used. The problem assumes axial symmetry in the distribution of all the macroscopic quantities $\rho$, $T$, $v$, $H$, $\partial/\partial\phi = 0$, but all components of the velocity $v$ and magnetic fields $H$ are calculated. The target (the central region of the plate to which the energy is applied) is a cylinder of radius $R_d$, of thickness $Z_d$. The scheme of the modeling domain is shown in Figure 2.

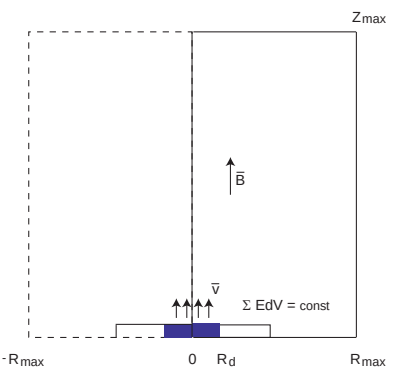

Fig. 2. Simulation region

We use an axisymmetric, resistive MHD code. The code incorporates the methods of local iterations and flux-corrected-transport developed by Zhukov, Zabrodin, Feodoritova[10]. The flow is described by the resistive MHD equations[9]:

$$\frac{\partial \rho}{\partial t} + \nabla\cdot(\rho\ \mathbf{v}) = 0\ , \tag{1}$$

$$\rho\frac{\partial \mathbf{v}}{\partial t} + \rho(\mathbf{v}\cdot\nabla)\mathbf{v} = -\nabla p + \frac{1}{c}\mathbf{J}\times\mathbf{H} \tag{2}$$

$$\frac{\partial \mathbf{H}}{\partial t} = \nabla\times(\mathbf{v}\times\mathbf{H}) + \frac{c^2}{4\pi\sigma}\nabla^2\mathbf{H}\ , \tag{3}$$

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \nabla\cdot(\rho\varepsilon\mathbf{v}) = -p\nabla\cdot\mathbf{v} + \frac{\mathbf{J}^2}{\sigma}\ , \tag{4}$$

$$\frac{4\pi}{c}\mathbf{J} = \nabla\times\mathbf{H}\ . \tag{5}$$

The magnetic field is the poloidal field ($H_z$, $H_r$). In order to fulfill exactly the condition $\nabla\cdot\mathbf{H} = 0$, in the calculations instead of the poloidal component of the magnetic field strength $H_z$ and $H_r$, the toroidal component $A_\phi$ vector potential $\mathbf{A}$ is used, $\mathbf{H} = \nabla\times\mathbf{A}$.

We use a set of characteristic dimensionless parameters. First parameter $\beta = 8\pi P_{0jet}/H_0^2$ determines the relation between the characteristic values of the pressure of the matter $P_{0jet}$ and the pressure of the magnetic field. The second parameter of the numerical model is the characteristic dimensionless magnetic viscosity $\tilde{\eta}_M = \eta_M/L_0V_{A0}$ , where $\sigma$ is the constant effective conductivity of the plasma; $L_0$ is the characteristic size and $V_{A0}$ is the characteristic Alfven velocity.

A detailed description of the numerical model, boundary and initial conditions can be found in our recent papers[5,6].

## 4. Results of numerical simulation

We performed MHD simulation of the laboratory experiment for creating plasma jets taking into account the constant poloidal magnetic field directed along the normal to the target $H$. We performed a series of calculations for different values of the parameter $\beta$. The characteristic parameters for demonstrated case are: $\beta = 10^{-1}$ and $\tilde{\eta}_M = 10^{-5}$

The initial density of matter in the whole calculation region, with the exception of the target, is homogeneous and has a small value: $\rho = \rho_0$. The initial velocity of the substance in the calculation region, with the exception of the target, is zero $v_z = v_r = 0$. The substance has no angular momentum, $v_\phi = 0$. In the target region $0 \le r \le R_d$, $0 \le z \le Z_d$, the density $\rho \approx 300\rho_0$ and the supersonic velocity of the particles emitted from the target $v \ge c_s$ are set, here $c_s = \sqrt{\gamma\frac{P_0}{\rho_0}}$ is the sound

speed in the unperturbed region. For simplicity of test calculations, the velocity of the emitted matter at the initial instant of time has only the z-component $v_z$; $v_r = 0$. The magnetic field is defined as follows: $A_\phi = rH$, $A_r = 0$, $A_z = 0$, $H_\phi = 0$.

The results of modeling the release of matter for this case are shown in Figure 3. The color background corresponds to the logarithm of the density, the arrows indicate the velocity vectors, the length of the arrow is proportional to the velocity value. Solid lines represent magnetic field lines. It can be seen that the target substance under the action of the thermal energy of the laser begins to fly along the axis $Z$ to the opposite wall of the chamber. After the release of matter it begins to expand in all directions, but then the flow is collimated by a magnetic field. The influence of the external gas on the collimation of the flow in this case is insignificant. Inside the flow, a shock wave is formed at a distance of $z \approx 1.6$.

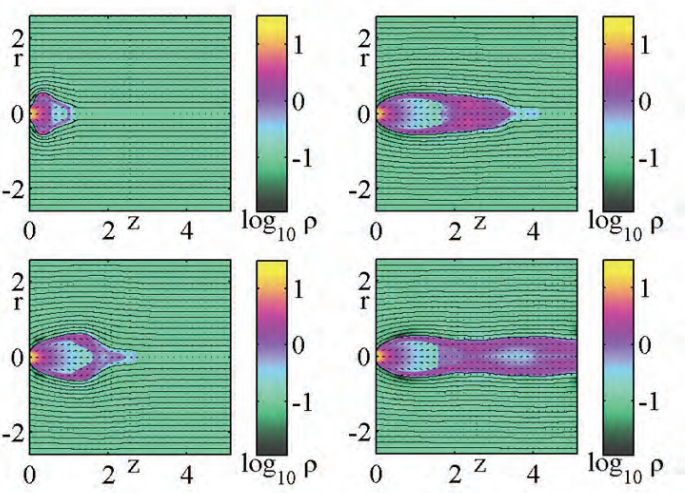

Fig. 3. Picture of the matter flow for MHD case $\beta = 10^{-1}$ at different moments.

We can see from the simulations that near the detector a cavity is formed. It is bounded by a shock wave. The size of the cavity depends on the magnitude of the magnetic field H. Similar results were obtained in work Albertazzi B. et al.[4].

This leads to the formation of ring structures, which are observed in the experiment. Figure 4 is shown the angle of these structures depends on the magnitude of the magnetic field. With a weak field (and also with its absence), this angle is large (left figure). With an increase in the field, the dimension of the cavity and, accordingly, the angle of the ring structure decreases, and then a solid spot is observed instead of the ring (right figure).

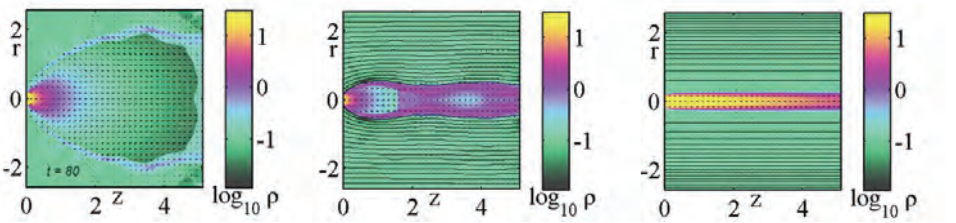

Fig. 4. Picture of the matter flow for HD case and MHD cases $\beta = 10^{-1}$ and $\beta = 10^{-3}$

## 5. Conclusions

The paper presents the results of numerical simulation of magnetized supersonic jets. Formation and development of jet in a laboratory laser experiment is a complex physical phenomenon involving a large number of different physical processes. Numerical simulation of such an experiment, allowing to account for all possible physical processes, is a complex problem and is currently difficult to implement. We used the approximation of magnetohydrodynamics, as the first step in the study of this problem.

We study a thin warped accretion disk around a spinning black hole in the viscous regime (i.e., $\alpha > H/R$; $\alpha$ is the Shakura-Sunyaev viscosity parameter, $H$ is the disk thickness and $R$ is the radial distance), and calculate the steady state radial profile of the disk tilt angle for a wide range of relevant parameters of the system (like the Kerr parameter of the black hole). Although the inner part of such a disk was proposed to become aligned with the spin direction of the black hole by the Bardeen-Petterson effect, we show that for a reasonable range of the parameters of the system, the inner disk can stay significantly tilted with respect to the black hole spin. A tilt in the inner accretion disk can affect the observed X-ray spectral and timing features, and hence it makes the inner accretion disk particularly useful for probing the strong gravity region.

*Keywords*: Accretion disks; Black hole physics; Relativistic processes; X-ray binaries.

## 1. Introduction

Accretion disks around spinning black holes are sometimes found to be warped, i.e., disks with changing orbital planes with the radius. For example, warped disks around spinning black holes were predicted for the AGN NGC 4258[1], the X-ray binaries SS433[2] and GRO J1655-40[3]. When there is a non-axisymmetric force, like the Lense-Thirring (LT) precession[4] induced by a misaligned black hole, acting on the disk, a warp is usually generated. Bardeen and Petterson[5] developed the theory of a thin warped disk around a Kerr black hole and showed that the inner part of the disk aligns itself with the spin direction of the black hole by the LT precession. This is known as the Bardeen-Petterson effect. As the LT torque falls off roughly as $1/R^3$ ($R$ is the radial distance), the outer part of the disk remains misaligned[5]. In between these two regions, the disk orients itself from the aligned inner part to the misaligned outer part creating a warped region in the disk. Although several inconsistencies[6] were found in their calculations, the inner part of the thin warped disk was mostly considered to be aligned with the black hole spin direction up to a certain radius, $R_w$ [7–10]. However, recently X-ray spectral and timing features of the Galactic accreting black hole H1743–322[11] has indicated that the inner disk could be tilted. On the theoretical side, Lodato and Pringle[12] found a possibility of tilt in the inner disk in their numerical investigation of a warped thin disk around a spinning black hole.

In this work[13], we revisit the case of a thin viscous warped disk around a Kerr black hole, and study the steady state behavior of the entire disk as a function of the relevant parameters of the astrophysical system. We take into account the contribution of the inner disk, which was mostly ignored in the past due to the alignment of the inner accretion disk, and explore the possibility of a tilt in the inner accretion disk by scanning over a wide range of the parameter space.

## 2. Warped accretion disk around a Kerr Black Hole in Steady State: Formalism

In this work[13], we consider an astrophysical system composed of a slowly rotating Kerr black hole (of mass $M$ and spin $a$) at the center, and a geometrically thin (disk aspect ratio $H/R << 1$, $H$ is the disk thickness and $R$ is the radial distance from the centre) and Keplerian accretion disk around the black hole. The spin of the black hole is directed along the z-axis in our coordinate system. The accretion disk far from the center is slightly tilted with respect to the spin axis of the black hole. We assume the disk to be sufficiently viscous, i.e., $\alpha > H/R$ such that the warp is transmitted diffusively in the disk[6]. Thus, the angular momentum density conservation equation on each annulus of the disk subjected to viscous and LT torques in steady state can be shown to be given by[7]

$$\frac{1}{R}\frac{\partial}{\partial R}\left[\left(\frac{3R}{L}\frac{\partial}{\partial R}\left(\nu_1 L\right)-\frac{3}{2}\nu_1\right)\mathbf{L}+\frac{1}{2}\nu_2 RL\frac{\partial \mathbf{l}}{\partial R}\right]+\frac{\boldsymbol{\omega}_p\times\mathbf{L}}{R^3}=0, \tag{1}$$

where $\mathbf{L}=\sqrt{GMR}\Sigma(R)\mathbf{l}$ is the angular momentum density vector, $\nu_1$ and $\nu_2$ are the kinematic viscosities acting along the plane (horizontal) of the disc and normal (vertical) to the disc respectively, $\omega_p/R^3$ is the LT precession frequency or nodal precession frequency with $\omega_p = 2GJ/c^2$ ($J$ is the total angular momentum of the black hole, $G$ is the gravitational constant and $c$ is the speed of light in vacuum), $\mathbf{l} \simeq (l_x, l_y, 1)$ is the unit tilt vector in the direction of angular momentum density and $\Sigma$ is the surface density of the disk. Here, $\nu_1$ is the usual Shakura-Sunyaev viscosity[14], and $\nu_2$ can be shown to be related to $\nu_1$ and $\alpha$ for small amplitude warp in the following way[15]

$$\frac{\nu_2}{\nu_1}=\frac{1}{2\alpha^2}.\frac{4(1+7\alpha^2)}{4+\alpha^2}. \tag{2}$$

We assume these two viscosities to be constant in the disk.

The modulus of steady state angular momentum density vector can be obtained by taking the scalar product of $\mathbf{l}$ with the equation (1). This gives[7,13]

$$L(R)=C_2R^{1/2}-2C_1, \tag{3}$$

where $C_1$ and $C_2$ are the integration constants. The expression of these two constants can be obtained by using the boundary conditions, $\Sigma(R_{\rm in}) = \Sigma_{\rm in}$ (where $R_{\rm in}$ is the ISCO radius, $R_{\rm ISC0}$, for a Kerr black hole), and $\Sigma \to \infty$ as $R \to \infty$. One obtains the following expressions upon using the above mentioned boundary

conditions[13]

$$C_2 = \sqrt{GM}\Sigma_\infty, \tag{4}$$

and

$$C_1 = \frac{1}{2}\sqrt{GMR_{\rm in}}\left(\Sigma_\infty - \Sigma_{\rm in}\right). \tag{5}$$

One finally arrives at the warped disk equations[13] under the influence of LT precession around a spinning black hole by substituting the expression of L (equation (3)) into equation (1)

$$\frac{\partial}{\partial R}\left(3\nu_1 C_1 l_x + \frac{1}{2}\nu_2 RL\frac{\partial l_x}{\partial R}\right) = \omega_p \frac{L}{R^2} l_y, \tag{6}$$

and

$$\frac{\partial}{\partial R}\left(3\nu_1 C_1 l_y + \frac{1}{2}\nu_2 RL\frac{\partial l_y}{\partial R}\right) = -\omega_p \frac{L}{R^2} l_x, \tag{7}$$

where $\boldsymbol{\omega}_p \times \mathbf{l} = (-\omega_p l_y, \omega_p l_x, 0)$ in our construction. The above two equations can also be combined in the following way[7,13]

$$\frac{\partial}{\partial R}\left(3\nu_1 C_1 W + \frac{1}{2}\nu_2 RL\frac{\partial W}{\partial R}\right) = -i\omega_p \frac{L}{R^2} W, \tag{8}$$

where $W = l_x + il_y = \beta e^{i\gamma}$. Here, $\beta = \sqrt{l_x^2 + l_y^2}$ and $\gamma = \tan^{-1}(l_y/l_x)$ are the tilt and twist angles respectively. We would use the following boundary conditions for solving the equations[13] (6,7)

$$l_x(R_{\rm in}) = \beta_i \cos(\gamma_i),\ l_y(R_{\rm in}) = \beta_i \sin(\gamma_i), \tag{9}$$

and

$$l_x(R_f) = \beta_f,\ l_y(R_f) = 0, \tag{10}$$

where $\gamma_i$, $\beta_i$, $R_f$ and $\beta_f$ are the twist angle at the inner boundary, the tilt angle at the inner edge, the outer edge radius and the outer edge tilt angle, respectively. The twist angle at the outer edge can be assumed to be zero as far from the black hole the effect of LT precession is negligibly small. Thus, $l_y$ becomes zero at the outer edge (see the definition of $l_y$ below equation (8)). This above boundary conditions can be shown to generate non-zero viscous torques at the inner edge[13].

As the inner part of a warped accretion disk was mostly assumed to be aligned with the black hole spin due to the BP effect, the contribution of the inner disk was ignored. Hence the terms associated with $C_1$ in the warped disk equations (6,7) were dropped as $C_1$ is related to the inner disk. In this work[13], we numerically solve the full warped disk equation(s) (6,7) with considering the effect of the terms associated with $C_1$ and the general boundary conditions in order to obtain the radial profile of disk tilt angle as a function of the parameters of the system. Since, our analysis is valid for the entire disk, we explore the behavior of the inner disk for different ranges of the relevant parameters (like the Kerr parameter $a$, $\nu_2$ and $\beta_{\rm in}$), and study how the inner disk alignment depends on these parameters.

## 3. Results and Discussion

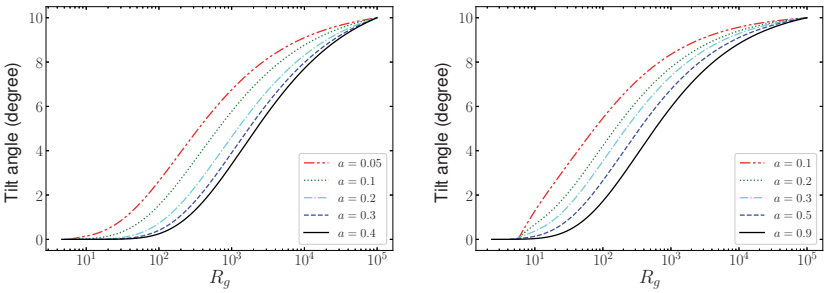

Fig. 1. Radial profiles of the disk tilt angle for different values of the Kerr parameter $a$ for the viscosities $\nu_2 = 10^{14}$ cm$^2$ $s^{-1}$ (Left panel) and $\nu_2 = 10^{15}$ cm$^2$ $s^{-1}$ (Right panel). Here, $R_g = GM/c^2$.

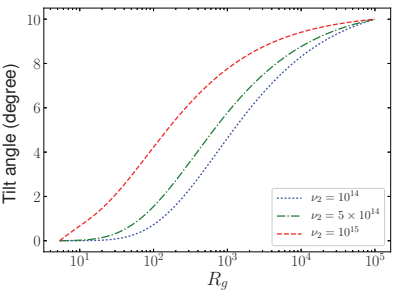

Fig. 2. Radial profiles of the disk tilt angle for different values of $\nu_2$ for the Kerr parameter $a = 0.2$. The viscosity values in the panel are given in cm$^2$ $s^{-1}$. Here, $R_g = GM/c^2$.

We investigate in detail the behavior of the radial profile of the disk tilt angle for a wide range of parameters $a$, $\nu_2$ (or $\nu_1$ and $\alpha$; see equation (2)) and the disk inner edge tilt angle $\beta_i$, and also pay close attention to how the inner disk responds to the changes in those parameters. For the purpose of demonstration, we choose the black hole mass $M = 10M_\odot$, i.e., a typical value of mass of a black hole in Galactic X-ray binaries[16], viscosity $\nu_2$ in the range[17] $10^{14} - 10^{15}$ cm$^2$ s$^{-1}$ and $\alpha = 0.15$[3]. We set the inner edge twist angle and the ratio between outer edge and inner edge surface densities to $\gamma_i = 1^\circ$ and $z_{\rm in} = 0.75$ respectively. Since, we are considering a slightly tilted disk, we set the outer edge disk tilt angle to $10^\circ$. Also, we consider only the case of prograde rotation in this work.

We see from the Fig.1 that as the Kerr parameter takes a higher value, the angle between the inner disk angular momentum vector and the black hole spin falls as the LT torque, being proportional to $a$, becomes more dominant for the fixed values

of the other parameters. But the viscous torque on the plane of the disk ($\nu_2$ is associated with this torque) hinders the process of reduction of tilt angle in the inner disk (see Fig.2), and hence a higher value of $\nu_2$ reduces the dominance of the LT torque in the inner disk (Fig.2). Thus, the alignment of the inner disk is determined by the interplay between the LT torque and the viscous torque on the plane, and their relative strength decides for what values of the Kerr parameter the disk will be aligned with the black hole spin for a given value of $\nu_2$. We see from the Fig.1 that for $\nu_2 = 10^{14}$ cm$^2$ $s^{-1}$, the inner disk alignment occurs if $a \gtrsim 0.3$[13], where for $\nu_2 = 10^{15}$ cm$^2$ $s^{-1}$ the alignment happens when $a \gtrsim 0.8$[13]. The radius up to which the disk is aligned was earlier approximated by the warp radius[3,7,10,12], $R_w = \omega_p/\nu_2$, and this warp radius is defined as the distance at which the warp diffusion time-scale ($R^2/\nu_2$) equals the LT precession time-scale ($R^3/\omega_p$). But, in reality the disk can stay significantly tilted at the warp radius (see Fig.3), and the tilt angle at $R_w$ is roughly 0.13 times the tilt angle at the outer edge[7]. In this work, we find that the alignment radius, i.e., the radius up to which the tilt angle is less than 0.01°, can be approximated by 0.094 $R_w$[13].

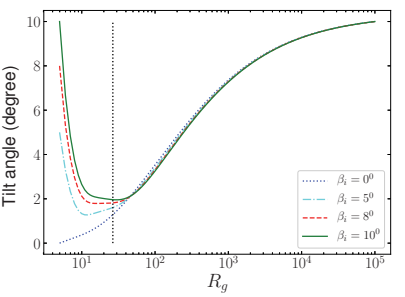

Fig. 3. Radial profiles of the disk tilt angle for different values of the disk inner edge tilt angle $\beta_i$. The other parameter values are $a = 0.3$, $M = 10M_\odot$, $\nu_2 = 10^{15}$ cm$^2$ $s^{-1}$. The vertical line refers to the warp radius as estimated by the relation $\omega_p/\nu_2$. This figure exhibits the dip feature, and also there is a nonzero tilt at the inner disk for all the values of $\beta_i$. Here, $R_g = GM/c^2$.

We have so far set the inner edge tilt angle to zero. Now we explore how different values of the inner edge tilt angle affect the radial profile of the disk tilt angle. Taking a nonzero disk inner edge tilt angle makes the LT torque more dominant near the inner edge. Thus, the more one increases $\beta_i$, the LT torque near the inner edge increases the more, and thus the mismatch between the black hole spin and the angular momentum vector near the inner edge is reduced more rapidly (see Fig.3). But the LT torque may not be reduce the inner disk tilt angle to zero as the viscous torque on the plane inhibits this process. Also after a certain value of radial distance, the LT torque becomes weak and the viscous torque on the plane of the disk takes over the control producing a dip in the radial profile of the disk tilt angle.

## 4. Conclusion

In our work[13], we solve the full prograde thin warped disk equation in the viscous regime in steady state, and obtain the radial profile of the disk tilt angle as a function of various parameters of the system. We take into account the contribution of the inner disk which was ignored in most earlier works, and also consider physically relevant boundary conditions for solving the the warped disk equation(s) (6,7). We find that the relative dominance between the LT torque and viscous torque on the plane of the disk decides the alignment of the inner disk. Thus, there exists a critical value of the Kerr parameter depending upon $M$ and $\nu_2$ beyond which the BP alignment switches on. As a tilt in the inner disk can have observational implication on the timing and spectral features of X-ray emanating from the disk, our analysis may be useful for studying the region close to the black hole.

We discuss the effects of electric charging on the equilibrium configurations of magnetized, rotating fluid tori around black holes of different mass. In the context of gaseous/dusty tori in galactic nuclei, the central black hole dominates the gravitational field and it remains electrically neutral, while the surrounding material acquires some electric charge that can separate in space and exhibit non-negligible self-gravitational effects. The structure of the torus is thus influenced by the balance between the gravitational and electromagnetic forces. A cusp can develop near the inner rim even in Newtonian tori due to the charge distribution. Furthermore, it is interesting to note that stable polar clouds can emerge near the rotation axis in reminiscence of "lamppost" scenario. For the latter, an appropriate distribution of the angular momentum and electric charge are essential.

*Keywords*: Gravitation; Black Holes; Accretion; Magnetic fields

## 1. Introduction

Within the framework of General Relativity, black holes are fully described by a small number of parameters[1]. The most relevant from the viewpoint of astrophysical applications are the mass of the black hole, $M_\bullet$, and angular momentum $J_\bullet$ or, in a dimension-less form, the spin parameter $a^* \equiv a/M_\bullet = J_\bullet c/GM_\bullet^2$. The classical black-hole solution of Kerr-Newmann can be equipped by electric charge, although any significant value appears to be astrophysically unlikely over an extended duration because of continued process of neutralization by a selective charge accretion from the surrounding plasma into any cosmic black holes must be embedded.

The Kerr-Newman solution the line element adopts the form adopts the form[2]

$$ds^2 = -\frac{\Delta}{\Sigma}\left(dt - a\sin\theta d\phi\right)^2 + \frac{\Sigma}{\Delta}dr^2 + \Sigma d\theta^2 + \frac{\sin^2\theta}{\Sigma}\left[\left(r^2+a^2\right)d\phi - adt\right]^2, \quad (1)$$

in dimensionless Boyer-Linquist coordinates $(t, r, \phi, \theta)$, where $\Delta(r) = r^2 - 2r + a^2 + e^2$ and $\Sigma(r, \theta) = r^2 + a^2 \sin^2 \theta$. Quantities $a$ and $e$ are the rotational and charge parameters of the spacetimes. The associated non-zero components of the antisymmetric electromagnetic field tensor $F_{ij} = A_{j,i} - A_{i,j}$ are

$$F_{rt} = \frac{e(r^2 - a^2 \cos^2 \theta)}{\Sigma^2}, \qquad F_{r\phi} = \frac{-ae \sin^2 \theta (r^2 - a^2 \cos^2 \theta)}{\Sigma^2}, \tag{2}$$

$$F_{\theta t} = \frac{-a^2 er \sin 2\theta}{\Sigma^2}, \qquad F_{\theta\phi} = \frac{aer \sin 2\theta (r^2 + a^2)}{\Sigma^2}. \tag{3}$$

The effective potential $W(r, \theta)$ for the motion of a particle with the specific charge $\tilde{q} = q/m$ satisfies the relation

$$XW = Y + \sqrt{Y^2 - XZ}, \tag{4}$$

where the functions $X(r, \theta) = (r^2 + a^2)^2 - \Delta a^2 \sin^2 \theta$, $Y(r, \theta) = (\tilde{L}a + \tilde{q}er)(r^2 + a^2) - \tilde{L}a\Delta$, and $Z(r, \theta) = (\tilde{L}a + \tilde{q}er)^2 - \Delta\Sigma - \Delta\tilde{L}^2/\sin^2 \theta$; here, $\tilde{L} = L/m$ is the conserved axial component of specific angular momentum. The effective potential (4) develops local minima outside the equatorial plane $\theta = \pi/2$, which suggests the possibility of halo orbits.[a] The minima occur provided that the electric charge of the accreted matter is non-zero and interacts with the global magnetic field of the central object and/or of the external origin due to currents flowing outside the horizon.

In the other words, the stable configuration allows for a distribution of charged matter near the equator, in lobes located symmetrically above and below the equatorial plane, or even around the polar axis (see Fig. 1). This represents general-relativistic version of Störmer's halo orbits that have been explored in connection with the motion of electrically charged dust grains in planetary magnetospheres.[5] In the case of Kerr-Newman solution, it can be found that the particular form of mutually connected gravitational and electromagnetic fields do not allow existence of stable halo orbits above the outer horizon; an additional external magnetic field is required.

The prevailing process of neutralization, however, may not prevent the surrounding material to undergo electric charging in the environment of complex plasma that is irradiated by energetic X-rays, as is often the case in active galactic nuclei. This mechanism leads to charge separation within the dusty tori. Therefore, we have proposed the process of charging as mechanism that can maintain geometrical thickness of the dusty tori in the vertical direction.[6]

Furthermore, the existence of mutually detached regions (lobes) of bound stable orbits can provide a framework to trigger oscillations; it allows us to imagine a situation when the bulk motion along the circular trajectories is superposed by

[a] Within the particle approximation the halo orbits are formed by stable bound trajectories which do not cross the equator. In the fluid analogy they correspond to toroidal structures with the pressure maxima at $\theta \neq \pi/2$ (i.e. $z \neq 0$).[3,4]

a fraction o material that performs oscillatory motion between the disconnected lobes. Halo orbits could have outstanding consequences for the radiation signal from accreting black holes. On the other hand, general relativity effects have a tendency to bring the halo orbits closer to the equatorial plane compared to corresponding Newtonian solutions. Also, to ensure the intrinsic self-consistency of the model we need to include self-gravity of the medium in the consideration, as this can further diminish the vertical thickness of the figures of equilibrium of electrically charged fluid.[8,9,11,12]

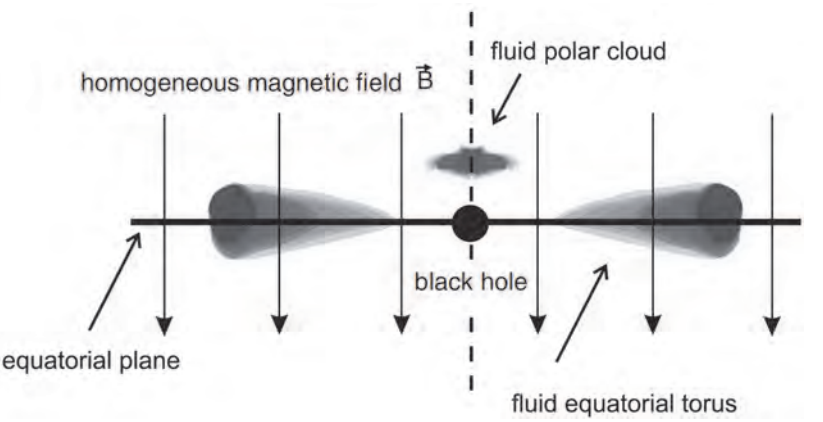

Fig. 1. A black hole is immersed in asymptotically homogeneous magnetic field $\vec{B}$ and encircled by a torus-like equatorial fluid configuration, and an off-equatorial polar cloud. The charge distribution within the fluid interacts with the magnetic field and helps to levitate the fluid above the equatorial plane. Similar effect occurs for trajectories of electrically charged particles. Regions of stability can emerge near the equatorial plane as well as near the polar axis, depending on the angular momentum and electric charge distribution within the fluid.[6–8]

## 2. Electrically charged tori near a magnetized black hole

We describe the fluid by polytropic equation of state, $p = \kappa\rho^{\Gamma}$, with $\kappa$ and $\Gamma$ being parameters of the polytrope. This relation ensures conservation of entropy, as is appropriate for a perfect fluid. Neglecting the electrostatic corrections to the equation of state we can use the polytropic equation consistently even to described an electrically charged state. In the case of sufficiently small $\rho$ the medium is non-relativistic and the contribution of the specific internal energy $\epsilon/\rho - 1$ to the total energy density becomes negligible (i.e., $\epsilon \approx \rho$), however, this assumption is not accurate enough once the density increases; in such a case the self-electromagnetic field cannot be ignored.

The configuration of the fluid is determined by its rotation in the $\phi$-direction with 4-velocity $U^{\alpha} = (U^t, U^{\phi}, 0, 0)$, specific angular momentum $\ell = -U_{\phi}/U_t$ and

angular velocity $\omega = U^\phi/U^t$. These are related by

$$\omega = -\frac{\ell g_{tt} + g_{t\phi}}{\ell g_{t\phi} + g_{\phi\phi}}, \quad (U_t)^2 = \frac{g_{t\phi}^2 - g_{tt} g_{\phi\phi}}{\ell^2 g_{tt} + 2\ell g_{t\phi} + g_{\phi\phi}}. \tag{5}$$

The shape of a charged fluid torus with a charge density profile $q$ and energy density $\epsilon$ is determined by isobaric surfaces of the pressure $p$ profile (equi-pressure surfaces), which can be derived from the conservation equation

$$\nabla_\beta T^{\alpha\beta} = F^{\alpha\beta} J_\beta, \tag{6}$$

where $J^\alpha$ is the fluid 4-current density and $T^{\alpha\beta}$ is the stress-energy tensor,

$$T^{\alpha\beta} = (\epsilon + p) U^\alpha U^\beta + p g^{\alpha\beta}. \tag{7}$$

From the above-given relation two partial differential equations follow for the radial and latitudinal distribution of pressure,

$$\frac{\partial p}{\partial r} = -(p+\epsilon)\mathcal{R}_1 + q\mathcal{R}_2 \equiv \mathcal{R}_0, \quad \frac{\partial p}{\partial \theta} = -(p+\epsilon)\mathcal{T}_1 + q\mathcal{T}_2 \equiv \mathcal{T}_0, \tag{8}$$

where $\mathcal{R}_0 = \mathcal{R}_0(r,\theta)$ and $\mathcal{T}_0 = \mathcal{T}_0(r,\theta)$ denote the right hand sides of the two latter equations.[6]

As a specific example of the imposed electromagnetic field we can write the static case of an asymptotically uniform magnetic field with intensity $B$. Such settings can be described by the special case (zero rotational parameter) of Wald's test-field solution of Einstein-Maxwell equations, which in dimensionless units reads

$$A_t = -\frac{e}{r}, \quad A_\phi = \tfrac{1}{2} B r^2 \sin^2\theta, \tag{9}$$

describing the electromagnetic field in the background of Schwarzschild geometry. A generalization of the adopted approach to the case of a rotating (Kerr) black hole is straightforward but technically more complicated and beyond the limited space of the present contribution.

## 3. Conclusions

We further explored off-equatorial configurations of electrically charged fluid near magnetized black holes. By comparison with previous works we showed that the conditions of existence of these configurations are diverse and they can be established in varied circumstances during the black hole accretion. By the mass-scaling paradigm for cosmic black-hole sources, similar effects can occur also in the context of stellar-mass black holes, where a massive torus can form as a remnant of a tidally disrupted companion.

Furthermore, electrically charged particles and fluid elements can be set on escaping trajectories and eventually released at a relativistic outflow velocity escaping from the atmosphere of the otherwise stable configuration. The case of charged particles differs from charged dust grains by their charge-to-mass ratio, but the acceleration mechanism operates in a similar manner.[10]

Let us conclude by emphasising the fact that electrically charged toroidal structures can adopt varied shapes from the rich topological family. They exist not only in the equatorial plane as a single torus, but also as two tori coupled and joint through a cusp, existing individually even out of the equatorial plane (as a pair of off-equatorial tori), or just around the polar axis (as a kind of realisation of the lamp-post model). Here adopted the fluid description; in the limit of very low-density the approach of kinetic theory turns out to be better suited.[13]

We discuss numerical method based on Implicit completely conservative Lagrangian operator-difference scheme on triangular grid of variable structure. The method was successfully applied for the simulations of magnetorotational supernova explosion.

*Keywords*: magnetohydrodynamics, supernovae, numerical methods.

## 1. Introduction

The numerical simulations is one of the important tools for study astrophysical problems. A number of astrophysical problems can be simulated by numerical solution of the magnetohydrodynamical(MHD) equations. There lot of different numerical approaches for the simulation of MHD equations. Many astrophysical problems are charactrised by huge variety of spatial and temporal parameters. Application of In this paper we consider the completely conservative Lagrangian operator-difference scheme on a triangular grid of variable structure suggested in ([1,2]).

Lagrangian numerical schemes are free of the artificial transfer of angular momentum, but in the case when in the flow there are nonuniform contraction or expansion, vortexes or shear flows the Lagrangian cells become flattened soon after the beginning of the simulations, thus significantly reducing the accuracy of calculations and preventing continuing the simulations. In such situation the grid remapping allows to overcome this drawback of Lagrangian schemes.

## 2. Completely conservative operator-difference method on a triangular grid of variable structure

The operator-difference scheme used in our simulation is a first-order implicit conservative Lagrangian scheme on an irregular triangular grid. For further details of the scheme, see[1,2]. We briefly describe the idea of the method for 2D cylindrical coordinates case. Define in the computational domain $\Omega$ a triangular grid $\omega = \omega_\times + \omega_\triangle$, which consists of a set of knots $\omega_\times$ and a set of triangular cells $\omega_\triangle$; define in particular the set of boundary knots $\omega_\gamma$. Introduce linear spaces $B_{\times,1}\,(B_{\gamma,1})$ of the vector functions defined in the knots ( boundary knots) $\overline{x}_j \in \omega_\times\,(\overline{x}_q \in \omega_\gamma)$ and

linear spaces $B^0_{\triangle,0}$ ($B_{\gamma,0}$) of scalar functions defined in the cells (boundary knots) $\triangle_i \in \omega_\triangle$ ($\overline{x}_q \in \omega_\gamma$). Introduce also the linear space $B_{\triangle,0}$ of scalar functions defined in the cells and boundary knots. The following relation is valid for the introduced spaces: $B_{\triangle,0} = B^0_{\triangle,0} \oplus B_{\gamma,0}$.

Define linear operators ${\nabla_\times}^0$, $\nabla_\triangle \cdot$ and $\Phi_\gamma$ in the following form:

$$\left(\nabla_\triangle \cdot \mathbf{v}\right)_i = \frac{1}{3V_i}\sum_{l=1}^{3} N_{l,l+1}(\mathbf{v}_l R_{l,l+1} + \mathbf{v}_{l+1} R_{l+1,l}), \tag{1}$$

$$\mathbf{v} \in B_{\times,1},\ \triangle_i \in \omega_\triangle. \tag{2}$$

$$\left({\nabla_\times}^0 p\right)_j = \frac{1}{3V_j}\sum_{k=1}^{K_j} {N_k}' p_k, \quad p \in B^0_{\triangle,0},\ \overline{x}_j \in \omega_\times. \tag{3}$$

$$(\Phi_j p)_q = \frac{1}{3V_q} N'_q p_q, \quad p \in B_{\gamma,0},\ \overline{x}_q \in \omega_\gamma, \tag{4}$$

where $R_{j_1,j_2} = r_{j\,1} + r_{j\,2}/2$,

$$N_{j_1,j_2} = \begin{pmatrix} z_{j\,2} - z_{j\,1} \\ r_{j\,1} - r_{j\,2} \end{pmatrix} \text{ is a normal vector to the segment} [x_{j\,1}, x_{j\,2}], \tag{5}$$

$${N_k}' = -(N_{j,k} R_{j,k} + N_{j,k+1} R_{j,k+1}),\ {N_q}' = (N_{q,q+1} R_{q,q+1} + N_{q-1,q} R_{q,q-1}). \tag{6}$$

Introduce also the grid operator $\nabla_\times$ in the following form: $\forall \tilde{p} = p + p_\gamma \in B_{\triangle,0}, \quad p \in B^0_{\triangle,0}, \quad p_\gamma \in B_{\gamma,0}$ :

$$\nabla_\times \tilde{p} = \begin{cases} {\nabla_\times}^0 p + \Phi_\gamma p_\gamma, & \overline{x}_j \in \omega_\times, \\ {\nabla_\times}^0 p, & \overline{x}_j \in \omega_\times \backslash \omega_\gamma. \end{cases} \tag{7}$$

The operator $\nabla_\triangle \cdot$ is a grid analog for the differential operator div , $\nabla_\times$ is a grid analog for grad. The following relation is valid for the introduced operators:

$$(\nabla_\times p, \mathbf{v})_\times + (\nabla_\triangle \cdot \mathbf{v}, p)_\triangle = (\Phi_\gamma p_\gamma, \mathbf{u}_\gamma)_\gamma. \tag{8}$$

where $p \in B^0_{\triangle,0}$, $\mathbf{v} \in B_{\times,1}$, $p_\gamma \in B_{\gamma,0}$, $\mathbf{v}_\gamma \in B_{\gamma,1}$.

The grid linear operators $\nabla^0_\times \cdot$, $\nabla_\triangle$, $\Phi_\gamma \cdot$ are defined analogously to (2), (3), (3′). Assume that $\mathbf{x}$, $\mathbf{u}, \Phi$ are defined in knots and $p, \rho$ – in cells. Define the time grid $\omega_\tau = \{t_n = n\triangle t,\ n = 0, 1, \ldots\}$; for the arbitrary grid function defined on $\omega_\tau$, introduce the following specifications: $f(t_n) = f^n = f, f^{n+1} = \hat{f}, f_t = \frac{\hat{f} - f}{\tau}, \quad f^{(\sigma)} = \sigma\hat{f} + (1-\sigma)f$.

For simplicity we consider set of gas dynamical equations with self-gravitation:

$$\begin{aligned} \frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} = \mathbf{u}, \quad \frac{\mathrm{d}\rho}{\mathrm{d}t} + \rho \mathrm{div}\mathbf{u} = 0, \\ \rho\frac{\mathrm{d}\mathbf{u}}{\mathrm{d}t} = -\mathrm{grad}p - \rho\mathrm{grad}\Phi, \\ \rho\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} + p\mathrm{div}\mathbf{u} = 0, \quad \eta = \frac{1}{\rho} = \frac{T\Re}{p}, \quad \varepsilon = \frac{T\Re}{\gamma - 1}, \\ \Delta\Phi = 4\pi G\rho. \end{aligned} \tag{9}$$

where $\frac{\mathrm{d}}{\mathrm{d}t}$ is total time $t$ derivative , $\mathbf{x} = (r, z)$, $\mathbf{u} = (u^r,\ u^\varphi,\ u^z)$ is velocity vector, $p$ is pressure, $\varepsilon$ is internal energy, $\Phi$ is gravitational potential, $\rho$ is density, $T$ is temperature, $G$ is gravitational constant, $\Re$ is universal gas constant, $\gamma$ is adiabatic index. Axial and cylindrical symmetry are assumed.

On the basis of the introduced operators, the following implicit difference scheme for (9) can be written[4]:

$$\rho_i V_i = {\rho_i}^0 {V_i}^0 = m_i, \quad \forall \triangle_i \in \omega_\triangle,\ \mathbf{x}_{jt} = {\mathbf{u}_j}^{(0.5)}, \quad \forall \overline{x}_j \in \omega_\times,$$

$$\rho_j \mathbf{u}_{jt} = -(\nabla_\times g)_j - q\rho_j \big(S_\times(\nabla_\triangle \Phi)\big)_j, \quad \forall \overline{x}_j \in \omega_\times,$$

$$\rho_i \varepsilon_{it} = -g_i \big(\nabla_\triangle \cdot \mathbf{u}^{(0.5)}\big)_i, \quad \forall \triangle_i \in \omega_\triangle,\ g = p^{(\alpha)} + \omega, \quad \omega = -\frac{\nu}{\eta}\eta_t, \quad \forall \triangle_i \in \omega_\triangle,$$

$$\eta_i = 1/\rho_i = T_i/p_i, \quad \varepsilon_i = T_i/(\gamma - 1), \quad \forall \triangle_i \in \omega_\triangle,$$

$$(\nabla_\times \cdot \nabla_\triangle \Phi)_j = \rho_j,\ \rho_j = (S_\times \rho)_j = \frac{1}{3V_j^\times} \sum_{k=1}^{K_j} \rho_k V_k^\triangle, \quad \forall \overline{x}_j \in \omega_\times.$$

Here $\nu$ is a coefficient of artificial viscosity. The total time derivatives for the velocity vector in the difference form are:

$$\mathbf{u}_{jt} = \big\{u_{jt}^r - \frac{u_j^{\varphi(0.5)}}{r_j^{(0.5)}} u_j^{\varphi(0.5)}, \quad u_{jt}^\varphi + \frac{u_j^{\varphi(0.5)}}{r_j{}^{(0.5)}} u_j^{r(0.5)}, \quad u_{jt}^z\big\}.$$

Substituting the boundary values known from the boundary conditions into (4), we get a set of non-linear operator equations for the grid functions $\mathbf{x}, \mathbf{u} \in B_{\times,1}$, $\rho, T \in B_{\triangle,0}$ at every time step, which is solved by a specially adjusted variant of the Newton method. The gravitational potential $\Phi$ was calculated explicitly at the beginning of every time step.

## 3. Triangular grid structure reconstruction procedure

One of the important problems for application of difference schemes in Lagrangian variables is grid distortion which prevents to continue the simulations and could lead also to the loss of accuracy of the results. In order to overcome this problem in the papers[2,3] and some other papers of these authors the grid remapping procedure for a triangular grid was developed.

Here the remapping procedure was modified what allows to carry out simulations in the presence of large differences in flow parameters[6,7].

The procedure for the remapping the grid, in turn, consists of two stages.The first is a local change in the structure of the grid. The second is to determine the values of the grid functions in the areas of the changed structure.The local change in the structure of the computational grid is reduced to three local operations:

(1) the diagonal of a quadrangle formed by two triangles is replaced by another diagonal
(2) combining two adjacent grid nodes
(3) adding a new node to the middle of the link between neighboring nodes

The structure of the grid is corrected using the first two operations. Mesh adaptation occurs through operations 2 and 3.

## 4. Grid functions remapping method for completely conservative Lagrangian operator-difference scheme for astrophysical MHD problems

At the second stage of the of the grid remapping, the values of the grid functions in the nodes and cells involved in changing the structure mesh are calculated. For the simulation of astrophysical problems, a method of conditional minimization of functionals was proposed and implemented, which ensures the exact implementation of conservation laws. To calculate the density in new cells, it was suggested to look for the conditional minimum of the following functional[6]:

$$\min_{\tilde{\rho}_i} \sum_{\tilde{I}} \frac{(\tilde{\rho}_i - \rho_{ci})^2}{\rho_{ci}/\tilde{V}_i}, \tag{10}$$

under the condition of mass conservation of vicinity of the remapping region:

$$\sum_{\tilde{I}} \tilde{\rho}_i \tilde{V}_i = \sum_{I} \rho_i V_i = M_{\text{vicinity}}. \tag{11}$$

Here $\rho_{ci}$ - is a linear interpolation of the density to a new grid cells. Applying the Lagrange multiplier method to minimize the conditional functional, we obtain:

$$\tilde{\rho}_i = \rho_{ci} \frac{M_{\text{vicinity}}}{\sum\limits_{\tilde{I}} \rho_{ci} \tilde{V}_i}. \tag{12}$$

It is easy to show that the density recalculation by the formula (12)allows us to fulfill the law of conservation of mass in the remapping region.

For the calculations of new values of the poloidal magnetic field components $H_r$, $H_z$ we use the following conditional minimization of the functionals[6]: $\min_{\tilde{H}_{ri}} \sum_{\tilde{I}} \{(\tilde{H}_{ri} - H_{rci})^2\} \tilde{V}_i$, $\min_{\tilde{H}_{zi}} \sum_{\tilde{I}} \{(\tilde{H}_{zi} - H_{zci})^2\} \tilde{V}_i$, under the conditions of conservation of every component of the magnetic energy in the remapping region: $\sum_{\tilde{I}} \tilde{H}_{ri}^2 \tilde{V}_i = \sum_I H_{ri}^2 V_i = E_{mag,\, r\ \text{vicinity}}$, $\sum_{\tilde{I}} \tilde{H}_{zi}^2 \tilde{V}_i = \sum_I H_{zi}^2 V_i = E_{mag,\, z\ \text{vicinity}}$. Here $H_{rci}$, $H_{zci}$ - is a linear interpolation of poloidal magnetic field components to a new grid cells.

Conditional minimum of these functionals is found by the Lagrange multiplier method.

For the calculation of the poloidal components of the magnetic field $H_r$, $H_z$ we get following formulae:

$$\tilde{H}_{ri} = H_{rci}\sqrt{\frac{E_{mag,\,r\text{ vicinity}}}{\sum\limits_{\tilde{I}} H_{rci}^2\tilde{V}_i}},\ \tilde{H}_{zi} = H_{zci}\sqrt{\frac{E_{mag,\,z\text{ vicinity}}}{\sum\limits_{\tilde{I}} H_{zci}^2\tilde{V}_i}},$$

For the calculations of the toroidal component of the magnetic field $H_\varphi$ on a new grid the following conditional minimum of the functional is calculated:

$$\min_{\tilde{H}_{\varphi i}} \sum_{\tilde{I}} \frac{(\tilde{H}_{\varphi i} - H_{\varphi ci})^2}{H_{\varphi ci}}\tilde{S}_i, \tag{13}$$

under the condition of the conservation of the toroidal magnetc flux $H_\varphi S$ in the remapping region: $\sum_{\tilde{I}} \tilde{H}_{\varphi i}\tilde{S}_i = \sum_I H_{\varphi i}S_i = F_{mag,\,\varphi\text{ vicinity}}$. Finally for the calculation if the toroidal components of the magnetic field $\tilde{H}_{\varphi i}$ we get the following formula:

$$\tilde{H}_{\varphi i} = H_{\varphi ci}\frac{F_{mag,\,\varphi\text{ vicinity}}}{\sum\limits_{\tilde{I}} H_{\varphi ci}\tilde{S}_i}.$$

Using this formula one can calculate the vales of the toroidal component of the magnetic field in a new cells preserving the toroidal magnetic flux.

In order to find the values of the toroidal component of the magnetic field in the cells of the remapping region, with conservation of the toroidal magnetic energy the conditional minimum of the following functional is sought (by analogy with the poloidal components of the magnetic field): $\min_{\tilde{H}_{\varphi i}} \sum_{\tilde{I}}\{(\tilde{H}_{\varphi i} - H_{\varphi ci})^2\}\tilde{V}_i$, provided that the toroidal magnetic energy is preserved in the remapping region: $\sum_{\tilde{I}} \tilde{H}_{\varphi i}^2\tilde{V}_i = \sum_I H_{\varphi i}^2 V_i = E_{mag,\,\varphi\text{ vicinity}}$. In this case, to calculate the toroidal components of the magnetic field $\tilde{H}_{\varphi i}$ we get the following formula:

$$\tilde{H}_{\varphi i} = H_{\varphi ci}\sqrt{\frac{E_{mag,\,\varphi\text{ vicinity}}}{\sum\limits_{\tilde{I}} H_{\varphi ci}^2\tilde{V}_i}}.$$

To find the new values of the temperature $\tilde{T}_i$ (the pressure $\tilde{p}_i$) in the remapping region, we seek the conditional minimum of the following functional: $\min_{\tilde{T}_{\varphi i}} \sum_{\tilde{I}}(\tilde{T}_{\varphi i} - T_{\varphi ci})^2\tilde{V}_i$, under the condition of preserving of the internal energy in the remapping region $\sum_{\tilde{I}} \tilde{\varepsilon}_i\tilde{V}_i = \sum_I \varepsilon V_i = E_{int,\,\text{vicinity}}$, We solve this system of equations by Newton method.

## 5. Application to the magnetorotational processes in astrophysics

The idea of the MR mechanism of core-collpased supernovae was suggested by G.S. Bisnovatyi-Kogan in[10]. During the nonuniform collapse of the rotating iron core differentially rotating configuration is formed. Internal parts of the collapsed core rotate faster than its periphery. In the case of presence even weak initial poloidal

magnetic field the magnetic field will be twisted due to the differential rotation. Increasing magnetic pressure will lead to the formation of MHD shock wave. The shock will move outwards producing supernova explosion. For the numerical study of the MR supernova explosion a set of ideal MHD equations with self-gravitation were numerically solved using described above numerical scheme[6,7]. During the simulations of MR supernova explosion the development of the special type of MR instability was found[11].

Theoretical and observational inferences reveal that accretion and outflows/jets are strongly correlated through fundamental conservation laws. All well-known jetted sources with accreting black hole systems indicate a signature of hot advective accretion flow and a dynamically important magnetic fields at the jet footprint. We inter-connect here the disc and outflow/jet for magnetized, viscous, optically thin, geometrically thick, 2.5-dimensional hot advective flows around black holes. The magnetic fields are captured from the environment, say interstellar medium or companion star, and dragged inward with continuous accretion process. This disc becomes magnetically dominated in vicinity of a black hole due to flux freezing. The accretion geometry as well as energetics of the accretion induced outflows/jets strongly depend on the mass and spin of the black hole, accretion rate, and magnetic field strength. We suggest, this magnetically dominated accretion powered system can easily explain the energetics of the ultraluminous X-ray sources in their hard power-law dominated states.

## 1. Introduction

The observational evidences show strong outflows and jets in various black hole (BH) accreting systems, in quasars or active galactic nuclei, microquasars, and gamma-ray bursts. These outflows and jets are more prone to emanate from the inner region of the accretion flow, particularly when the flow is hot, puffed-up, and advective. Observational evidences predict that all BH X-ray binaries to exhibit strong radio jets in its low/hard spectral state[1]. The low/hard state basically indicates the accretion regime with quite low mass accretion rate and the disc is radiatively inefficient. However, the proper mechanisms for the formation, collimation, and acceleration of relativistic jets are still not well understood.

Theoretical models suggest the role of large-scale magnetic fields in the angular momentum transport in accretion, in the formations of strong outflows/jets, and in high-energy radiation mechanism[2,3]. The large-scale open magnetic fields threaded the disc can extract energy and angular momentum in the form of outflows by tapping gravitational potential energy of a BH[4]. The energy extraction is also possible from the rotational energy of a BH in the presence of sufficient amount of magnetic flux through Blandford and Znajek mechanism[5]. This is verified numerically in general relativistic magnetohydrodynamics framework for magnetically arrested disc (MAD) paradigm, where poloidal magnetic fields are playing the underlying role[6]. Also, vertically inflated toroidal fields can enhance outflow power through the formation of 'magnetic tower jets'[7]. Observational evidences of jetted sources also suggest the presence of dynamically important magnetic fields at the jet launching

region in the vicinity of a BH[8]. All these insights motivate us to model disc-outflow symbiosis in the presence of large-scale strong magnetic fields for hot, geometrically thick, advective accretion flow around BHs. Here the advection of both poloidal and toroidal components of magnetic fields occur. We compute the power associated with the magnetically driven accretion induced outflows in this proceeding.

## 2. Model equations

We propose a magnetized, advective, optically thin, geometrically thick disc-outflow/jet symbiotic model around BHs in the framework of pseudo-Newtonian potential. Here we use cylindrical coordinate assuming a steady and axisymmetric flow, i.e., $\partial/\partial t \equiv \partial/\partial\phi \equiv 0$. Hence the flow variables, namely, radial velocity ($v_r$), specific angular momentum ($\lambda$), vertical velocity ($v_z$), the radial ($B_r$), azimuthal ($B_\phi$), and vertical ($B_z$) components of magnetic field, fluid pressure ($p$), and mass density ($\rho$) are functions of both radial ($r$) and vertical ($z$) coordinates. Throughout in our computation, we express radial and vertical coordinates in units of $r_g = GM_{\rm BH}/c^2$, where $G$ is Newton's gravitational constant, $M_{\rm BH}$ is the mass of the BH, and $c$ is the speed of light. We also express other variables accordingly (e.g. velocity in units of $c$, $\lambda$ in units of $GM_{\rm BH}/c$ etc.) to make all the variables dimensionless. Hence, the continuity equation, the momentum balance equations, the equation for no magnetic monopole, the components of induction equation, and the energy equation are respectively

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\rho v_r\right) + \frac{\partial}{\partial z}\left(\rho v_z\right) = 0, \tag{1}$$

$$v_r\frac{\partial v_r}{\partial r} + v_z\frac{\partial v_r}{\partial z} - \frac{\lambda^2}{r^3} + \frac{1}{\rho}\frac{\partial p}{\partial r} + F = \frac{1}{4\pi\rho}\left[-\frac{B_\phi}{r}\frac{\partial}{\partial r}\left(rB_\phi\right) + B_z\left(\frac{\partial B_r}{\partial z} - \frac{\partial B_z}{\partial r}\right)\right], \tag{2}$$

$$v_r\frac{\partial \lambda}{\partial r} + v_z\frac{\partial \lambda}{\partial z} = \frac{r}{\rho}\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 W_{r\phi}\right) + \frac{\partial W_{\phi z}}{\partial z}\right] + \frac{r}{4\pi\rho}\left[\frac{B_r}{r}\frac{\partial}{\partial r}\left(rB_\phi\right) + B_z\frac{\partial B_\phi}{\partial z}\right], \tag{3}$$

$$v_r\frac{\partial v_z}{\partial r} + v_z\frac{\partial v_z}{\partial z} + \frac{1}{\rho}\frac{\partial p}{\partial z} + \frac{Fz}{r} = \frac{1}{4\pi\rho}\left[B_r\left(\frac{\partial B_z}{\partial r} - \frac{\partial B_r}{\partial z}\right) - B_\phi\frac{\partial B_\phi}{\partial z}\right], \tag{4}$$

$$\frac{1}{r}\frac{\partial}{\partial r}\left(rB_r\right) + \frac{\partial B_z}{\partial z} = 0, \tag{5}$$

$$\frac{\partial}{\partial z}\left[r\left(v_zB_r - v_rB_z\right)\right] = 0, \tag{6}$$

$$\frac{\partial}{\partial r}\left(v_rB_\phi - \frac{\lambda B_r}{r}\right) = \frac{\partial}{\partial z}\left(\frac{\lambda B_z}{r} - v_zB_\phi\right), \tag{7}$$

$$\frac{\partial}{\partial r}\left[r\left(v_zB_r - v_rB_z\right)\right] = 0, \tag{8}$$

$$\frac{v_r}{\Gamma_3 - 1}\left[\frac{\partial p}{\partial r} - \Gamma_1\frac{p}{\rho}\frac{\partial \rho}{\partial r}\right] + \frac{v_z}{\Gamma_3 - 1}\left[\frac{\partial p}{\partial z} - \Gamma_1\frac{p}{\rho}\frac{\partial \rho}{\partial z}\right] = Q^+ - Q^- = fQ^+, \tag{9}$$

where $F$ is the magnitude of the gravitational force for a rotating BH corresponding to the pseudo-Newtonian potential[9]. The generalized viscous stress tensor ($W_{ij}$) is written in terms of Shakura-Sunayev[10] $\alpha$-viscosity parameter with proper modifications[11] due to advection and is given by $W_{r\phi} = \alpha(p + \rho v_r^2)$ and $W_{\phi z} \approx \frac{z}{r}W_{r\phi}$[12]. We consider here the induction equation in the limit of very large magnetic Reynolds number. The energy generation rate per unit volume ($Q^+$) due to magnetic and viscous dissipations are followed from the Ref. 13. $Q^-$ represents the radiative cooling rate per unit volume through different cooling mechanisms[3]. However in this

proceeding, we do not consider cooling processes explicitly. The factor '$f$' included here to represent the degree of cooling which varies from 0 (for very efficient cooling) to 1 (for no cooling). In this disc-outflow symbiosis region, we also assume that within the disc flow region the vertical variation of any flow variables is much less compared to the corresponding radial variation. This allow us to introduce the vertical variation as $\partial/\partial z \approx s/z$, where the scale variable '$s$' is very small number ($|s| \sim 0.01$).

## 3. Solution procedure

The set of nine coupled differential equations $(1) - (9)$ for eight flow variables $v_r$, $\lambda$, $v_z$, $p$, $\rho$, $B_r$, $B_\phi$, and $B_z$, along with vertical scale height ($z$) are solved simultaneously to obtain the solutions as functions of independent variable $r$. The sub-sonic matter at very far away from the BH, passes through the sonic/critical location and becomes super-sonic near the event horizon of a BH for such BH accretion process. The outer boundary for our solution is the transition radius between Keplerian to sub-Keplerian flow. The event horizon where matter velocity reaches the speed of light, is the inner boundary. We also use the critical point as one of the boundaries. The different types of sonic/critical points, say, saddle, spiral, and nodal, are described in the Ref. 14.

## 4. Results

We address here the role of large-scale magnetic fields in the outward transport of angular momentum, as well as in the formation of outflows/jets for this hot advective disc-outflow symbiosis around BHs. Fig. 1 describes the variation of flow parameters, whereas Fig. 2 indicates the variation of magnetic field properties and outflow power as functions of $r$ along the disc-outflow surface for both non-rotating (solid line) and fast rotating (dotted line) BHs. Fig. 1($a$) describes the profile for Mach number ($M$) defined as the ratio of radial velocity to the sound speed. The critical location and the corresponding specific angular momentum are $r_c = 6.0$, $\lambda_c = 3.0$ for BHs with spin parameter $a = 0$, and $r_c = 4.2$, $\lambda_c = 1.8$ for BHs with $a = 0.998$, respectively. Very far away from the BH, matter is sub-sonic, whereas near the event horizon matter becomes super-sonic ($M > 1$). The outward transfer of angular momentum is shown in Fig. 1($b$). The vertical velocity and the sound speed are higher for rapidly spinning BHs as shown in Figs. 1($c$) and ($d$) respectively. The vertical velocity at the horizon increases from 0.065 when $a = 0$ to 0.145 when $a = 0.998$. The increase of $c_s$ with spin indicates that the temperature of the coupled disc-induced outflow is higher for rapidly spinning BHs.

The magnetic field components and their relative strength are shown in Figs. 2($a$) and ($b$) respectively. The advection of both the toroidal and poloidal field components occur in our computation. Very far away from the BH, the disc is toroidal field dominated due to presence of differential rotation. Within the plunging region,

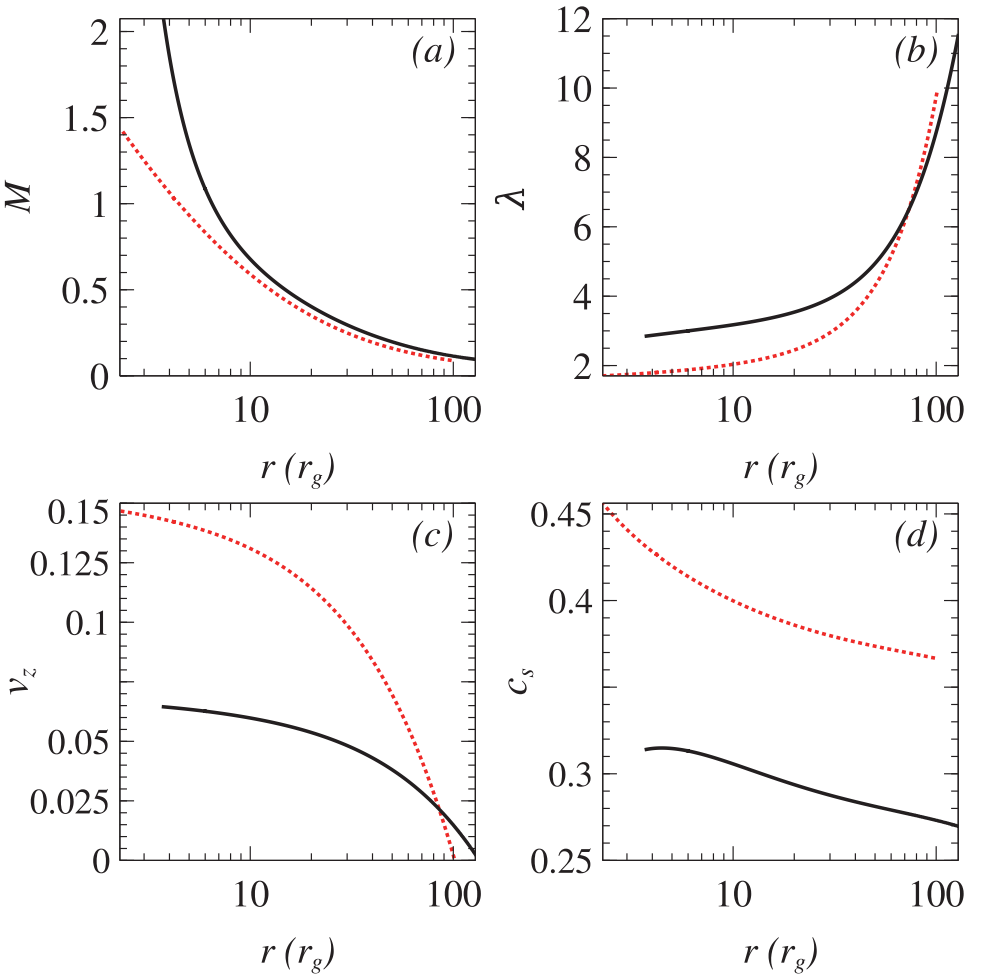

Fig. 1. The variation of ($a$) Mach number, ($b$) specific angular momentum, ($c$) vertical/outflow velocity, and ($d$) sound speed, as functions of $r$. Solid lines are for non-rotating ($a = 0$) BHs and dotted lines are for fast spinning ($a = 0.998$) BHs. The model parameters are $M_{\rm BH} = 20M_{\odot}$, $\dot{M} = 0.05\dot{M}_{\rm Edd}$, $f = 0.5$, and $\alpha = 0.01$.

the poloidal field enhances more compared to the toroidal one due to dominant inward advection and lack of differential rotation. Note that the maximum magnetic field strength near the BH is few factor times $10^7$ G for $20M_{\odot}$ BH. The ratios of the magnetic- to viscous-stresses are shown in Fig. 2($c$). The dominant nature of large-scale magnetic stress over viscous one indicates that the magnetic stresses are playing the underlying role in angular momentum transport, as well as in outflow formation. The corresponding outflow power is shown in Fig. 2($d$). The extracted power from the disc-outflow surface is the combination of mechanical, enthalpy, viscous, and Poynting parts[13]. The maximum reachable power in such configuration is $6 \times 10^{39}$ erg/s for BHs with $a = 0$, and $8.65 \times 10^{39}$ erg/s for BHs with $a = 0.998$.

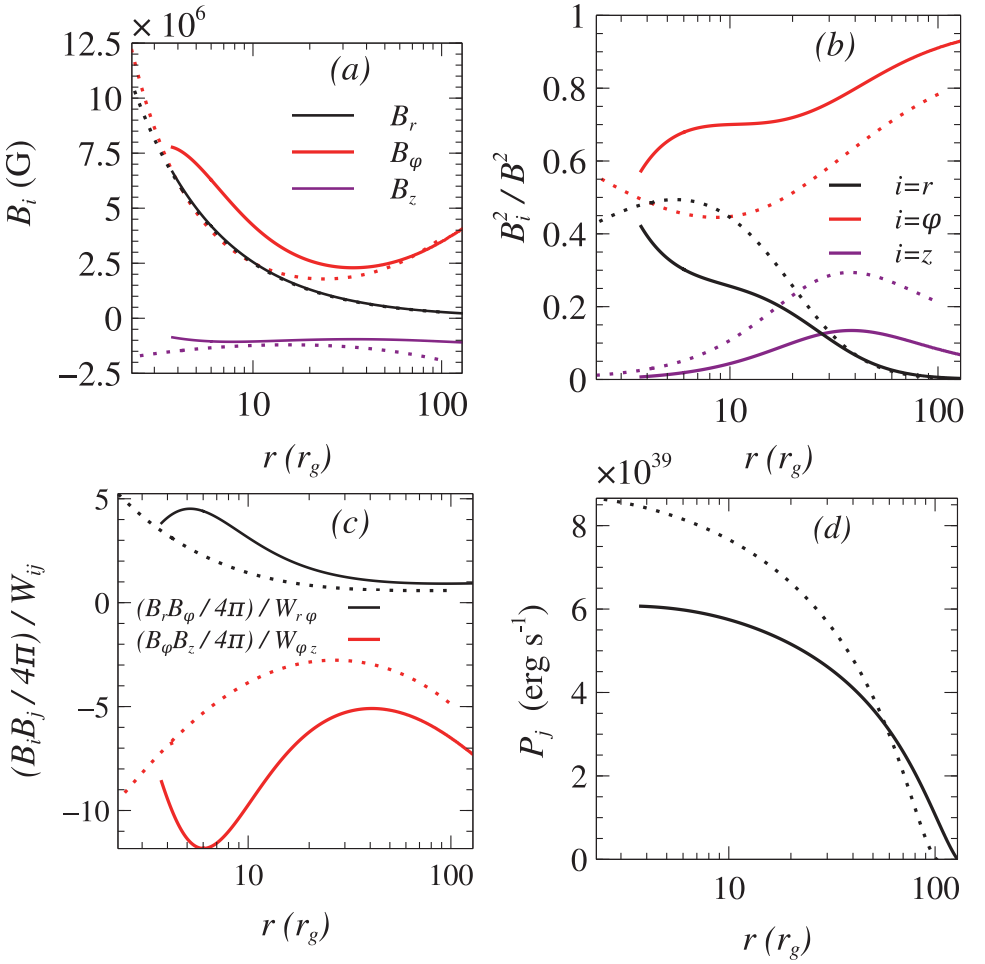

Fig. 2. The variation of ($a$) magnetic field components, ($b$) magnetic- to viscous-stress ratios, ($c$) relative magnetic field strength, and ($d$) the outflow power, as functions of $r$. Solid lines are for non-rotating ($a = 0$) BHs and dotted lines are for fast spinning ($a = 0.998$) BHs. The model parameters are same as in Fig 1 (colour online).

## 5. Discussions

In this proceeding, we discuss the disc flow behaviours and the formation of strong outflows from 2.5-dimensional magnetized, viscous, advective disc-outflow symbiotic model around BHs. The disc is hot puffed-up with (ion) temperature $\sim 10^{11} - 10^{12}$ K for non-rotating to fast-rotating BHs. The magnetic field strength near the stellar mass BHs is few factor times $10^7$ G, which is well below the Eddington magnetic field limit [13]. The components of magnetic stress dominate over the corresponding viscous ones, and hence the outward transfer of angular momentum is mainly controlled by large-scale magnetic stress. However, the origin of such strong magnetic

field in the vicinity of a BH is not clear yet. It was suggested that the externally generated fields are captured from environment, say, interstellar medium or companion star, and dragged inward with continuous accretion process[15]. The fields become dynamically dominant near the event horizon of a BH due to flux freezing in this quasi-spherical advective process. In our computation, the advection of both the toroidal and poloidal components of magnetic field occur.

We compute the power associated with magneto-centrifugally driven outflows from this magnetically dominated disc-outflow surface around BHs. Note that the effect of BHs' spins does not appear to play efficient role in such power measurement in this model. This is because we introduce the spin effect through the pseudo-Newtonian potential around rotating BHs. To operate Blandford and Znajek mechanism[5] properly, we have to formulate this disc-outflow/jet symbiosis in general relativistic magnetohydrodynamics framework. The observational implication to ultra-luminous X-ray sources is discussed in the other proceeding[16] of this volume based on such magnetically dominated disc-outflow symbiosis including cooling.

Ringed accretion disks (**RADs**) are aggregates of corotating and counterrotating toroidal accretion disks orbiting a central Kerr super-massive Black Hole (**SMBH**) in **AGNs**. The dimensionless spin of the central **BH** and the fluids relative rotation are proved to strongly affect the **RAD** dynamics. There is evidence of a strict correlation between **SMBH** spin, fluid rotation and magnetic fields in **RADs** formation and evolution. Recently, the model was extended to consider **RADs** constituted by several magnetized accretion tori and the effects of a toroidal magnetic field in **RAD** dynamics have been investigated. The analysis poses constraints on tori formation and emergence of **RADs** instabilities in the phases of accretion onto the central attractor and tori collision emergence. Magnetic fields and fluids rotation are proved to be strongly constrained and influence tori formation and evolution in **RADs**, in dependence on the toroidal magnetic fields parameters. Eventually, the **RAD** frame investigation constraints specific classes of tori that could be observed around some specific **SMBHs** identified by their dimensionless spin

## 1. Introduction

Ringed accretion disks (**RADs**) are aggregates of axi-symmetric tori orbiting Kerr **SMBHs**. The orbiting agglomerate is composed by both corotating and counterrotating tori. These configurations might be generated after different periods of the attractor life, where the angular momentum of the material in accretion on the central attractor in different phases of the **BH** life could have very different direction and magnitude. The **RAD** model was first developed considering tori centered on the equatorial plane of the central **BH**. **RAD** can be associated to jet emission in many ways, because of the inner edge of accreting disks jet launch point correlation and because the model adopted for each toroidal disk component of the aggregate provides an open solution, proto-jets, consisting of shells funnels of matter along the axis of the **BH**[2,3,5]. It should be noted that the occurrence of double accretion in the **RAD** is restricted to the case of two tori only, for a couple made by an inner corotating torus and by an outer counterrotating one. Consequently, the double jet shell emission in this system is limited to a jet from external counterrotating matter and an inner jet from the internal corotating matter[2]. It was also provided a general classification of the **RAD** and of the attractors according to their dimensional spin, providing an indication on the configurations and situation where observational evidences can be found. In Ref. 6 a large part of modellization was dedicated to describing the **RAD** as a single disk: in fact it has been shown that such kind od agglomerate is generically a geometrically thin disk, axis-symmetric, with knobby surface, and a very varied internal activity–Figs (1). The **RAD** could

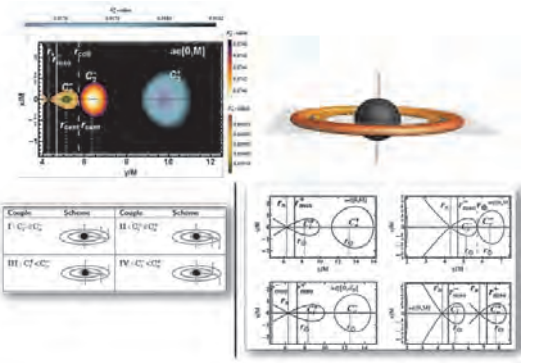

Fig. 1. Upper Left: **RAD** of the order 3, 2D-GRHD density profiles. Upper Right: **RAD** of the order 2, 3D-GRHD density profiles of corotating colliding tori. Below Left: schemes for the $\ell$corotating ($\ell$ **c**) or $\ell$counterrotating ($\ell$ **r**) couples. Below Right: correspondent **RAD** density profiles. Upper line is for the ($\ell$ **c**) of counterrotating (left) and corotating (right) tori [1,3].

be disguised as one disk characterized buy articulated phases of super-Eddington accretion, which could explain the masses problem of super-massive **BH** at high redshift, after a series of interrupted phase of accretion [1].

The model was introduced in Ref. 8 and fully developed in Ref. 6. In Ref. 5 the unstable configurations were analyzed and particularly constrains on locations of inner and outer edges of the **RAD** and the toroidal components were given. A detail analysis of **RAD** tori sequences as remnants of multiple accreting periods of Kerr **SMBHs**, in active galactic nuclei (**AGNs**) was considered in Ref. 3. In Ref. 4, the constraints on double configurations, constituted by two tori centered on the **BH** were given considering the possibility of collision emergence. Energetics associated to the **RAD** processes occurring in the ringed structure between its components and particularly the evaluation of **BH** accretion rates is presented in Ref. 1. Here we present the main results of the hydrodynamic (HD) and magnetized **RAD** based on the investigation in Refs 6, 5, 4, 3, 2, 1, 7.

**Overview** In Sec. (2) General considerations on hydrodynamic **RAD** models are discussed. In Sec. (3) constraints are discussed. In Sec. (4) we discuss the effects of toroidal magnetic fields on **RADs**. Concluding remarks follow in Sec. (5).

## 2. Orbiting Axi-symmetric tori in a Kerr spacetime

Because of the stationarity (time $t$ independence) and the axis-symmetry ($\phi$-independence) of each toroid of the aggregate, each torus is regulated by the Euler equation only with a barotropic equation of state $p = p(\rho)$, there is

$$\int_z^p \frac{dp}{p+\rho} = W(p) - W(0) = -\ln \frac{U_t}{(U_t)_{in}} + \int_{l_in}^{l} \frac{\Omega dl}{1-\Omega l}, \tag{1}$$

where $\Omega$ is the fluid relativistic angular frequency, $\ell$ specific angular momenta, here assumed constant and conserved inside each torus but not in the **RAD**, $(t, r, \phi, \theta)$

are Boyer-Lindquist (B-L) coordinates. We consider $\ell > 0$ for *corotating* and $\ell < 0$ for *counterrotating* fluids, within the notation $(\mp)$ respectively. $a = J/M \in ]0, M]$ is the **BH** spin, $J$ is the total angular momentum of the gravitational source and $M$ is the gravitational mass parameter. For the tori couple $(C_{(i)}, C_{(o)})$, orbiting in the equatorial plane of a given Kerr **BH** with specific angular momentum $(\ell_{(i)}, \ell_{(o)})$, we introduce the concept of $\ell$*corotating* ($\ell$**c**) disks, defined by the condition $\ell_{(i)}\ell_{(o)} > 0$, and $\ell$*counterrotating* ($\ell$**r**) disks defined by the relations $\ell_{(i)}\ell_{(o)} < 0$. The two ($\ell$**c**) tori can be both corotating, $\ell a > 0$, or counterrotating, $\ell a < 0$, with respect to the central attractor $a > 0$. Each **RAD** torus is a General Relativistic (GR) model based on the Boyer theory of the equi-pressure surfaces. Boyer surfaces are constant pressure surfaces and $\Sigma_i = \Sigma_j$ for $i, j \in (p, \rho, \ell, \Omega)$. Toroidal surfaces correspond to the equipotential surfaces, critical points of $V_{eff}(\ell)$ as function of $r$, thus solutions of $W: \ \ln(V_{eff}) = \mathrm{c} = \text{constant}$ or $V_{eff} = K =$constant **C**–cross sections of the closed Boyer surfaces (equilibrium quiescent torus); $\mathbf{C_x}$ –cross sections of the closed cusped Boyer surfaces (accreting torus); $\mathbf{O_x}$–cross sections of the open cusped Boyer surfaces, generally associated to proto-jet configurations. In the following we use the notation () to indicate a configuration which can be closed, $C$, or open $O$–Figs (1). The model in constructed investigating the angular momentum distribution inside the disk (which is not constant):

$$\pm\ell_n^{\mp} = \pm \left. \frac{a^3 + a r_n (3r_n - 4M) \mp \sqrt{r_n^3 \Delta_n^2}}{a^2 - (r_n - 2M)^2 r_n} \right|_{r_n^*}, \quad \Delta_n \equiv r_n^2 - 2M r_n + a^2 \qquad (2)$$

where $n$ is for the toroidal **RAD** component, and $\Delta_n$ is here a metric factor. In fact an essential part of the **RAD** analysis is the characterization of the boundary conditions on each torus in the agglomerate and of the disk. We considered also the function

$$\mathrm{K}^{\pm}(\Delta_{(\pm)}, r) \equiv \frac{1}{2} \left. \sqrt{\frac{r\left[(\Delta_- - \Delta_+)^2 + 4(r-2)r\right]}{2\Delta_-^2 - \Delta_-\Delta_+ r + r^3}} \right|_{\ell_n^{\mp}},$$
$$\ell = \frac{\Delta_- + \Delta_+}{2}, \ a = \frac{(\Delta_+ - \Delta_-)}{2}, \qquad (3)$$

(dimensionless units), provides constrains on the matter density distribution inside the disk and stitching together the **RAD** tori.

## 3. Constraints

In the Bondi quasi spherical accretion, the fluid angular momentum is everywhere smaller than the Keplerian one and therefore dynamically unimportant. In this analysis, however, we consider a full GR model for each **RAD** toroid where in fact there exists an extended region where the fluids angular momentum in the torus is larger (in magnitude) than the Keplerian (test particle) angular momentum. More precisely as first canvas model we adopt for each toroid a thick, opaque (high optical depth) and super-Eddington, radiation pressure supported accretion disk (in the

toroidal disks, pressure gradients are crucial) cooled by advection with low viscosity. As a consequence, during the evolution of dynamical processes, the functional form of the angular momentum and entropy distribution depends on the initial conditions of the system and on the details of the dissipative processes. From these considerations, using the distribution of relativistic specific angular momentum in the **RAD** as in Eq. (2) we can fix, as in Refs 6, 5, 4, 1, the constraints on the range of variation of the inner edge of accreting torus, $r_x$, and on the point of maximum density (pressure) in each torus, $r_{cent}$, in dependence from the range of variation of the specific angular momentum in the disk. Precisely, constraints on the angular momentum $\ell$ ranges are as follow:

**[Range- L1]** $\mp\mathbf{L1}^{\pm} \equiv [\mp\ell^{\pm}_{mso}, \mp\ell^{\pm}_{mbo}[$ where topologies $(C_1, C_\times)$ are possible, with accretion point in $r_\times \in ]r_{mbo}, r_{mso}]$ and center with maximum pressure $r_{cent} \in ]r_{mso}, \rho_{mbo}]$;
**[Range- L2]** $\mp\mathbf{L2}^{\pm} \equiv [\mp\ell^{\pm}_{mbo}, \mp\ell^{\pm}_{\gamma}[$ where topologies $(C_2, O_\times)$ are possible, with unstable point $r_j \in ]r_\gamma, r_{mbo}]$ and center with maximum pressure $r_{cent} \in ]\rho_{mbo}, \rho_\gamma]$;
**[Range- L3]** $\mp\mathbf{L3}^{\pm} \equiv \ \ell \geq \mp\ell^{\pm}_{\gamma}$ where only equilibrium torus $C_3$ is possible with center $r_{cent} > \rho_\gamma$; (in the following indices $i \in \{1, 2, 3\}$ refer to the ranges of angular momentum $\ell \in \mathbf{Li}$) being $mso$ =marginally stable orbit and $mbo$ =marginally bounded orbit, $\gamma$ =marginally circular orbit (photon orbit.) Alongside the geodesic structure of the Kerr spacetime represented by the set of radii $R \equiv (r^{\pm}_{mso}, r^{\pm}_{mbo}, r^{\pm}_{\gamma})$, and $r^{\pm}_{\mathcal{M}}$ solution of $\partial^2_r \ell = 0$, relevant to the location of the disk center and outer edge are $R_\rho \equiv (\rho^{\pm}_{mbo}, \rho^{\pm}_{\gamma}, \rho^{\pm}_{\mathcal{M}})$ ::

$$r^{\pm}_{\gamma} < r^{\pm}_{mbo} < r^{\pm}_{mso} < \rho^{\pm}_{\rm mbo} < \rho^{\pm}_{\gamma} \quad \text{where} \quad \rho^{\pm}_{\rm mbo} : \ \ell_{\pm}(r^{\pm}_{mbo}) = \ell_{\pm}(\rho^{\pm}_{\rm mbo}) \equiv \ell^{\pm}_{\mathbf{mbo}},$$
$$\rho^{\pm}_{\gamma} : \ell_{\pm}(r^{\pm}_{\gamma}) = \ell_{\pm}(\rho^{\pm}_{\gamma}) \equiv \ell^{\pm}_{\gamma}, \quad \rho^{\pm}_{\mathcal{M}} : \ell_{\pm}(\rho^{\pm}_{\mathcal{M}}) = \ell^{\pm}_{\mathcal{M}}. \tag{4}$$

This expanded structure rules good part of the geometrically thick disk physics and multiple structures. The presence of these radii stands as one of the main effects of the presence of a strong curvature of the background geometry [1,3,5].

### 3.1. *The RAD constraints*

The **RAD** of the order $n = 2$ (the order $n$ is the number of toroidal components) can be composed by the the following toridal couples:

**i)** $C^{\pm}_{\times} < C^{\pm}$, **ii)** $C^{+}_{\times} < C^{\pm}$, **iii)** $C^{-}_{\times} < C^{\pm}$ and **iv)** $C^{-}_{\times} < C^{+}_{\times}$. We indicated with $<$ the relative rotation of maximum density points in the tori–Figs (1). The situation concerning the emergence of more accretion points in **RAD** and presence of double accretion and screening tori, is summarized as follows:

$$\text{for} \quad a \in ]0, M[: \quad \underbrace{\mathbf{C^{-}_{x}}}_{\mathbf{(a)}} < \underbrace{... < C_{-} < ...}_{\mathbf{(b)}} < \underbrace{\mathbf{C^{+}_{x}}}_{\mathbf{(c)}} < ... \underbrace{< C_{\pm} <}_{\mathbf{(d)}} ... \tag{5}$$

where (**a**) is the inner ring in accretion, (**b**) is the inner subsequence of corotating tori in equilibrium, (**c**) is the outer accreting tori and (**d**) is the outer (mixed or separated) subsequence composed by equilibrium tori only. Further constraints (for the

specific angular momentum, elongation and number $n$ of tori) on the subsequences (**b**) and (**d**) depend on the attractor spin mass ratio–Figs (1). More precisely:

**The RAD canvas**

• There is a maximum $n = 2$ of accreting tori of the king $C_x^- < C_x^+$ around supermassive **BHs** with $a \neq 0$. Such tori are strongly constrained in their values of $\ell$ and $K$ depending on the spin-mass ratio of the attractor.

•"Screening"-tori located between the accreting disk and the central **BH** in a **RAD** sequence as $C_x^- < C^- < ... < C_x^+ < C^\pm$ are possible only as corotating, quiescent $C^-$ inner tori. A screening torus is a corotating (non-accreting) torus eventually detectable by X-ray spectra emission obscuration.

• If a counterrotating torus of a **RAD** is accreting onto the central **BH**, then a **RAD** with a corotating outer $C_1^-$ torus, is as $()_x^- < C_x^+ < C_1^- < C^\pm$, only orbiting "slow" **SMBHs** ($a < 0.46M$).

**[•-Corotating Tori]** A corotating torus can be the outer of a couple with an inner counterrotating accreting torus. Then the outer torus may be corotating (non accreting), or counterrotating in accretion or quiescent. Both the inner corotating and the outer counterrotating torus of the couple can accrete onto the attractor.

**[•-Counterrotating Tori]** A counterrotating torus can therefore reach the instability being the inner of a ($\ell$**r**)-($\ell$**c**), or the outer torus of a ($\ell$**r**) couple. If the *accreting* torus is *counterrotating*, $C_\times^+$, with respect to the Kerr attractor, there is *no* inner counterrotating torus, but there is $C_\times^+ < C^\pm$ or $()^- < C_\times^+$.

## 4. Influence of toroidal magnetic field in multi-accreting tori

We considered a toroidal magnetic field contribution in each **RAD** component where the magnetic field is[9]:

$$B^\phi = \sqrt{\frac{2p_B}{g_{\phi\phi} + 2\ell g_{t\phi} + \ell^2 g_{tt}}} \quad \text{with} \quad p_B = \mathcal{M}\left(g_{t\phi}g_{t\phi} - g_{tt}g_{\phi\phi}\right)^{q-1}\omega^q \tag{6}$$

the magnetic pressure, $\omega$ is the fluid enthalpy, $q$ and $\mathcal{M}$ (magnitude) are constant; $V_{eff}$ is a function of the metric and the angular momentum $\ell$. Euler equation (1) is modified by the term:

$$\partial_\mu \tilde{W} = \partial_\mu \left[\ln V_{eff} + \mathcal{G}\right] \quad \mathcal{G}(r,\theta) = \mathcal{S}\left(g_{t\phi}g_{t\phi} - g_{tt}g_{\phi\phi}\right)^{q-1}, \; \mathcal{S} \equiv \frac{q\mathcal{M}\omega^{q-1}}{q-1}, \tag{7}$$

(where $a \neq 0$) $q = 1$, is a singular values for the magnetic parameter $\mathcal{S}$, which is negative at $q < 1$, in this case excretion tori are possible. We here concentrate on $q > 1$. We therefore consider the equation for the $\tilde{W} = K$. For $\mathcal{S} = 0$ (or $\mathcal{M} = 0$) this reduces to the HD case. The **RAD** angular momentum distribution is:

$$\widetilde{\ell}^\mp \equiv \frac{a^3 + ar\left[4\mathcal{Q}(r-M)\mathcal{S}\Delta^{\mathcal{Q}} + 3r - 4\right] \mp \sqrt{r^3\Delta^2\left[1 + [2\mathcal{Q}(r-1)^2 r\mathcal{S}\Delta^{\mathcal{Q}-1}(2\mathcal{Q}\mathcal{S}\Delta^{\mathcal{Q}} + 1)]\right]}}{\Delta^{-1}[a^4 - a^2(r-3)(r-2)r - (r-2)r\left[2\mathcal{Q}(r-1)\mathcal{S}\Delta^{\mathcal{Q}+1} + (r-2)^2 r\right]]} \tag{8}$$

$\mathcal{Q} \equiv q - 1$ (dimensionless units). However the introduction of a toroidal magnetic field $B$, makes the study of the momentum distribution within the disk rather

complicated, instead In Ref. 7 it was adopted the function derived from $\mathcal{S}$-**RAD** parameter:

$$\mathcal{S}_{crit} \equiv -\frac{\Delta^{-\mathcal{Q}}}{\mathcal{Q}} \frac{a^2(a-\ell)^2 + 2r^2(a-\ell)(a-2\ell) - 4r(a-\ell)^2 - \ell^2 r^3 + r^4}{2r(r-1)\left[r(a^2-\ell^2) + 2(a-\ell)^2 + r^3\right]} \tag{9}$$

(dimensionless units) capable of setting the location of maximum density points in the disk and the existence and location of the instability points. Eq. (9) clearly enucleates the magnetic field contribution in the $\mathcal{Q}$ term, while interestingly highlights the role of the parameters $\ell$ versus $a$ [2,8]. The effects of the toroidal magnetic field in the **RAD** composition are evident in Fig. (2). In Ref. 7 it is noted that a **RAD** can be formed by having generally a sufficiently small parameter ($\mathcal{S}q$). Profiles of ($\ell$**c**) cases are similar independently by the corotation or counterrotation of the fluids in the **RAD** with the respect to the central Kerr **SMBH**. Generally the inner torus has maximum values of the $\mathcal{S}$ smaller the maximum $\mathcal{S}$ found in the outer tori. The most interesting results perhaps emerge in the case of ($\ell$**r**) couples where it is clear that the magnetic profiles for the couple $C_- < C_+$ (where double accretion occurs) are radically different from the case $C_+ < C_-$. The analysis shows also the importance of the coupling between the toroidal component of the magnetic field and the fluid angular momentum, particularly in the counter-rotating case, $\ell < 0$; for this case, for values $q < 1$ excretion can arise [7,10].

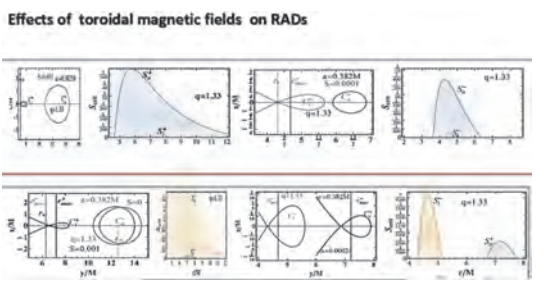

Fig. 2. Magnetized **RAD** of the order $n = 2$. Density profiles versus $\mathcal{S}$ functions profiles. Upper line features the $\ell$corotating couples of corotating (-) and counterrotating (+) tori. Bottom line features the $\ell$counterrtating couples made by $C_+ < C_-$ (left) or $C_- < C_+$ (right) [7].

## 5. Concluding Remarks and Future perspectives

The **RAD** investigation has revealed a very rich scenario with interesting phenomenology linked to the activity inside the agglomeration, correlated to the processes of instability and interaction between tori and the tori and central **SMBH** attractor. In this scenario constrains on the presence of screening and obscuring tori were discussed. The analysis of the screening and obscuring tori in particular could lead to observational evidences of a double tori **RAD** system from the emission

spectrum as X-ray emission screening, showing as fingerprints of the discrete radial profile of the **RAD**. In Ref. 11 then relatively indistinct excesses of the relativistically broadened emission-line components were predicted arising in a well-confined radial distance in the accretion structure originating by a series of episodic accretion events. Another interesting aspect of this model is the possibility of having inter-disk activity resolved in tori collision or double accretion phase with a double jet emission phase. From the **RAD** investigation this activity is limited to only two specific tori of aggregate made by a special couple constituted by a corotating and a counterrotating torus. As sideline result we provided a full characterization of the counterrotating tori in the multi-accreting systems. This model is designed for an extension to a dynamic GRMHD setup. Currently the toroidal model adopted to picture each **RAD** components is used as initial configuration for such systems. Another significant aspect is the possibility of inter-correlate the oscillations of the **RAD** components with **QPOs**. Generally instabilities of such configurations, can reveal to be of great significance for the High Energy Astrophysics related to accretion onto supermassive **BHs**, in Quasars and **AGNs**. Such activities could be targeted by the planned X-ray observatory `ATHENA`[a].

** E-mail:abbassi@um.ac.ir*

In this work we consider the effects of vertical self-gravity on a magnetized neutrino-dominated accretion disk, which is supposed to be a candidate for central engine of gamma-ray bursts (GRBs). We study some of the physical timescales that are considered to play a crucial role in the disk's late-time activity, such as viscous, cooling, and diffusion timescales. We are also interested to probe the emission of X-ray flares' probability, observed in GRBs' extended emission by an investigation on the "magnetic barrier" and "fragmentation". Our results approve the self-gravity as an amplifier for Blandford–Payne luminosity (BP power) and the magnetic field produced through the accretion process, but a suppressor for neutrino luminosity and magnetic barrier. The latter takes place as a result of the fragmentation enhancement in the outer disk, which is more likely to happen for the higher mass accretion rates.

*Keywords*: Gamma-ray Burst; Accretion Discs; Neutrino; Magnetic Field; Self-gravity.

## 1. Physical Model

### 1.1. *Basic Formalism*

We study a steady and axisymmetric magnetized NDAF ($\partial/\partial t = 0$, $\partial/\partial\phi = 0$) in which self-gravity has been taken into account, vertically. Considering the magnetic field influence in both large scale (magnetic braking mechanism) and small scale (viscous dissipation effects), yields the following results for the continuity and angular momentum equations

$$\dot{M} = -2\pi R\Sigma v_R = constant \tag{1}$$

$$\dot{M} = \frac{2\pi\alpha R^2 \Pi}{\Omega_k R^2 - j} + \frac{B_\phi B_z R^2}{\frac{\partial}{\partial R}(R^2\Omega_k)} \tag{2}$$

The energy balance equation reads

$$Q_{vis} = Q_{adv} + Q_\nu^- + Q_B^- \tag{3}$$

The neutrino cooling rate is expressed by a bridging formula (e.g., Di Matteo et al. [1]; Kohri et al. [3]) as follows:

$$Q_\nu = \sum_i \frac{(7/8)\sigma T^4}{(3/4)[\frac{\tau_{\nu_i}}{2} + \frac{1}{\sqrt{3}} + \frac{1}{3\tau_{a,\nu_i}}]} \tag{4}$$

For $Q_B$, we have

$$Q_B^- = 2R\Omega(B_\phi B_z/4\pi) \tag{5}$$

The equation of state (EOS) is written as (e.g., Di Matteo et al. [1]; Liu et al. [5])

$$p = p_{gas} + p_{rad} + p_{deg} + p_\nu \tag{6}$$

Last term denotes the neutrino pressure $P_\nu = \frac{u_\nu}{3}$, in which $u_\nu = \sum_i \frac{(7/8)aT^4(\tau_{\nu_i}/2+1/\sqrt{3})}{\tau_{\nu_i}/2+1/\sqrt{3}+1/(3\tau_{a,\nu_i})}$ is the neutrino-energy density (Di Matteo et al. [1]; Kohri et al. [3]).

Moreover, we consider the polytropic equation of state in vertical direction $p = K\rho^{4/3}$, where $K$ is a constant (Liu et al. [5]).

The hydrostatic balance equation in vertical direction reads

$$4\pi G\Sigma_z + \frac{\partial\Psi}{\partial z} + \frac{1}{\rho}\frac{\partial p}{\partial z} + \frac{1}{8\pi\rho}(\frac{\partial B_\varphi^2}{\partial z} + \frac{\partial B_R^2}{\partial z}) - \frac{1}{4\pi\rho}B_R\frac{\partial B_z}{\partial R} = 0 \tag{7}$$

We adopt the pseudo-Newtonian potential, written by Paczynski and Wiita (Paczynski et al. [7]):

$$\Psi = \frac{-GM}{\sqrt{R^2+z^2}-R_g} \tag{8}$$

Regarding some mathematical considerations and relations between magnetic field components achieved by simulations (table 2 of Stone et al. [11]) gives

$$\begin{aligned} &2\pi G\rho_0^2H^2 + \Omega^2\frac{\rho_0H^2}{2} + p_0(e^{-1/2}-1) - 10^{-5}H\frac{dp_0}{dR} \\ &-2p_0(\frac{\beta_2}{1-\beta_2}\gamma_2e^{-2/3} + \frac{\beta_1}{1-\beta_1}\gamma_1) - \frac{10^{-5}p_0H}{R} \\ &+p_0(\frac{\beta_2}{1-\beta_2}e^{-2/3} + \frac{\beta_1}{1-\beta_1}) = 0 \end{aligned} \tag{9}$$

where $\beta$s and $\gamma$s are constants.

Furthermore, the magnetic viscosity equation is

$$\frac{B_RB_\phi}{4\pi} = -\frac{3}{2}\alpha p. \tag{10}$$

In order to achieve a better understanding of the effects of magnetic field and self-gravity through an analogy among the three cases: self-gravitating magnetized NDAF, magnetized case and self-gravitating one, we may get the required equations by ignoring the terms associated with the magnetic field and self-gravity in the above mentioned equations. For instance, considering the hydrostatic balance equation (7), the magnetized NDAF can be obtained via ignoring the first term (which reflects the self-gravity impact)

$$\frac{\partial\Psi}{\partial z} + \frac{1}{\rho}\frac{\partial p}{\partial z} + \frac{1}{8\pi\rho}(\frac{\partial B_\varphi^2}{\partial z} + \frac{\partial B_R^2}{\partial z}) - \frac{1}{4\pi\rho}B_R\frac{\partial B_z}{\partial R} = 0. \tag{11}$$

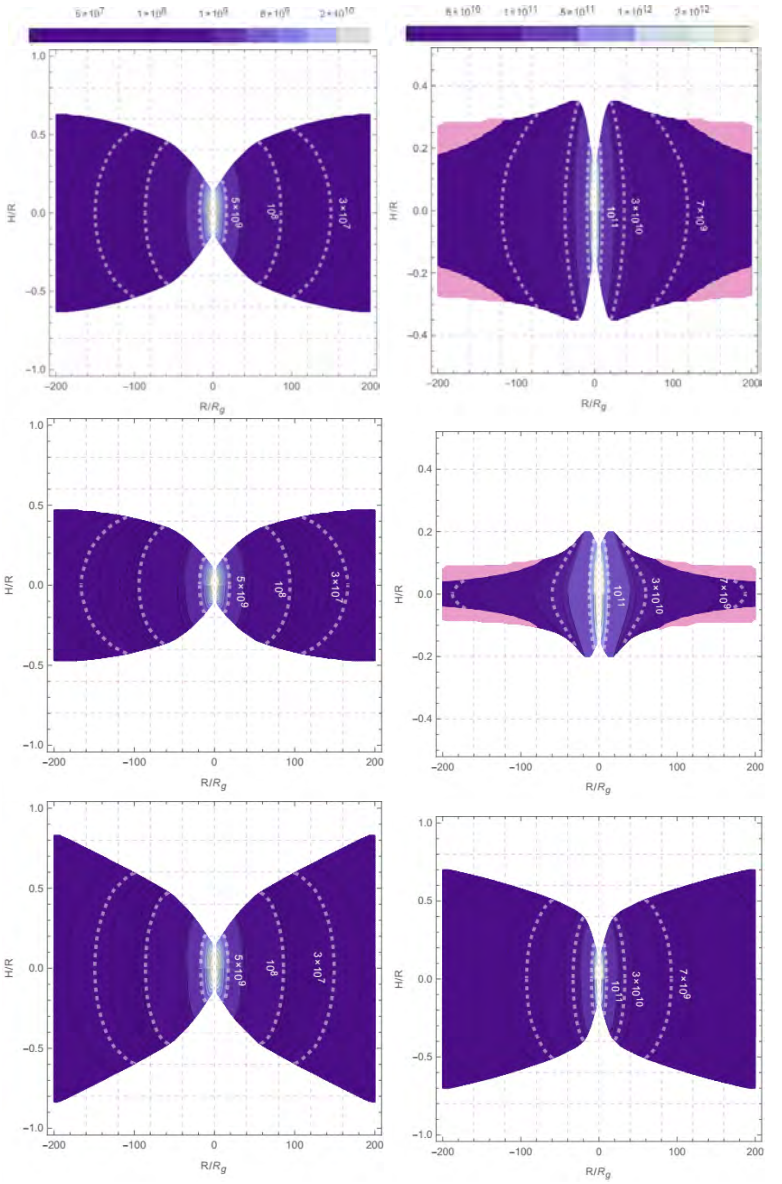

Fig. 1. Contours of density for $\dot{M} = 0.1 M_{\odot}/s$ (three left plots) and $\dot{M} = 10 M_{\odot}/s$ (three right plots), with three orders of density are highlighted through dashed lines ($5 \times 10^9$, $10^8$, $3 \times 10^7$ $gr/cm^3$ for the left panels, and $10^{11}$, $3 \times 10^{10}$, $7 \times 10^9$ $gr/cm^3$ for the right ones ). The two top panels are devoted to the self-gravitating magnetized NDAF, the tow middle plots are related to the self-gravitating case and the two bottom ones show the magnetized NDAF. Additionally, the shaded areas in pink show the gravitationally unstable zones.

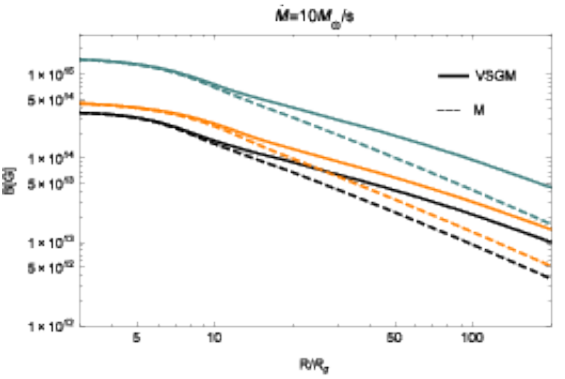

Fig. 2. Magnetic field components, $B_R, B_\phi, B_z$, for two cases of magnetized NDAF: with (VSGM) and without self-gravity (M) (solid and dashed curves). The radial, azimuthal and poloidal components are plotted in orange, blue and black, respectively.

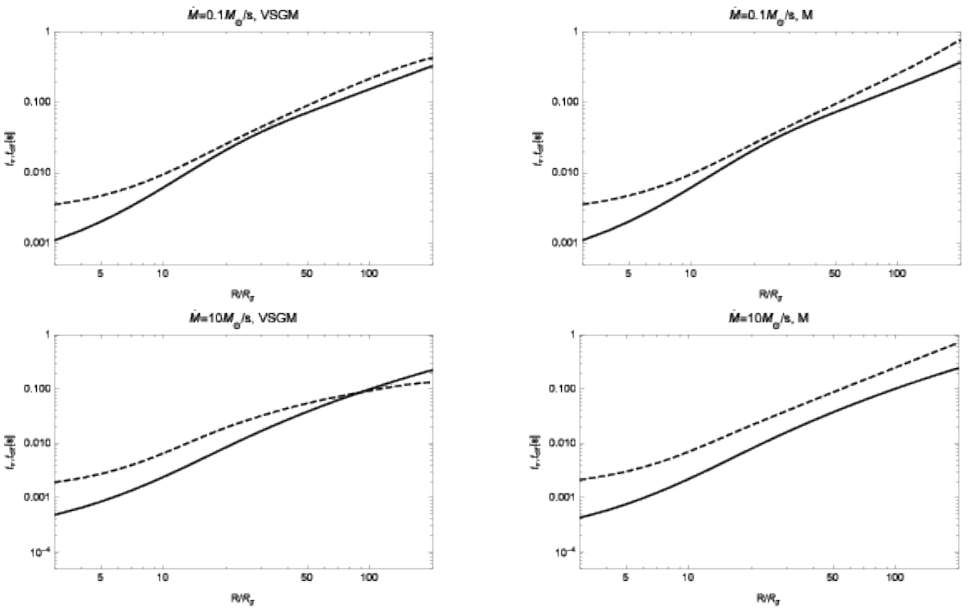

Fig. 3. Viscous and diffusion time scales for $\dot{M} = 0.1, 10 M_\odot/s$ illustrated by solid and dashed lines. Both magnetized (M) and vertically self-gravitating magnetized (VSGM) cases are considered.

The self-gravitating case is also achievable through an elimination of the magnetic terms

$$4\pi G\Sigma_z + \frac{\partial \Psi}{\partial z} + \frac{1}{\rho}\frac{\partial p}{\partial z} = 0. \tag{12}$$

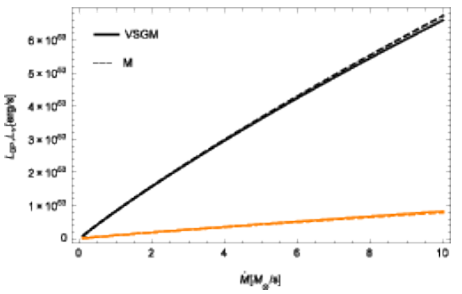

Fig. 4. Neutrino luminosity and BP power (black and orange lines) versus mass accretion rate. Solid lines represent the magnetized NDAF with vertical self-gravity (VSGM), but in dashed lines it is ignored (M).

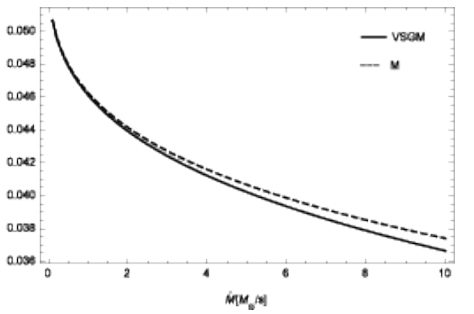

Fig. 5. Neutrino cooling efficiency versus mass accretion rate. Solid and dashed curves display the magnetized NDAF considering (VSGM) and ignoring self-gravity (M), respectively.

It can be written in the form of

$$2\pi G\rho_0^2 H^2 + \Omega^2 \frac{\rho_0 H^2}{2} + p_0(e^{-1/2} - 1) = 0. \tag{13}$$

Toomre parameter is as follows (e.g., Shu [10])

$$Q_M = Q(1 + \frac{\beta}{1-\beta}) \tag{14}$$

The magnetic field buoyancy and its rising time toward the disc surface can be estimated as

$$t_{dif} \approx \frac{H}{v_A} \tag{15}$$

Besides, the viscous time $t_\nu$ can present the timescale of the magnetic flux accumulating in the vicinity of the black-hole, then we have

$$t_\nu = \int_{3R_g}^{R} \frac{1}{v_R} dR \tag{16}$$

In case of $t_\nu < t_{diff}$ one may expect magnetic barrier to happen. In the gravitational context, fragmentation is possible if (Gammie [2]; Perna et al. [8])

$$t_{cool} < t_{cirt} \approx 3\Omega^{-1}, \tag{17}$$

where cooling timescale is denoted by $t_{cool} \approx (H/R)^2 t_\nu$ (Pringle [9]).

The neutrino luminosity, $L_\nu$, is expressed as

$$L_\nu = 2\pi \int_{R_{in}}^{R_{out}} Q_\nu R dR \tag{18}$$

The BP power output from a disc is equal to the power of disc magnetic braking and can be calculated as (Livio et al. [6]; Lee et al. [4])

$$L_{BP} = 2\pi \int_{R_{in}}^{R_{out}} Q_B R dR. \tag{19}$$

## 2. Conclusions

We study the structure and evolution of neutrino dominated accretion discs, in which the consideration of self-gravity and magnetic field provide us with a more realistic picture of these central engines of GRBs. We find self-gravity a booster of magnetic field, mainly in the outer disc. Such an effect, especially in higher accretion rates, enhances the BP power and descends the neutrino luminosity fraction. The latter is against Liu et al.[5] outcomes but seems a natural result of the strong magnetic field presence as we discussed formerly. On the other hand, the probable fragmentation process, lessens the magnetic barrier possibility by a decrease in magnetic field diffusion time scale in higher mass accretion rates. This result can also be deduced from the estimations, we have already made, and their comparison with the observational evidences.

On the whole, we find both MHD and neutrino processes effective enough ($10^{50-54} erg/s$) to produce GRBs' spectrum. Of course, in the case of higher accretion rates, the drop in neutrino efficiency (Fig. 5), as a result of a growth in neutrino opacity, may confirm a decrease in neutrinos capability to transport the energy outside. In the context of late time X-ray flares, the magnetic barrier process would be more probable to power such extended emissions in low accretion rates, because fragmentation is less likely to happen. Yet, this might not be the case for higher accretion rates as fragmentation can overcome magnetic barrier to produce energetic X-ray flares.

A unification of dark matter and dark energy based on a dynamical space time theory is discussed. By introducing a dynamical space time vector field $\chi_\mu$ as a Lagrange multiplier, a conservation of an energy momentum tensor $T^{\mu\nu}_{(\chi)}$ is implemented in addition to the conservation of the metric energy momentum tensor. This Lagrangian generalizes the Unified dark energy and dark matter from a scalar field different from quintessence which did not consider a Lagrangian formulation. This generalization allows the solutions which were found previously, in addition to a-non singular bouncing solutions that rapidly approach to the ΛCDM model. The dynamical time vector field exactly coincides with the cosmic time for the a ΛCDM solution and suffers a slight shift (advances slower) with respect to the cosmic time in the region close to the bounce for the bouncing non singular solutions. For some exponential potential which gives a possible interaction between DE and DM and could explain the coincidence problem.

*Keywords*: Unified Dark Energy and Dark Matter; Dynamical time

## 1. Introduction

Dark energy and Dark matter constitute most of the observable Universe. Yet the true nature of these two phenomena is still a mystery. One fundamental question with respect to those phenomena is the coincidence problem which is trying to explain the relation between dark energy and dark matter densities.

A model, which also continues to be valid after GW170817 event, for a unification of dark energy and dark matter from a single scalar field $\phi$, was suggested by Gao, Kunz, Liddle and Parkinson[1]. Their model is close to traditional quintessence, and gives dynamical dark energy and dark matter, but introduces a modification of the equations of motion of the scalar field that apparently are impossible to formulate in the framework of an action principle. The basic stress energy tensor which was considered in addition to Einstein equation was:

$$T^{\mu\nu} = -\frac{1}{2}\phi^{,\mu}\phi^{,\nu} + U(\phi)g^{\mu\nu} \tag{1}$$

where $\phi$ is a scalar field and $U(\phi)$ is the potential for that scalar. Assuming homogeneous and isotropic behavior the scalar field should be only time dependent $\phi = \phi(t)$.

Then the kinetic term $-\frac{1}{2}\phi^{,\mu}\phi^{,\nu}$ is parameterizing the dark matter because it contains only energy density with no pressure and $U(\phi)g^{\mu\nu}$ is parameterizing the dark energy. The basic requirement for this stress energy tensor is it's conservation law $\nabla_\mu T^{\mu\nu} = 0$. By assuming a constant potential $U(\phi) = \mathbf{Const}$ the model provides from the potential the traditional cosmological constant and the kinetic term of the scalar field is shown to provide, from the conservation law of the energy momentum tensor, that the kinetic term dependence has a dust like behavior.

$$-\frac{1}{2}\nabla_\mu(\phi^{,\mu}\phi^{,\nu}) = 0 \quad \Rightarrow \quad \dot{\phi}^2 \sim \frac{1}{a^3} \tag{2}$$

This simple case refers to the classical ΛCDM model. The special advantage of this model is a unification of dark energy and dark matter from one scalar field and has an interesting possibility for exploring the coincidence problem.

The lack of an action principle for this model brought us to reformulate the unification between dark energy and dark matter idea put forward by Gao, Kunz, Liddle and Parkinson[1] in the framework of a Dynamical Space Time Theory[2,3] which forces a conservation of energy momentum tensor in addition to the covariant conservation of the stress energy momentum tensor that appears in Einstein equation. In the next chapter we explore the equations of motion for these theories. In the third chapter we solve analytically the theory for constant potentials which reproduce the ΛCDM model with a bounce, which gives a possibility to solve the initial big bang singularity. In the last chapter we solve the theory for an exponential potential which gives a good possibility for solving the coincidence problem.

## 2. Dynamical Space Time Theory

One from the basic features in the standard approach to theories of gravity is the local conservation of an energy momentum tensor. In the field theory case it's derived as a result rather than a starting point. For example, the conservation of energy can be derived from the time translation invariance principle. The local conservation of an energy momentum tensor can be a starting point rather than a derived result. Let's consider a 4 dimensional case where a conservation of a symmetric energy momentum tensor $T^{\mu\nu}_{(\chi)}$ is imposed by introducing the term in the action:

$$\mathcal{S}_{(\chi)} = \int d^4x\sqrt{-g}\,\chi_{\mu;\nu}T^{\mu\nu}_{(\chi)} \tag{3}$$

where $\chi_{\mu;\nu} = \partial_\nu\chi_\mu - \Gamma^\lambda_{\mu\nu}\chi_\lambda$. The vector field $\chi_\mu$ called a dynamical space time vector, because of the energy density of $T^{\mu\nu}_{(\chi)}$ is a canonically conjugated variable to $\chi_0$, which is what we expected from a dynamical time:

$$\pi_{\chi_0} = \frac{\partial\mathcal{L}}{\partial\dot{\chi}^0} = T^0_0(\chi) \tag{4}$$

If $T^{\mu\nu}_{(\chi)}$ is being independent of $\chi_\mu$ and having $\Gamma^\lambda_{\mu\nu}$ being defined as the Christoffel connection coefficients (the second order Formalism), then the variation with respect

to $\chi_\mu$ gives a covariant conservation law:

$$\nabla_\mu T^{\mu\nu}_{(\chi)} = 0 \tag{5}$$

From the variation of the action with respect to the metric, we get a conserved stress energy tensor $G^{\mu\nu}$ (in appropriate units), which is well known from Einstein equation:

$$G^{\mu\nu} = \frac{2}{\sqrt{-g}}\frac{\delta\sqrt{-g}}{\delta g^{\mu\nu}}[\mathcal{L}_\chi + \mathcal{L}_m]\,, \quad \nabla_\mu G^{\mu\nu} = 0\,. \tag{6}$$

where $G^{\mu\nu}$ is Einstein tensor, $\mathcal{L}_\chi$ is the Lagrangian in (3) and $\mathcal{L}_m$ is an optional action that involve other contributions.

## 3. DE-DM Unified Theory from Dynamical Space-Time

A suggestion of an action which can produce DE-DM unification takes the form:[5]

$$\mathcal{L} = \frac{1}{2}R + \chi_{\mu;\nu}T^{\mu\nu}_{(\chi)} - \frac{1}{2}g^{\alpha\beta}\phi_{,\alpha}\phi_{,\beta} - V(\phi) \tag{7}$$

Consisting of an Einstein Hilbert action ($8\pi G = 1$), quintessence and Dynamical space-time action, when the original stress energy tensor $T^{\mu\nu}_{(\chi)}$ is the same as the stress energy tensor (1) Gao and colleagues used:

$$T^{\mu\nu}_{(\chi)} = -\frac{1}{2}\phi^{,\mu}\phi^{,\nu} + U(\phi)g^{\mu\nu} \tag{8}$$

The action depends on three different variables: the scalar field $\phi$, the dynamical space time vector $\chi_\mu$ and the metric $g_{\mu\nu}$. Therefore there are 3 sets in for the equation of motions. For the solution we assume homogeneity and isotropy, therefore we solve our theory with a FLRW metric:

$$ds^2 = -dt^2 + a(t)^2(\frac{dr^2}{1-Kr^2} + r^2 d\Omega^2) \tag{9}$$

According to this ansatz, the scalar field is just a function of time $\phi(t)$ and the dynamical vector field will be taken only with a time component $\chi_\mu = (\chi_0, 0, 0, 0)$, where $\chi_0$ is also just a function of time. A variation with respect to the dynamical space time vector field $\chi_\mu$ will force a conservation of the original stress energy tensor, which in FRWM gives the relation:

$$\ddot{\phi} + \frac{3}{2}\mathcal{H}\dot{\phi} + U'(\phi) = 0 \tag{10}$$

Compared with the equivalent equation which comes from quintessence model, this model gives a different and smaller friction term, as compared to the canonical scalar field. Therefore for increasing redshift, the densities for the scalar field will increase slower than in the standard quintessence.

The second variation with respect to the scalar field $\phi$ gives a non-conserved current:

$$\chi^\lambda_{;\lambda}U'(\phi) - V'(\phi) = \nabla_\mu j^\mu \tag{11a}$$

$$j^{\mu} = \frac{1}{2}\phi_{,\nu}(\chi^{\mu;\nu} + \chi^{\nu;\mu}) + \phi^{,\mu} \tag{11b}$$

and the derivatives of the potentials are the source of this current. For constant potentials the source becomes zero, and we get a covariant conservation of this current. In a FLRW metric this equation of motion takes the form:

$$\ddot{\phi}(\dot{\chi}_0 - 1) + \dot{\phi}[\ddot{\chi}_0 + 3\mathcal{H}(\dot{\chi}_0 - 1)] = U'(\phi)(\dot{\chi}_0 + 3\mathcal{H}\chi_0) - V'(\phi) \tag{12}$$

The last variation, with respect to the metric, gives the stress energy tensor that is defined by the value of the Einstein's tensor:

$$\begin{gathered} G^{\mu\nu} = g^{\mu\nu}(\frac{1}{2}\phi_{,\alpha}\phi^{,\alpha} + V(\phi) + \frac{1}{2}\chi^{\alpha;\beta}\phi_{,\alpha}\phi_{,\beta} + \chi^{\lambda}\phi_{,\lambda}U'(\phi)) \\ -\frac{1}{2}\phi^{,\mu}((\chi^{\lambda}_{;\lambda} + 2)\phi^{,\nu} + \chi^{\lambda;\nu}\phi_{,\lambda} + \chi^{\lambda}\phi^{\ ;\nu}_{;\lambda}) - \frac{1}{2}(\chi^{\lambda}\phi^{\ ;\mu}_{;\lambda}\phi^{,\nu} + \chi^{\lambda;\mu}\phi_{,\lambda}\phi^{,\nu}) \end{gathered} \tag{13}$$

For the specially homogeneous, cosmological case, the energy density and the pressure of the scalar field are:

$$\rho = (\dot{\chi}_0 - \frac{1}{2})\dot{\phi}^2 + V(\phi) \tag{14a}$$

$$p = \frac{1}{2}\dot{\phi}^2(\dot{\chi}_0 - 1) - V(\phi) - \chi_0\dot{\phi}U'(\phi) \tag{14b}$$

## 4. A bouncing ΛCDM solution

In order to compute the evolution of the scalar field and to check whether it is compatible with observable universe, we have to specify a form for the potentials. Let's take a simplified case of constant potentials:

$$U(\phi) = C, \quad V(\phi) = \Omega_{\Lambda} \tag{15}$$

Overall, in the equations of motions only the derivative the potential $U(\phi)$ appears, not the potential itself. Therefore a constant part of the potential $U(\phi)$ does not contribute to the solution. However $V(\phi)$, as we shall see below, gives the cosmological constant. The conservation of the stress energy tensor from equation (10) gives:

$$\dot{\phi}^2 = \frac{2\Omega_m}{a^3} \tag{16}$$

where $\Omega_m$ is an integration constant which appears from the solution. From the second variation, with respect to the scalar field $\phi$, a conserved current is obtained, which from equation (12) gives the exact solution of the dynamical time vector field:

$$\dot{\chi}_0 = 1 - \kappa\, a^{-1.5} \tag{17}$$

where $\kappa$ is another integration of constant. Eventually, the densities and the pressure for this potentials are given by (18). By substituting the solutions for the scalar $\dot{\phi}$ and the vector $\dot{\chi}_0$ (in units with $\rho_c = \frac{8\pi G}{3H_0^2} = 1$) we get:

$$\rho = \Omega_{\Lambda} - \frac{\Omega_{\kappa}}{a^{4.5}} + \frac{\Omega_m}{a^3} \quad , \quad p = -\Omega_{\Lambda} - \frac{1}{2}\frac{\Omega_{\kappa}}{a^{4.5}} \tag{18}$$

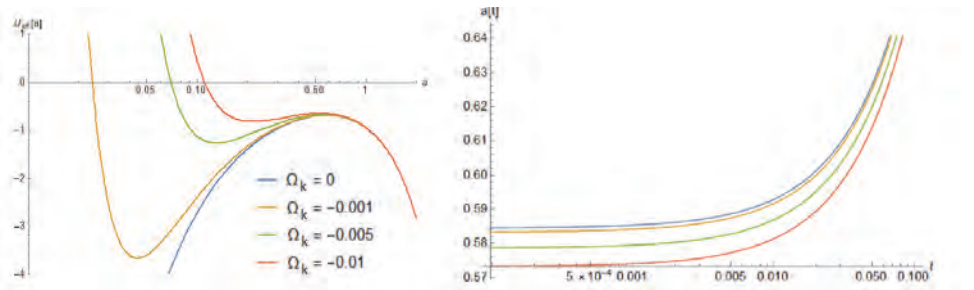

Fig. 1. Left hand side: Plot of the effective potential. For $\Omega_\kappa \neq 0$, there is a bouncing universe with dynamical dark energy. Right hand side: Plot of the scale parameter vs. the cosmic time. In any case $\dot{\chi}_0 \approx 1$

where $\Omega_\kappa = \kappa\Omega_m$. Notice that $\Omega_m, \Omega_\kappa$ are integration constants the solution contains and $\Omega_\Lambda$ is parameter from the action of the theory. We can separate the result into three different "dark fluids": dark energy ($\omega = -1$), dark matter ($\omega = 0$) and an exotic part ($\omega = \frac{1}{2}$), which is the responsible for the bounce (for $\kappa > 0$). From Eq. (16) the solution produces a positive $\Omega_m$ since it's proportional to $\dot{\phi}^2$. For $\Omega_\Lambda$ the measurements for the late universe forces the choice of this parameter to be positive. However for another solutions (in the context of Anti de-Sitter space, for instance) this parameter could be negative from the beginning. In Fig. 1 we can see the effective potential for different values of $\Omega_\kappa$. For $\Omega_\kappa = 0$ the solution returns to the known $\Lambda$CDM model. However for $\Omega_\kappa < 0$ we obtain a bouncing solution which also returns to the $\Lambda$CDM for late time expansion. The scale parameter evolution depicted in Fig.(1) can show us the initial conditions where $\dot{a}(t) = 0$, because at that point $a(t)$ is a minimum. In addition, for all cases the initial condition for the scale parameter is not zero $a(0) \neq 0$. These features imply a bouncing universe solutions.

In addition to those solutions, there is a strong correspondence between the zero component of the dynamical space time vector field and the cosmic time. For $\Lambda$CDM there is no bouncing solution $\kappa = 0$ and therefore from equation (17) we get $\chi_0 = t$ that implies that the dynamical time is exactly the cosmic time. For bouncing $\Lambda$CDM we obtain a relation between the dynamical and the cosmic time with some delay between the dynamical time and the cosmic time for the early universe (in the bouncing region). For the late universe the dynamical time returns back to run as fast as the cosmic time again. This relation between the dynamical and the cosmic time may have interesting application in the solution to "the problem of time" in quantum cosmology which will discussed elsewhere. Notice that the dynamical time is a field variable while the cosmic time is a coordinate.

## 5. Discussion

Here "unified dark energy and dark matter from a scalar field different from quintessence" is formulated through an action principle. Introducing the coupling

of a dynamical space time vector field to an energy momentum tensor that appears in the action, determines the equation of motion of the scalar field from the variation of the dynamical space time vector field or effectively from the conservation law of an energy momentum tensor, as in Ref.[1]. The energy momentum tensor that is introduced in the action is related but not in general the same as the one that appears in the right hand side of the gravitational equations, as opposed to the non-Lagrangian approach of[1], so our approach and that of[1] are not equivalent. In many situations the solutions studied in[1] can be also obtained here asymptotically. However, there are some solutions, as the non-singular bounce solutions, which are not predicted by[1].

In those solutions the dynamical time behaves as the cosmic time. In particular, an exact ΛCDM solution, the cosmic time and the dynamical time exactly the same. This correspondence could be solve the problem of time in quantum cosmology. Possible signatures for this model or for more generalized forms could be could be identified from cosmological perturbations theory. For instance, the perturbation for the scalar field is clear. However, the perturbation for the vector field could be represented with more degrees of freedom which can reproduce a different power spectrum for the Cosmic Microwave Background Anisotropies for instance. But more over than this, the model that was suggested in the last part was only with an exponential potential. However many combinations of potentials are applicable for testing the evolution for the energy densities, and using data fitting for those models. The benefits for this models are that they still preserve the speed of gravity equal to the speed of light, and also that arises from an action principle. Researching those families of solutions with more general potentials could help solve the coincidence problem.

It is known that one can formulate an action in teleparallel gravity which is equivalent to general relativity, up to a boundary term. In this geometry we have vanishing curvature, and non-vanishing torsion. The action is constructed by three different contractions of torsion with specific coefficients. By allowing these coefficients to be arbitrary we get the theory which is called "new general relativity". In this note, the Lagrangian for new general relativity is written down in ADM-variables. In order to write down the Hamiltonian we need to invert the velocities to canonical variables. However, the inversion depends on the specific combination of constraints satisfied by the theory (which depends on the coefficients in the Lagrangian). It is found that one can combine these constraints in 9 different ways to obtain non-trivial theories, each with a different inversion formula.

*Keywords*: Teleparallel gravity; New general relativity; ADM-variables.

## 1. Conventions

Greek indices denote global coordinate indices running from 0 to 3, small Latin indices are spatial coordinate indices running from 1 to 3, whereas capital Latin indices denote Lorentz indices running from 0 to 3. We are always dealing with Lorentzian metrics. Sign convention for the Minkowski metric is $\eta_{AB} = \mathrm{diag}(-1, 1, 1, 1)$.

## 2. Introduction

Gravity is conventionally described with the Levi-Civita connection which is induced by a pseudo-Riemannian metric. This means that the covariant derivative of the metric is zero, and the connection is torsion-free but has curvature. However, there are equivalent theories to general relativity[1]. We will focus on teleparallel gravity[2] where we have vanishing curvature, but non-vanishing torsion.

In particular we will perform the Hamiltonian analysis of "new general relativity" (NGR)[a]. For discussions of certain issues with these theories see[4–6] Previous work on the Hamiltonian analysis on teleparallel gravity theories have been performed in[6–18]. However, the full Hamiltonian analysis of NGR has not been performed. NGR is described by the following action:

$$S_{\mathrm{NGR}} = m_{Pl}^2 \int |\theta| \left( a_1 T^{\mu}{}_{\nu\rho} T_{\mu}{}^{\nu\rho} + a_2 T^{\mu}{}_{\nu\rho} T^{\rho\nu}{}_{\mu} + a_3 T^{\mu}{}_{\rho\mu} T^{\nu\rho}{}_{\nu} \right) \mathrm{d}^4 x, \tag{1}$$

[a] With NGR, we refer to the more general three-parameter teleparallel gravity in contrast to the special one-parameter teleparallel gravity theory which NGR originally referred to[3].

where $m_{Pl}$ is the Planck mass, $T^{\mu}{}_{\nu\rho} = \Gamma^{\mu}{}_{\rho\nu} - \Gamma^{\mu}{}_{\nu\rho}$ is the torsion component with $\Gamma^{\mu}{}_{\nu\rho} = e_A{}^{\mu}\partial_\rho\theta^A{}_{\nu} + e_A{}^{\mu}\left(\Lambda^{-1}\right)^A{}_D\,\partial_\rho\Lambda^D{}_B\theta^B{}_{\nu}$, with $\theta$ being the tetrad, $e$ its inverse and $\Lambda$ is a Lorentz matrix. Global spacetime indices are raised and lowered with $g_{\mu\nu} = \theta^A{}_{\mu}\theta^B{}_{\nu}\eta_{AB}$, while Lorentz indices are raised and lowered with $\eta_{AB}$. A theory equivalent to general relativity is obtained by setting $a_1 = \frac{1}{4},\ a_2 = \frac{1}{2},$ and $a_3 = -1$.

Alternatively, the NGR action can be written down in the so-called axial, vector, and tensor decomposition[19]. Then

$$S_{\rm NGR} = m_{\rm Pl}^2 \int |\theta|\left(c_1 T_{\rm ax} + c_2 T_{\rm ten} + c_3 T_{\rm vec}\right), \tag{2}$$

with $a_1 = -\frac{1}{3}(c_1 + 2c_2),\ a_2 = \frac{2}{3}(c_1 - c_2),\ a_3 = \frac{2}{3}(c_2 - c_3)$, and

$$\begin{aligned} T_{\rm vec} &= T^{\rho}{}_{\rho\mu}T_{\nu}{}^{\nu\mu}, \\ T_{\rm ax} &= \frac{1}{18}\left(T_{\rho\mu\nu}T^{\rho\mu\nu} - 2T_{\rho\mu\nu}T^{\mu\rho\nu}\right), \\ T_{\rm ten} &= \frac{1}{2}\left(T_{\rho\mu\nu}T^{\rho\mu\nu} + T_{\rho\mu\nu}T^{\mu\rho\nu}\right) - \frac{1}{2}T^{\rho}{}_{\rho\mu}T_{\nu}{}^{\nu\mu}\,. \end{aligned} \tag{3}$$

## 3. Method

In order to go from the Lagrangian to the Hamiltonian analysis we need to identify the velocities, derive the conjugate momenta and express everything in canonical variables. We may decompose the torsion scalar in the ADM variables[18] lapse $\alpha$, shift $\beta^i$ and the spatial components of the tetrad $\theta^A{}_i$:

$$\begin{aligned} \mathbb{T} = {} & \frac{1}{2\alpha^2}T^A{}_{i0}T^B{}_{j0}M^{i\ j}_{\ A\ B} \\ & + \frac{1}{\alpha^2}T^A_{i0}T^B_{kl}\left[M^{i\ l}_{\ A\ B}\beta^k + 2\alpha a_2 h^{il}\xi_B\theta_A{}^k + 2\alpha a_3 h^{il}\xi_A\theta_B{}^k\right] \\ & + \frac{1}{\alpha^2}T^A{}_{ij}T^B{}_{kl}\left[\frac{1}{2}M^{\ i\ k}_{A\ B}\beta^j\beta^l + 2\alpha a_2 h^{jl}\xi_A\theta_B{}^i\beta^k + 2\alpha a_3 h^{jl}\xi_A\theta_B{}^k\beta^i\right] + {}^3\mathbb{T}, \end{aligned} \tag{4}$$

where $h_{ij} = \theta^A{}_i\theta^B{}_j\eta_{AB}$ is the induced metric, which is used to raise and lower spatial indices, $\xi^A = -\frac{1}{6}\epsilon^A{}_{BCD}\theta^B{}_i\theta^C{}_j\theta^D{}_k\epsilon^{ijk}$ ,

$$M^{i\ j}_{\ A\ B} = -2a_1 h^{ij}\eta_{AB} + (a_2 + a_3)\xi_A\xi_B h^{ij} - a_2\theta_A{}^j\theta_B{}^i - a_3\theta_A{}^i\theta_B{}^j, \tag{5}$$

and

$$\begin{aligned} {}^3\mathbb{T} \equiv {} & a_1\eta_{AB}T^A{}_{ij}T^B{}_{kl}h^{ik}h^{jl} + a_2\eta_{AC}\theta^C{}_m h^{im}\eta_{BD}\theta^D{}_p h^{jp}T^A{}_{kj}T^B{}_{li}h^{kl} \\ & + a_3\eta_{AC}\theta^C{}_m h^{im}\eta_{BD}\theta^D{}_p h^{jp}h^{kl}T^A{}_{ki}T^B{}_{lj}. \end{aligned} \tag{6}$$

Without any loss of generality[7] we can restrict ourselves to the Weitzenböck gauge for which the torsion components are expressed as $T^A{}_{\mu\nu} = \partial_\nu\theta^A{}_\mu - \partial_\mu\theta^A{}_\nu$, and hence the conjugate momenta become,

$$\alpha\frac{\pi^i_A}{\sqrt{h}} = T^B_{j0}M^{i\ j}_{\ A\ B} + T^B_{kl}\left[M^{i\ l}_{\ A\ B}\beta^k + 2\alpha a_2 h^{il}\xi_B\theta_A{}^k + 2\alpha a_3 h^{il}\xi_A\theta_B{}^k\right]. \tag{7}$$

The velocities can now be inverted and expressed in canonical variables using

$$S_A^i = \dot{\theta}^B_{\ j} M^{i\ \ j}_{\ A\ B}, \tag{8}$$

with

$$\begin{aligned} S_A^i = & D_j \left(\alpha \xi^B + \beta^m \theta^B_{\ m}\right) M^{i\ \ j}_{\ A\ B} \\ & - T^B_{kl} \left[M^{i\ \ l}_{\ A\ B} \beta^k + 2\alpha a_2 h^{il} \xi_B \theta_A^{\ k} + 2\alpha a_3 h^{il} \xi_A \theta_B^{\ k}\right] + \alpha \frac{\pi_A^i}{\sqrt{h}}, \end{aligned} \tag{9}$$

where $D_i$ is the Levi-Civita covariant derivative with respect to the induced metric. However, $M$ in equation (8) is singular for certain combinations of parameters of the theory and can hence only be inverted by the Moore-Penrose pseudo-inverse matrix[12]. This is apparent if one decomposes the equation into irreducible representations of the rotation group, which generates the following constraints,

$$2a_1 + a_2 + a_3 =: {}^{\mathcal{V}}A = 0 \implies {}^{\mathcal{V}}C^i := S_A^i \xi^A = 0, \tag{10}$$

$$2a_1 - a_2 =: {}^{\mathcal{A}}A = 0 \implies {}^{\mathcal{A}}C_{ij} := S_A^k \theta^A_{\ [j} h_{i]k} = 0, \tag{11}$$

$$2a_1 + a_2 =: {}^{\mathcal{S}}A = 0 \implies {}^{\mathcal{S}}C_{ij} := S_A^k \theta^A_{\ (j} h_{i)k} - \frac{1}{3} S_A^k \theta^A_{\ k} h_{ij} = 0, \tag{12}$$

$$2a_1 + a_2 + 3a_3 =: {}^{\mathcal{T}}A = 0 \implies {}^{\mathcal{T}}C := S_A^i \theta^A_{\ i} = 0. \tag{13}$$

These are primary constraints, since these constrain both the tetrad field and their conjugate momenta, which also can be decomposed into irreducible parts. In the axial, vector, tensor decomposition we have that

$$2c_2 + c_3 \propto {}^{\mathcal{V}}A = 0, \tag{14}$$

$$2c_1 + c_2 \propto {}^{\mathcal{A}}A = 0, \tag{15}$$

$$c_2 \propto {}^{\mathcal{S}}A = 0, \tag{16}$$

$$c_3 \propto {}^{\mathcal{T}}A = 0. \tag{17}$$

In this language the primary constraints get some further geometrical meaning. Equations (14) and (15) together imposes the teleparallel equivalent to general relativity and impose invariance of the Lagrangian under pure tetrad local Lorentz transformations[9]. This is, however, not more apparent from the axial, vector, tensor decomposition we made. What is more interesting are the constraints imposed by equations (16) and (17). In this decomposition of the torsion scalar they exactly correspond to putting $T_{\text{ten}}$ and $T_{\text{vec}}$ to zero respectively.

## 4. Results

Different combinations of (10)-(13) yield 9 non-trivial classes of theories:

| Theory | Constraints | Location in figure 1 |
|---|---|---|
| $A_I \neq 0 \; \forall I \in \{\mathcal{V}, \mathcal{A}, \mathcal{S}, \mathcal{T}\}$ | No constraints | white area |
| $A_\mathcal{V} = 0$ | ${}^\mathcal{V}C_i = 0$ | red line |
| $A_\mathcal{A} = 0$ | ${}^\mathcal{A}C_{ji} = 0$ | black line |
| $A_\mathcal{S} = 0$ | ${}^\mathcal{S}C_{ji} = 0$ | vertical green line |
| $A_\mathcal{T} = 0$ | ${}^\mathcal{T}C = 0$ | horizontal blue line |
| $A_\mathcal{V} = A_\mathcal{A} = 0$ | ${}^\mathcal{V}C_i = {}^\mathcal{A}C_{ji} = 0$ | turquoise point |
| $A_\mathcal{A} = A_\mathcal{S} = 0$ | ${}^\mathcal{A}C_{ji} = {}^\mathcal{S}C_{ji} = 0$ | purple points (perimeter) |
| $A_\mathcal{A} = A_\mathcal{T} = 0$ | ${}^\mathcal{A}C_{ji} = {}^\mathcal{T}C = 0$ | orange point |
| $A_\mathcal{V} = A_\mathcal{S} = A_\mathcal{T} = 0$ | ${}^\mathcal{V}C_i = {}^\mathcal{S}C_{ji} = {}^\mathcal{T}C = 0$ | gray point (center) |

Any other solutions would be trivial ($c_1 = c_2 = c_3 = 0$). Excluding these trivial solutions we can normalize our parameters to

$$\tilde{c}_i = \frac{c_i}{\sqrt{c_1^2 + c_2^2 + c_3^2}}, \tag{18}$$

for $i = 1, 2, 3$, which means that we can make a 2-dimensional plot to visualize these theories in the normalized parameter-space. This can be nicely visualized in polar coordinates $(\theta, \phi)$ on the unit sphere with

$$\tilde{c}_1 = \cos\theta, \quad \tilde{c}_2 = \sin\theta\cos\phi, \quad \tilde{c}_3 = \sin\theta\sin\phi. \tag{19}$$

Every pair of antipodal points on the sphere corresponds to a ray in the 3-dimensional parameter space, whose elements describe the same theory. Hence, it suffices to display only the upper half sphere $\tilde{c}_1 \geq 0$, which is done in figure 1. However, note that points on the equator $\tilde{c}_1 = 0$ still appear twice, and both copies should be identified with each other. This applies in particular to the two purple points in figure 1, both describing the class of theories defined by pure vector torsion $\tilde{c}_1 = \tilde{c}_2 = 0$. The Hamiltonian is found to always appear with four Lagrange multipliers (linearity in lapse and shifts) with,

$$H = \alpha\mathcal{H}\left(\theta, M^{-1}\right) + \beta^k\mathcal{H}_k\left(\theta, M^{-1}\right) + D_i\left[\left(\alpha\xi^A + \beta^j\theta^A_{\ j}\right)\pi^i_A\right], \tag{20}$$

in the unconstrained case[7].

## 5. Discussion

One can distinguish 9 different classes of NGR theories by the presence or absence of primary constraints appearing in their Hamiltonian formulation. What remains to be determined is how many secondary constraints are induced by demanding closure of the constraint algebra. Some considerations in this direction have been studied in[6,18], however, our work invites for further investigation. The theories satisfying $A_I \neq 0, \forall\ I \in \{\mathcal{V}, \mathcal{A}, \mathcal{S}, \mathcal{T}\}$ can be parameterized by two free parameters (and a global rescaling of the Lagrangian, fixing the value of the Planck mass, which does not affect the presence or absence of primary constraints). Models which exhibit one primary constraint $A_I = 0$ have one free parameter left, while for those with

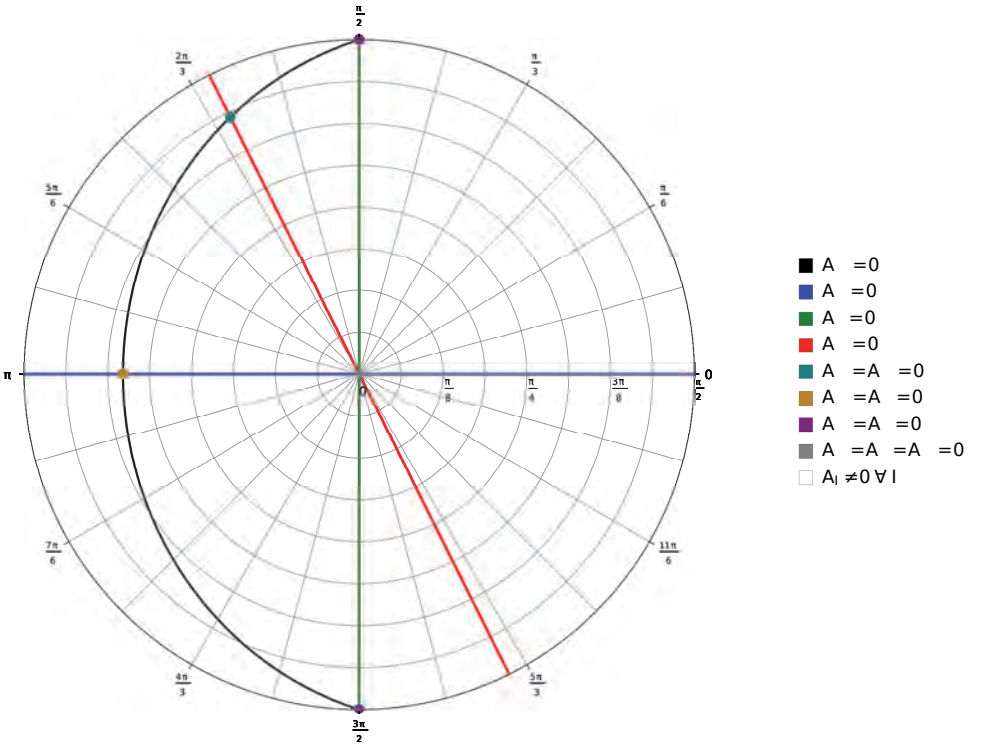

Fig. 1. Visualization of the parameter space of new general relativity in coordinates reflecting the axial, vector, tensor decomposition of the Lagrangian, colored by the occurrences of primary constraints. The radial axis shows the zenith angle $\theta$, while the (circular) polar axis shows the azimuth angle $\phi$, following the definition (19).

more primary constraints all parameters are fixed. The free parameters might affect the vanishing, or non-vanishing of certain Poisson brackets, which therefore have to be calculated in order to obtain the number of degrees of freedom.

The number of degrees of freedom can be compared with polarization modes in gravitational waves[20]. Furthermore, it can be compared with the linear level in order to find out if the theories are strongly coupled. One may extend this analysis to $f(T_{\rm ax}, T_{\rm ten}, T_{\rm vec})$[19] or include parity violating terms.

*E-mail: lbuoninfante@sa.infn.it*

In this short paper we study how black hole singularities can be tackled in the context of nonlocal ghost-free gravity, in which the action is characterized by the presence of non-polynomial differential operators containing infinite order covariant derivatives. The ghost-freeness condition can be preserved by requiring that such nonlocal operators are made up of exponential of entire functions, thus avoiding the emergence of extra unhealthy poles in the graviton propagator. We will mainly focus on how infinite order derivatives can regularize the singularity at the origin by making explicit computations in the linear regime. In particular, we will show that this kind of non-polynomial operators can smear out point-like distribution and that the Schwarzschild metric can not be a solution of the field equations in the ghost-free infinite derivative gravity.

*Keywords*: : Nonlocal gravity; higher-derivative gravity; quantum gravity; spacetime singularities; black holes.

## 1. Introduction

Gravitational theories whose actions are made up of terms quadratic in the curvature invariants, besides the Einstein-Hilbert piece, are perturbatively renormalizable[1], but incomplete due to the presence of a massive spin-2 ghost mode which makes the Hamiltonian unstable at the classical level classically, while from a quantum mechanical point of view breaks the unitarity condition[a].

The problem of ghosts in higher derivative theories has been known for long time[9], but only recently it was realized that the emergence of pathological degrees of freedom can be prevented when the order of the derivatives in the action is not finite but *infinite*. Indeed, by choosing certain non-polynomial analytic differential operators in the action one can preserve the number of physical degrees of freedom of the local theory, without introducing any unhealthy mode[10–13]. Having non-polynomial operators means that the order of derivatives is infinite and this makes the action *nonlocal*.

In Refs.[14–17], this kind of non-polynomial operators were used in a gravitational context to construct a quadratic curvature theory of gravity which is classically stable and unitary at the quantum level. It was noticed that the presence of nonlocality through infinite order derivatives can regularize infinities and many progresses ave been made in order to resolve black hole[15,16,18–29] and cosmological[14,30–33] singularities. At the quantum level, this class of ghost-free shows an improved UV behaviour[15,34–36] but the renormalizability has been shown only for

[a]See Refs.[2–6,8,8], and references therein, for astrophysical and cosmological applications involving quadratic curvature gravitational actions.

a peculiar subclass of non-polynomial operators[35]; see also Refs.[34,37–40] for nonlocal extensions of the standard model of particle physics, and Refs.[41,42] for applications beyond standard quantum mechanics.

In this manuscript we will review the main aspects regarding avoidance of singularities in ghost-free infinite derivative gravity, showing how infinite order derivatives can smear out point-like sources and, thus, regularize singularities. The paper is organized as follows: in Section 2, we introduce the gravitational action and, by working in the linear regime, we derive the form of the spacetime metric for a static point-like source; in Section 3 we show the regularizing properties of infinite derivative operators and explain why the Schwarzschild metric can not be a solution in ghost-free nonlocal gravity.

Throughout the paper we work in Natural Units, $\hbar = 1 = c$, and adopt the mostly positive metric convention, $\eta = \mathrm{diag}(-1, +1, +1, +1)$.

## 2. Nonlocal gravitational action and linearized metric solution

For simplicity we will only work with one of the simplest model of quadratic nonlocal gravity which captures all the relevant properties of nonlocality. Let us consider the following gravitational action[15,16,18]

$$S = \frac{1}{2\kappa^2}\int d^4x\sqrt{-g}\,\{\mathcal{R} + G_{\mu\nu}\mathcal{F}(\Box)\mathcal{R}^{\mu\nu}\}\,, \tag{1}$$

where $G_{\mu\nu} = \mathcal{R}_{\mu\nu} - g_{\mu\nu}\mathcal{R}/2$ is the Einstein tensor, $\kappa^2 \equiv 8\pi G$ with $G = 1/M_p^2$ being the Newton constant.

In local theories the form factor $\mathcal{F}(\Box)$ is a polynomial of $\Box$, while in the case of nonlocal theories it is a non-polynomial function of $\Box$. We consider one of the simplest example[16]:

$$\mathcal{F}(\Box) = \frac{1 - e^{-\Box/M_s^2}}{\Box} \tag{2}$$

which is analytic and modify the short-distance (UV) behavior of Einstein's GR as only positive power of $\Box$ appear when Taylor expanding; $M_s$ is needed to make the argument of the exponential dimensionless, while from a physical point of view it is a new fundamental energy scale at which nonlocal effects should manifest.

If we perturb the Minkowski metric by small a perturbation,

$$g_{\mu\nu} = \eta_{\mu\nu} + \kappa h_{\mu\nu}\,, \tag{3}$$

where $h_{\mu\nu}$ is the graviton perturbation, the action can be written up to order $\mathcal{O}(h_{\mu\nu}^2)$ as follows[16]:

$$S^{(2)} = \frac{1}{4}\int d^4x\, h_{\mu\nu}\, e^{-\Box/M_s^2}\mathcal{O}^{\mu\nu\rho\sigma}\, h_{\rho\sigma}, \tag{4}$$

where

$$\begin{aligned}\mathcal{O}^{\mu\nu\rho\sigma} \equiv{}& \frac{1}{4}\left(\eta^{\mu\rho}\eta^{\nu\sigma} + \eta^{\mu\sigma}\eta^{\nu\rho}\right)\Box - \frac{1}{2}\eta^{\mu\nu}\eta^{\rho\sigma}\Box \\ &+\frac{1}{2}\left(\eta^{\mu\nu}\partial^\rho\partial^\sigma + \eta^{\rho\sigma}\partial^\mu\partial^\nu - \eta^{\mu\rho}\partial^\nu\partial^\sigma - \eta^{\mu\sigma}\partial^\nu\partial^\rho\right)\end{aligned} \tag{5}$$

is a four-rank operator $\mathcal{O}^{\mu\nu\rho\sigma}$ which is totally symmetric in all its indices. By inverting the kinetic operator $e^{-\Box/M_s^2}\mathcal{O}^{\mu\nu\rho\sigma}$ one can obtain the graviton propagator around Minkowski; see Refs. [10,13,15,16,43,44] for details. While, by variating the action in Eq. (4) we obtain the linearized field equations, which we wish to solve in presence of a Delta Dirac distribution placed at $r = 0$, i.e. the stress-energy tensor is given by $T_{\mu\nu} = m\delta^0_\mu\delta^0_\nu\delta^{(3)}(\vec{r})$. By working in the conformal Newtonian gauge, we can write the perturbed metric (3) in isotropic coordinates as follows:

$$ds^2 = -(1 + 2\Phi(r))dt^2 + (1 - 2\Psi(r))(dr^2 + r^2 d\Omega^2), \tag{6}$$

where $r = \sqrt{x^2 + y^2 + z^2}$ is the isotropic radial coordinate, so that the field equations reads

$$e^{-\nabla^2/M_s^2}\nabla^2\Phi = e^{-\nabla^2/M_s^2}\nabla^2\Psi = 4\pi G\delta^{(3)}(\vec{r}) \tag{7}$$

where $T \equiv \eta^{\mu\nu}T_{\mu\nu}$, and we have used $\kappa h_{00} = -2\Phi$, $\kappa h_{ij} = -2\Psi\delta_{ij}$, $\kappa h = 2(\Phi - 3\Psi)$ and $\Box \simeq \nabla^2$.

The infinite derivative differential equation in Eq. (7) can be easily solved by going to Fourier space and then anti-transforming back to coordinate space:

$$\Phi(r) = \Psi(r) = -4\pi Gm\int d^3k\frac{e^{-k^2/M_s^2}}{k^2}e^{i\vec{k}\cdot\vec{r}} = -\frac{Gm}{r}\mathrm{Erf}\left(\frac{M_s r}{2}\right), \tag{8}$$

where $\mathrm{Erf}(x) := \frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt$ is the so called error-function.

The gravitational potential in Eq. (8) turns out to be non-singular at $r = 0$, $\Phi(0) = 2GmM_s/\sqrt{\pi} < \infty$; while for large distances it reduces to Newton's law $\Phi(r) \sim -Gm/r$, as expected. From a physical point of view, nonlocality is able to regularize the point-like source at $r = 0$ smearing it out on a region of size $1/M_s$ thanks to the infinite order derivatives. Also, the linearized curvature invariants turn out to be non-singular at $r = 0$; in particular, the metric becomes conformally-flat, since all the components of the Weyl tensor vanish at the origin [23].

## 3. Towards non-linear and non-singular metric solutions

The metric solution in Eq. (8) is linear and says nothing about the non-linear regime where singularity may still appear. We now wish to move towards the non-linear regime and explain why nonlocality may help also in this case, in particular we want to understand whether the Schwarzschild singularity is admissible in ghost-free nonlocal gravity.

First of all, let us remind that in Einstein's general relativity the Schwarzschild metric, whose components contain the mass $m$, is derived by imposing a boundary condition at the origin, i.e. by putting a delta-Dirac distribution at $r = 0$, which means that on the right-hand side of the Einstein field equations we have vacuum everywhere except at $r = 0$ [45]. Indeed, strictly speaking the Schwarzschild metric is not a vacuum solution of the Einstein's field equation.

To check whether the Schwarzschild metric is a solution in ghost-free infinite derivative gravity we need to substitute $\mathcal{R} \sim \delta^{(3)}(\vec{r})$ and $\mathcal{R}_{\mu\nu} \sim \delta^{(3)}(\vec{r})$ in the full non-linear field equations[18]. In such a case, we do not obtain exactly zero on the left-hand side but we will have some complicated expression involving derivatives of delta. For example, in a fourth order theory of gravity one would generate up to third order derivatives of the delta-Dirac, so that the Schwarzschild metric is still an exact solution which couples to a more complicated point-source which is not just a simple delta, and is not positive definite, which means that it is not a physical solution. We can understand this feature by looking at the linear regime for the action in Eq. (1). The modified Poisson equation for the gravitational potential would be of the following kind:

$$[1 - \mathcal{F}(\nabla^2)\nabla^2]\nabla^2\Phi(r) = 4\pi G\rho(r). \tag{9}$$

In fourth order gravity we have a constant form-factor $\mathcal{F}(\Box) = -\alpha$, with $\alpha > 0$, from which it is clear that there always exists a source which generates the Schwarzschild solution, $\Phi(r) \sim 1/r$, and such a source is given by

$$\rho(r) = \frac{1}{4\pi G}[1 + \alpha\nabla^2]\nabla^2\left(-\frac{Gm}{r}\right) = -\frac{m}{2\pi r}\left[\delta'(r) + \alpha\,\delta'''(r)\right] \tag{10}$$

which is not positive defined. A similar scenario will also hold for any local higher derivative theory of gravity: for any gravitational theory with a polynomial form factor $\mathcal{F}$ there exist always a source which generates a the $1/r$ Schwarzschild singularity. For instance, in sixth order gravity, $\mathcal{F}(\Box) = -\alpha\Box$, the $1/r$ potential is generated by the density distribution $\rho(r) = -m/(2\pi r)[\delta'(r) + \alpha\,\delta^{(5)}(r)]$.

In ghost-free infinity derivative gravity, the form factor is a non-polynomial function, therefore one has infinite order derivatives acting on $1/r$, or in other words, by looking at the full field equations they will act on the Schwarzschild curvature $\mathcal{R} \sim \delta^{(3)}(\vec{r})$. Unlike the local scenario in which we have a finite number of terms, nonlocal differential operators would generated a complicated expression on the left-hand side involving infinite order derivatives of the delta-Dirac, which generically would not correspond to a point-like source but to an object with a non-point support.

A-priori the Schwarzschild metric could be still a solution but coupled to a source which is not point-like. However, we argue that in infinite derivative gravity there exist *no* source which can couple to the Schwarzschild metric. We have a strong hint coming from the linear regime in favour of our claim. Indeed, by looking at the modified Poisson equation in Eq. (9) with the form factor in Eq. (2) and using the method of Fourier transform, we obtain:

$$\rho(r) = \frac{1}{4\pi G}e^{-\nabla^2/M_s^2}\left(-\frac{Gm}{r}\right) = \frac{1}{2\pi^2 r}\int_0^\infty dk\,k\sin(k\,r)\,e^{+k^2/M_s^2} = \infty. \tag{11}$$

From the last equation, we can notice that, at least in the linear regime, it is impossible to define any source $\rho(r)$ which can generated the Schwarzschild metric

with $1/r$ behaviour. In fact, the only option could be $\rho(r) \sim e^{-\nabla^2/M_s^2}\delta(\vec{r})$, but it turns out that it cannot be mathematically defined since $e^{-\nabla^2/M_s^2}\delta(\vec{r}) = \infty$.

Hence, non-locality through infinite order derivatives does not allow the Schwarzschild metric as an exact solution, and this is a very strong hint which allow us to claim that the same feature will be also present in the full non-linear regime[25]; see also Ref.[46] for further developments regarding the non-linear level.

The Horizon Quantum Mechanics allows one to analyse the gravitational radius of spherically symmetric systems and compute the probability that a given quantum state is a black hole. We first review the global formalism and show that it reproduces a gravitationally inspired GUP relation but also leads to unacceptably large fluctuations in the horizon size of astrophysical black holes if one insists in describing them as (smeared) central singularities. On the other hand, if they are extended systems, like in the corpuscular models, no such issue arises and one can in fact extend the formalism to include asymptotic mass and angular momentum with the harmonic model of rotating corpuscular black holes. The Horizon Quantum Mechanics then shows that, in simple configurations, the appearance of the inner horizon is suppressed and extremal (macroscopic) geometries seem highly disfavoured.

*Keywords*: Black holes; Quantum physics

## 1. HQM for spherical sources

The world as we know it, is best described by quantum physics, and black holes should be represented as quantum objects as well. A first non-trivial question that follows is how much of the classical description of black holes given by general relativity we can still keep at the quantum level. One feature that should presumably live up into the quantum realm is that black holes are "gravitational bound states". Nonetheless, most of the existing literature simply analyses quantum effects on classical black hole space-times, and the proper quantum nature of the background itself is not fully accounted for. Finally, one might notice that a classical quantity that characterises such bound states (in the particular case when spherical symmetry is preserved) is the so called "gravitational radius",

$$R_{\rm H} = 2\,G_{\rm N}\,M\ , \tag{1}$$

where $M$ here can be the local Misner-Sharp mass $M = M(r)$ or the total ADM mass of the system. A quantum treatment of the gravitational radius could therefore be a good starting point for developing a fully quantum theory of black holes, much like quantising the position of the electron proved to be a good starting point for a quantum description of the hydrogen atom.

The Horizon Quantum Mechanics (HQM)[1–13] was precisely proposed with the purpose of describing the gravitational radius of spherically symmetric compact sources and for determining the existence of a horizon in a quantum mechanical fashion. In a classical spherically symmetric system, the gravitational radius (1) uniquely determines the location of the trapping surfaces where the null geodesic expansion vanishes. The latter surfaces are proper horizons in a time-independent configuration, which is the case we shall consider here for simplicity. It is then straightforward to uplift this description of the causal structure of space-time to the quantum level by simply imposing the relation between the gravitational radius and the Misner-Sharp mass as a constraint to be satisfied by the physical states of the system[2], that is

$$0 = \left( \hat{M} - \frac{\hat{R}_{\rm H}}{2\,G_{\rm N}} \right) \mid \Psi \,\rangle = \sum_{\alpha,\beta} \left( E_\alpha - \frac{R_{{\rm H}\beta}}{2\,G_{\rm N}} \right) C(E_\alpha, R_{{\rm H}\beta}) \mid E_\alpha \,\rangle \mid R_{{\rm H}\beta} \,\rangle \ , \tag{2}$$

where $\mid E_\alpha \,\rangle$ are eigenstates "Hamiltonian" operator $\hat{M}$, that is

$$\hat{M} = \sum_\alpha E_\alpha \mid E_\alpha \,\rangle\langle\, E_\alpha \mid \ , \tag{3}$$

and likewise $\mid R_{{\rm H}\alpha} \,\rangle$ are eigenstates of the gravitational radius operator,

$$\hat{R}_{\rm H} = \sum_\alpha R_{{\rm H}\alpha} \mid R_{{\rm H}\alpha} \,\rangle\langle\, R_{{\rm H}\alpha} \mid \ . \tag{4}$$

Solutions to the constraint (2) are given by

$$C(E_\alpha, R_{{\rm H}\beta}) = C(E_\alpha, 2\,G_{\rm N}\,E_\alpha)\,\delta_{\alpha\beta} \equiv C_{\rm S}(R_{{\rm H}\alpha}/2\,G_{\rm N})\,\delta_{\alpha\beta} \ , \tag{5}$$

and one can then define the horizon wave-function (HWF)[1] as

$$\psi_{\rm H}(R_{{\rm H}\alpha}) = \langle\, R_{{\rm H}\alpha} \mid \psi_{\rm H} \,\rangle = C_{\rm S}(R_{{\rm H}\alpha}/2\,G_{\rm N}) \ . \tag{6}$$

Once the HWF is introduced, one can define the probability that a given source with position wave-function $\psi_S = \psi_S(r)$ is a black hole as

$$P_{\rm BH} = \int_0^\infty \mathcal{P}_<(r < R_{\rm H})\,{\rm d}R_{\rm H} \ , \tag{7}$$

where $\mathcal{P}_<(r < R_{\rm H}) = P_{\rm S}(r < R_{\rm H})\,\mathcal{P}_{\rm H}(R_{\rm H})$ is the probability density that the source is found within its gravitational radius. The latter is in turn defined in terms of the probability

$$P_{\rm S}(r < R_{\rm H}) = 4\,\pi \int_0^{R_{\rm H}} |\psi_{\rm S}(r)|^2\,r^2\,{\rm d}r \tag{8}$$

that the source lies inside the radius $r = R_{\rm H}$ and the probability density

$$\mathcal{P}_{\rm H}(R_{\rm H}) = 4\,\pi\,R_{\rm H}^2\,|\psi_{\rm H}(R_{\rm H})|^2 \tag{9}$$

that $R_{\rm H}$ equals the gravitational radius.

Beside formal developments, we have applied the HQM to specific states of the harmonic black hole model[14], which can be considered as a working realisation of the corpuscular black holes proposed by Dvali and Gomez[15]. If the black hole contains only one quantum constituent, with energy $M \simeq \hbar/\lambda$, where $\lambda$ is the Compton length of the constituent, the results is a black hole only provided $\lambda \lesssim \ell_{\rm p}$ (the Planck length), corresponding to a mass $M \gtrsim m_{\rm p}$ (the Planck mass). For this case one also recovers a Generalised Uncertainty Principle[3]

$$\Delta r \sim \frac{\hbar}{\Delta p} + \Delta R_{\rm H} \sim \frac{\hbar}{\Delta p} + \Delta p\ , \tag{10}$$

and a quantum hoop conjecture[4]. However, the fluctuations in the horizon size are given by

$$\langle\,\Delta \hat{R}_{\rm H}^2\,\rangle \sim \lambda^{-2} \sim \Delta p^2\ , \tag{11}$$

which becomes extremely large for macroscopic black holes with $M \simeq \hbar/\lambda \gg m_{\rm p}$. This result supports the idea that a black hole must instead be made by a large number $N$ of constituents of energy $\varepsilon \simeq \hbar/\lambda$ (such that $M \simeq N\,\varepsilon \sim \sqrt{N}\,m_{\rm p}$ and $\lambda \sim R_{\rm H} \sim \sqrt{N}\,\ell_{\rm p}$). For the latter case, horizon fluctuations can be very small, of order $1/N$, and the quantum harmonic model is simple enough that one can determine explicitly the probability that the chosen states are indeed black holes[16].

## 2. HQM for rotating sources

In a space-time generated by an axially-symmetric rotating source, we exploit the fact that the asymptotic behaviour of the system is described by the Kerr metric. We can then uplift to a quantum condition for the physical states the classical relation that determines the two horizon radii

$$R_\pm = M \pm \sqrt{M^2 - a^2} \tag{12}$$

from the mass $M$ and angular momentum $J = a^2\,M^2$ of the source which holds in the (asymptotic) Kerr metric[10]. The formalism described in the previous section now doubles with the introduction of two gravitational radius operators, $\hat{R}_\pm$, and corresponding HWF's we can denote as $\psi_\pm = \psi_{\rm H}(R_\pm)$. The probability $P_{\rm BH} = P_+$ that the whole source is a black hole is then obtained from $\psi_+$, and the probability $P_-$ that the inner horizon is also realised is likewise determined from $\psi_-$.

The harmonic black hole model[14] also allows one to compute the above two probabilities for states of a large number $N$ of gravitons with non-vanishing total angular momentum[10]. The main result is that, for extremal configurations with $M^2 \simeq a^2$, one finds

$$P_+ \simeq P_{1+}^N \ll 1\ , \tag{13}$$

where $P_{1+} \lesssim 1$ is the probability that each constituent is inside $R_+$. For instance, we typically obtain $P_1 \simeq 0.7$ and, since $N \sim M^2/m_{\rm p}^2 \gg 1$ for astrophysical sources, it appears that such configurations are very unlikely to have a horizon and be black holes. Moreover, the inner horizon $R_-$ also has a small probability to exist for large sources, to wit

$$P_- \simeq P_{1-}^N \ll 1 \,, \tag{14}$$

where now $P_{1-} \ll 1$ is the probability that each constituent is inside the inner horizon $R_-$. A typical value is $P_{1-} \simeq 0.05$ and $N \gg 1$.

The overall conclusion is that quantum fluctuations for rotating geometries, although negligibly small for the horizon of non extremal configurations, appear to be large enough to spoil the causal structure of extremal configurations and eliminate the presence of inner horizons. We recall that the latter are in fact rather problematic in the semiclassical description, because of the effect called mass inflation[17]. We remark that the HQM seems to provide a solution to this problem in general, since the inner horizon is removed also for electrically charged sources[5].

**E-mail: claudio.ditroia@enea.it*

The curve in space occupied by the mass during time evolution, is a geodesic on the space-time manifold curved by the presence of masses: the mass can only follow its trajectory consistently with the underlying gravitational field. Is it possible to think at the charge trajectory in a similar fashion? Is it possible to say that the charge trajectory, the curve in phase-space occupied by the charge during time evolution, is the geodesic on the extended phase-space curved by the presence of charges? If yes then it should be possible to obtain an Einstein's equation also for electromagnetism. This is done by considering a metric on the whole extended phase-space, which is the phase-space $(x, v)$ plus the time, $t$. It is proposed to add a Hilbert-Einstein term in the lagrangian when velocities are considered as dynamical variables. Here, it will be analyzed what happens if the (non perturbative) guiding center description of motion is adopted [1]. In such case, a similar mechanism to the one proposed by Kaluza and Klein (KK) [3,4] a century ago is found. The advantage of using the present description is that, now, there is no need of looking for a compactification scheme as required in the original KK mechanism. Indeed, the extra-dimension that appears in the guiding center transformation is a physical and, in principle, measurable variable being the gyro-phase, the angle obtained when the velocity space is described by a sort of cylindrical transformation of velocities coordinates. Regardless of the equations that are really similar to the one seen in the KK mechanism, the new claim is in the interpretation of the extra dimension as a coordinate coming from the velocity space. Until now, all the compactification mechanisms have been shown to give problems, like the inconsistency of the scale of masses with observations. Instead, without a compactification at the Planck scale length and giving a physical meaning to the extra-coordinate, it seems that the KK mechanism can finally be accepted as a realistic explanation of the presence of gravitation and electromagnetism treated in a unified manner in general relativity theory extended to higher dimensions.

*Keywords*: Kaluza Klein, Guiding Center Transformation, Einstein's equation in higher dimensions

## 1. Introduction

The thesis of the present work is that through the guiding center transformation [1,2] it is possible to support the Kaluza-Klein model [3–6] without the need to use new physical dimensions with respect to those of the phase space extended to time, $(t, x, v)$. What turns out is that the extra dimension comes from the velocity space. There are two constants of motion, the single particle lagrangian that does not change value with respect to the guiding center transformation and the magnetic moment, $\mu$, that does not change value with respect to the variation of the gyrophase, $\gamma$. In the non perturbative guiding center transformation it is assumed that there exist a reference point, the guiding center $(X, U)$, from where the particle motion is seen to be closed and periodic. Thus the motion of a charged particle is represented by the product of the guiding center orbit times the circle with gyroradius, $\rho$. Such

helicoidal motion is implicitly written in a flat phase space as

$$x = X + \rho(t, X, \gamma; \mu, \varepsilon) \tag{1}$$
$$u = U(t, X; \mu, \varepsilon) + \nu(t, X, \gamma; \mu, \varepsilon),$$

where, $\varepsilon$ is the energy, $u = x'$ is the relativistic velocity of the particle, $U = X'$ is the relativistic velocity of the guiding center and $\nu = \rho'$ is the difference of the formers or the proper time derivative of the gyroradius. The relativistic lagrangian is:

$$L = -p_\alpha u^\alpha, \tag{2}$$

being the co-momentum $p_\alpha = u_\alpha + (e/m)A_\alpha(x^\beta)$, with $A_\alpha$ the e.m. potential. Also the guiding center has a co-momentum defined as $P_\alpha = U_\alpha + (e/m)A_\alpha(X^\beta)$, in such a way that the lagrangian in (2) is

$$L = -p_\alpha u^\alpha = -P_\alpha U^\alpha - (e/m)g'. \tag{3}$$

If the gauge function $g$ is proportional to the product of the magnetic moment, $\mu$, times the gyro-phase, $\gamma$, it is called the *guiding center gauge function* : $g = (m/e)\mu\gamma$. Such gauge function doesn't alter the equation of motion but it is useful for preserving the same value of the lagrangian along the motion. The link with the KK model starts from denoting the values $z^0 = t$, $z = X$, $z^4 = \gamma$ and $w_0 = P_0 = U_0 + (e/m)\Phi$, $w = P = U + (e/m)A$ and $w_4 = (m/e)\mu$, then

$$L = -w_a z'^a, \qquad \text{for a=0,1,2,3,4.} \tag{4}$$

which is equivalent to a scalar product in a space-time of five dimensions. Moreover, if you require that $w_5 = w_6 = 0$ and $z^5 = \mu$, $z^6 = \varepsilon$ is the particle energy (per unitary mass), then you can also write

$$L = -w_A z'^A, \qquad \text{for A=0,1,2,3,4,6.} \tag{5}$$

The latter is what is called the phase-space lagrangian from which it is possible to find the *Hamilton's equations*. It is better to denote with a *hat* the guiding center phase-space lagrangian: $L = \hat{L}(z^A, z'^B)$, for $A, B = 0, 1, 2, 3, 4, 6$. As said in[7], the reason for the vanishing of $w_5$ and $w_6$ is due to the fact that $\varepsilon$ is the conjugate coordinate of $t$ and $(m/e)\mu$ is the conjugate coordinate of $\gamma$.

Now, the lagrangian is invariant at a glance with respect to general non-canonical phase-space coordinates transformations, that include also the gauge transformations.

## 2. Kaluza-Klein solution

The coordinates $z^A$ with $A = 0, 1, 2, 3, 4, 5, 6$, just introduced, belong to the extended phase space, *e.g.* $z^A = (t, X, \gamma, \mu, \varepsilon)$ are the guiding center coordinates. As for general relativity, where a geometry is given to the space-time, in this section a geometry is given to the extended phase-space.

Let's start from the *Poincaré-Cartan* one-form from (5): $\hat{L}d\hat{s} = -w_A dz^A$, for $A = 0, 1, 2, 3, 4, 5, 6$. The same one-form can be written as

$$\hat{L}d\hat{s} = -\hat{g}_{AB} w^B dz^A, \tag{6}$$

being $\hat{L}$ a scalar quantity and where $\hat{g}_{AB}$ is the metric tensor on the extended phase-space with the property that $w_A \equiv \hat{g}_{AB} w^B$. Thus, $w^B$ are the *contra-variant* momenta. Once the metric tensor on the extended phase-space is appeared, it is possible to apply a variational principle for finding it. For this reason, we consider a *lagrangian density over the extended phase space* where the single particle lagrangian is multiplied for the distribution of masses and, then, added to the HE lagrangian in extended dimensions. In the following the lagrangian density on the extended phase-space is

$$\ell a = f_m \hat{L} - \frac{\hat{\mathcal{R}}}{16\pi\hat{G}}, \tag{7}$$

Thus, the action is:

$$S = \int \ell a \, d\mathcal{M}, \tag{8}$$

which is a definite integration in a domain $\partial\mathcal{M}$ of the extended phase space. In the guiding center transformation the volume element of the extended phase-space is $d\mathcal{M} = \tilde{J}_p dt d^3X d\gamma d\mu d\varepsilon$.

It is possible to separate in $\ell a$ the effects of different contributions: a *matter*, a *field* and an *interaction* lagrangian densities on the extended phase-space. Concerning the *field action*, $S_{\rm f}$, we have:

$$\begin{aligned} S_{\rm f} &= -\int \frac{\hat{\mathcal{R}}}{16\pi\hat{G}} \sqrt{|\hat{g}|} d^7 z = \\ &= -\int \frac{F_{\alpha\beta}F^{\alpha\beta}}{4} \sqrt{-g} dt d^3X - \int \frac{R}{16\pi G} \sqrt{-g} dt d^3X. \end{aligned} \tag{9}$$

In order to obtain the latter result the KK mechanism is applied setting the following fifth dimensional metric tensor:

$$\tilde{g}_{ab} = \begin{vmatrix} g_{\alpha\beta} - 16\pi G A_\alpha A_\beta & -16\pi G (m/e)^2 \mu A_\alpha \\ -16\pi G (m/e)^2 \mu A_\beta & -16\pi G (m/e)^4 \mu^2 \end{vmatrix}. \tag{10}$$

The gravitational constant, $\hat{G}$, is obtained from

$$\frac{\hat{G}}{G} = 4 \int (m/e)^2 \sqrt{\pi G} \mu \tilde{J}_{\mathcal{P}} d\gamma d\varepsilon d\mu. \tag{11}$$

At the same time, the action due to the interaction is

$$S_{\rm id} = \int f_m (1 + \hat{L}) \sqrt{|\hat{g}|} d^7 z = -\int A_\alpha J^\alpha \sqrt{-g} dt d^3X, \tag{12}$$

where $J^\alpha$ is the charge four-current density which is a field depending on $(t, X)$. Thus the sources of fields are the guiding centers. The former equation is obtained through the non perturbative guiding center transformation and through the *misleading* symmetry, below described. It is worth noticing that once integrated in the velocity space, the obtained lagrangian density is the one used for describing the presence of matter as source of a gravitational field, which gives the *Einstein*'s equation, together with a charge four-current density as source of an e.m. field, which gives the *Maxwell*'s equations. It is worth noticing that after the integration over the velocity space the model equations have lost locality, being $X$ the position of the guiding center and not of the particle. Without locality all the singularities of gravitation, *e.g.* the problems concerning black holes treated as singularities, and of electrodynamics, *e.g.* the self-energy problem, are ruled out.

Moreover, from (7) it is also possible to deduce a *Boltzmann*'s equation.

#### 2.0.1. Boltzmann*'s equation from geometry*

By writing $\hat{L} = s'$, as the proper time derivative of the *principal Hamilton function*, $s$, then it is possible to recognize a *Legendre*'s transformation in equation (7) that explicitly becomes

$$\ell a = f_m s' - \frac{\hat{\mathcal{R}}(f_m, s)}{16\pi\hat{G}}. \tag{13}$$

Surprisingly, the distribution of masses is the conjugate momentum of the single particle action. By varying such lagrangian density on extended phase-space with respect to $s$ and $s'$, then the *Euler-Lagrangian* equation is

$$f'_m = \frac{\nabla_s \hat{\mathcal{R}}}{16\pi\hat{G}}. \tag{14}$$

The former is a *Boltzmann*'s equation, describing the evolution of the distribution function, with a $RHS$ that depends on the geometry instead of a collision operator. However, it is not possible to arrive at a Fokker-Planck's equation without considering fluctuations, not considered here.

### 2.1. *The* misleading *symmetry*

In the relativistic case, it is chosen to preserve the product $u^\alpha A_\alpha(x^\beta) = U^\alpha A_\alpha(X^\beta)$ that allows to write $L = -1 - (e/m)u^\alpha A_\alpha(x^\beta) = \hat{L}$ with

$$\hat{L} = -1 - (e/m)U^\alpha A_\alpha(X^\beta), \tag{15}$$

which is the same form of $L$. The required condition is reached if

$$(m/e)\mu\gamma' = 1 - U^\alpha U_\alpha. \tag{16}$$

The latter relation is also more interesting if $(m/e)\mu\gamma' = U^4 U_4$, where $U^4 = z^{4\prime} = \gamma'$ and $U_4$ is firstly defined as $U_4 \equiv w_4 = (m/e)\mu$. In such way that

$$U^a U_a = 1, \qquad \text{for } a = 0, 1, 2, 3, 4. \tag{17}$$

Moreover, if the relation $w_a = U_a + (e/m)A_a$ is used, then $A_4 = 0$ for consistency: there is not a $5^{th}$ component of the e.m. potential. The symmetry that leaves invariant the form of $L = -1 - (e/m)u^\alpha A_\alpha(x^\beta) = -1 - (e/m)U^\alpha A_\alpha(X^\beta)$ is said *misleading* because there is no way, starting from the dynamics, *e.g.* from the lagrangian, to distinguish particle's coordinates from guiding center's coordinates. The only chance for appreciating the difference is by measuring the dispersion relation: from kinematics, the particle has $u^\alpha u_\alpha = 1$ whilst the guiding center doesn't, $U^\alpha U_\alpha \neq 1$, that means that the guiding center is a virtual particle. It is worth noticing that in such extended phase-space approach, the space-time is defined as the domain where the e.m. four-potential is defined, in such a way that electromagnetism occurs for separating the space-time where uncharged particles moves from the whole extended phase-space.

## 3. Conclusion

We have just seen that the guiding center transformation, which is a particular *local* translation in the extended phase space, *e.g.* see (1), is a symmetry because it leaves the same lagrangian form. In analogy to what happens for the *local* translation in spacetime, the conserved quantity for the present symmetry should be called the *extended energy-momentum* tensor $\hat{T}_{AB}$. Now, the *Einstein tensor* for the extended phase space is obtained from the variation of $-\hat{\mathcal{R}}/16\pi\hat{G}$ with respcet to $\delta\hat{g}^{AB}$:

$$\hat{G}_{AB} = \hat{Ric}_{AB} - \hat{R}\,\hat{g}_{AB}/2, \tag{18}$$

and the *Einstein equation* can be written also for the extended phase space,

$$\hat{G}_{AB} = 8\pi\hat{G}\,\hat{T}_{AB}. \tag{19}$$

It is worth noticing that, if confirmed, we have just obtained gravitation and electromagnetism from a geometrical perspective.

A little known symmetry group of Brans-Dicke gravity in the presence of conformally invariant matter (including electrovacuo) is used as a solution-generating technique, starting from a known solution as a seed. This novel technique is applied to generate, as examples, new spatially homogeneous and isotropic cosmologies, a 3-parameter family of spherical time-dependent spacetimes conformal to a Campanelli-Lousto geometry, and a family of cylindrically symmetric geometries.

*Keywords*: Brans-Dicke gravity, exact solutions, symmetry.

## 1. Introduction

Scalar-tensor gravity is the prototype theory alternative to general relativity (GR). The main motivation to modify gravity comes from cosmology: to explain the present acceleration of the universe, the GR-based ΛCDM model introduces a completely *ad hoc* dark energy.[1] Modifying gravity is an alternative.[2,3] The most popular approach is metric $f(R)$ gravity, which is an $\omega = 0$ Brans-Dicke (BD) theory (with a potential) in disguise. But this is not the only fundamental motivation: all attempts to quantize gravity introduce corrections to GR, consisting of quadratic terms in the curvature (giving rise to Starobinsky inflation[4]), scalar fields, or nonlocal terms (for example, the low-energy limit of bosonic string theory is an $\omega = -1$ BD theory[5,6]). What is more, Dirac's idea of varying fundamental "constants" of physics[7] is partially realized in scalar-tensor gravity, where the scalar degree of freedom $\phi \sim G^{-1}$ is dynamical. More recently, with quantum gravity in mind, it has been found that generalized BD solutions describe asymptotically Lifschitz black holes.[8]

When available, analytic solutions provide insight into various aspects of a theory, but they are relatively rare in scalar-tensor gravity. Therefore, it is valuable

to find new solution-generating techniques. We explore a new one based on a 1-parameter symmetry group of BD theory. As an application, we found three new families of solutions of BD theory with potential $V \propto \phi^\beta$, and of $f(R) = R^n$ gravity.[9] They include Friedmann-Lemaître-Robertson-Walker (FLRW) cosmologies with power-law or exponential scale factor; spherical, time-dependent, asymptotically FLRW solutions; and axially symmetric (cosmic string-like) geometries.

## 2. Symmetry Group of Brans-Dicke Theory

The action of vacuum BD theory with a potential

$$S_{BD} = \int d^4x\sqrt{-g}\left[\phi R - \frac{\omega}{\phi}\, g^{ab}\nabla_a\phi\nabla_b\phi - V(\phi)\right] \tag{1}$$

is invariant in form under the transformation $(g_{ab}, \phi) \to \left(\tilde{g}_{ab}, \tilde{\phi}\right)$, where

$$\tilde{g}_{ab} = \Omega^2 g_{ab} = \phi^{2\alpha} g_{ab}\,, \tag{2}$$

$$\tilde{\phi} = \phi^{1-2\alpha}\,, \qquad \alpha \neq 1/2 \tag{3}$$

and where we follow the notation of Ref.[10]. Using the standard transformation properties under conformal transformations

$$\tilde{g}^{ab} = \Omega^{-2} g^{ab}\,, \qquad \sqrt{-\tilde{g}} = \Omega^4\sqrt{-g}\,, \tag{4}$$

$$\tilde{R} = \Omega^{-2}\left(R - \frac{6\Box\Omega}{\Omega}\right)\,, \tag{5}$$

one obtains

$$R = \phi^{2\alpha}\tilde{R} - \frac{6\alpha(1-\alpha)}{(1-2\alpha)^2}\,\phi^{6\alpha-2}\tilde{g}^{ab}\tilde{\nabla}_a\tilde{\phi}\tilde{\nabla}_b\tilde{\phi} + \frac{6\alpha}{1-2\alpha}\,\phi^{4\alpha-1}\tilde{\Box}\tilde{\phi}\,. \tag{6}$$

The last term contributes only a total divergence to $\sqrt{-g}\,\phi R$ in the action (1),

$$\frac{6\alpha}{1-2\alpha}\,\sqrt{-\tilde{g}}\,\tilde{\Box}\tilde{\phi} = \frac{6\alpha}{1-2\alpha}\,\partial_\mu\left(\sqrt{-\tilde{g}}\,\tilde{g}^{\mu\nu}\partial_\nu\tilde{\phi}\right) \tag{7}$$

and the BD action (1) then becomes

$$S_{BD} = \int d^4x\sqrt{-\tilde{g}}\left\{\tilde{\phi}\tilde{R} - \left[\frac{\omega}{(1-2\alpha)^2} + \frac{6\alpha(1-\alpha)}{(1-2\alpha)^2}\right] \cdot\frac{\tilde{g}^{ab}}{\tilde{\phi}}\tilde{\nabla}_a\tilde{\phi}\tilde{\nabla}_b\tilde{\phi} - \tilde{\phi}^{\frac{-4\alpha}{1-2\alpha}}V(\phi)\right\}\,. \tag{8}$$

By redefining the BD coupling and the potential according to

$$\tilde{\omega}(\omega,\alpha) = \frac{\omega + 6\alpha(1-\alpha)}{(1-2\alpha)^2}\,, \tag{9}$$

$$\tilde{V}(\tilde{\phi}) = \tilde{\phi}^{\frac{-4\alpha}{1-2\alpha}}V\left(\tilde{\phi}^{\frac{1}{1-2\alpha}}\right)\,, \tag{10}$$

we write

$$S_{BD} = \int d^4x\sqrt{-\tilde{g}}\left[\tilde{\phi}\tilde{R} - \frac{\tilde{\omega}}{\tilde{\phi}}\,\tilde{g}^{ab}\tilde{\nabla}_a\tilde{\phi}\tilde{\nabla}_b\tilde{\phi} - \tilde{V}(\tilde{\phi})\right], \tag{11}$$

*i.e.*, the action (1) is invariant in form. The transformations (3) form a 1-parameter Abelian group.[11,12]

A special case is given by a power-law potential $V(\phi) = V_0\phi^n$, which becomes $\tilde{V}(\tilde{\phi}) = V_0\tilde{\phi}^{\tilde{n}}$ with $\tilde{n} = \frac{n-4\alpha}{1-2\alpha}$ (and is invariant if $n = 2$).

### 2.1. *Electrovacuum Brans-Dicke theory*

Electrovacuum BD theory is described by the action

$$S_{BD} = \int d^4x\sqrt{-g}\left[\phi R - \frac{\omega}{\phi}\,g^{ab}\nabla_a\phi\nabla_b\phi - V(\phi) - \frac{1}{4}\,F^{ab}F_{ab}\right]; \tag{12}$$

since $\tilde{F}_{ab} = F_{ab}$ and $\sqrt{-g}\,F^{ab}F_{ab} = \sqrt{-\tilde{g}}\,\widetilde{F^{ab}F_{ab}}$, also $\sqrt{-g}\,\mathcal{L}_{(m)}$ remains invariant under the transformations (3).

### 2.2. *Conformally invariant matter*

For simplicity, let us use now the field equations

$$R_{ab} - \frac{1}{2}\,g_{ab}R = \frac{8\pi}{\phi}\,T_{ab} + \frac{\omega}{\phi^2}\left(\nabla_a\phi\nabla_b\phi - \frac{1}{2}\,g_{ab}g^{cd}\nabla_c\phi\nabla_d\phi\right) + \frac{1}{\phi}\left(\nabla_a\nabla_b\phi - g_{ab}\Box\phi\right) - \frac{V}{2\phi}\,g_{ab}\,, \tag{13}$$

$$\Box\phi = \frac{1}{2\omega+3}\left[\frac{8\pi T}{\phi} + \phi\,\frac{dV}{d\phi} - 2V\right]. \tag{14}$$

The symmetry transformation (3) gives

$$\tilde{\Box}\tilde{\phi} = \frac{1}{2\tilde{\omega}+3}\left[\frac{8\pi}{1-2\alpha}\,\tilde{\phi}^{\frac{-4\alpha}{1-2\alpha}}T + \tilde{\phi}\,\frac{d\tilde{V}}{d\tilde{\phi}} - 2\tilde{V}\right] \tag{15}$$

and the field equations are conformally invariant only if $T = 0$. Moreover,

$$\tilde{R}_{ab} - \frac{1}{2}\,\tilde{g}_{ab}\tilde{R} = \frac{8\pi}{\tilde{\phi}^{\frac{1}{1-2\alpha}}}T_{ab} + \frac{\tilde{\omega}}{\tilde{\phi}^2}\left(\tilde{\nabla}_a\tilde{\phi}\tilde{\nabla}_b\tilde{\phi} - \frac{1}{2}\,\tilde{g}_{ab}\tilde{g}^{cd}\tilde{\nabla}_c\tilde{\phi}\tilde{\nabla}_d\tilde{\phi}\right) + \frac{1}{\tilde{\phi}}\left(\tilde{\nabla}_a\tilde{\nabla}_b\tilde{\phi} - \tilde{g}_{ab}\tilde{\Box}\tilde{\phi}\right) - \frac{\tilde{V}}{2\tilde{\phi}}\,\tilde{g}_{ab} \tag{16}$$

where $\tilde{T}_{ab} = \Omega^{-2}\,T_{ab}$, so the first term in the right hand side becomes $8\pi\tilde{T}_{ab}/\tilde{\phi}$ and it is invariant. Hence, the field equations are invariant for arbitrary $V(\phi)$ but only for conformally invariant matter.

## 3. Example: Brans-Dicke Cosmology

In the case of FLRW cosmology, the Lagrangian reduces to a point-like one, but the symmetry (3) is not a Noether nor a Hojman symmetry. Moreover, the classical symmetry is broken by Wheeler-DeWitt quantization in minisuperspace: quantum effects cause an anomalous symmetry breaking similar to that occuring in condensed matter systems.[13]

This time our "seed" is[14,15]

$$ds^2 = -dt^2 + S^2(t)\left(\frac{dr^2}{1-kr^2} + r^2 d\Omega^2_{(2)}\right) \tag{17}$$

with power-law scale factor $S(t)$. We have vacuum BD theory with $V \equiv 0$ and

$$S(t) = S_0 t^p\,, \tag{18}$$

$$\phi(t) = \phi_0 t^q\,. \tag{19}$$

The symmetry transformation yields

$$d\tilde{s}^2 = -t^{2\alpha q}dt^2 + S_0^2 t^{2(p+\alpha q)}\left(\frac{dr^2}{1-kr^2} + r^2 d\Omega^2_{(2)}\right)\,; \tag{20}$$

we introduce a new time $\tau$ with $t = (\alpha q+1)^{\frac{1}{\alpha q+1}}\,\tau^{\frac{1}{\alpha q+1}}$, then the new solution is recast in the form

$$d\tilde{s}^2 = -d\tau^2 + \tilde{S}_0^2 \tau^{\frac{2(p+\alpha q)}{\alpha q+1}}\left(\frac{dr^2}{1-kr^2} + r^2 d\Omega^2_{(2)}\right)\,, \tag{21}$$

$$\tilde{\phi}(\tau) = (\alpha q+1)^{\frac{q(1-2\alpha)}{\alpha q+1}}\,\phi_0^{1-2\alpha}\tau^{\frac{q(1-2\alpha)}{\alpha q+1}}\,, \tag{22}$$

or $\tilde{S}(\tau) = \tilde{S}_0\tau^{\tilde{p}}$, $\tilde{\phi}(\tau) = \tilde{\phi}_0\tau^{\tilde{q}}$ with

$$\tilde{p} = \frac{p+\alpha q}{\alpha q+1}\,, \qquad \tilde{q} = \frac{q(1-2\alpha)}{\alpha q+1}\,, \tag{23}$$

$$\tilde{S}_0 = (\alpha q+1)^{\frac{p+\alpha q}{\alpha q+1}}\,S_0\,, \quad \tilde{\phi}_0 = (\alpha q+1)^{\frac{q(1-2\alpha)}{\alpha q+1}}\,\phi_0^{1-2\alpha}\,. \tag{24}$$

## 4. A New Family of Spherical Time-Dependent Solutions

Begin now from a special case of a family of spherical, time-dependent solutions of vacuum BD gravity conformal to the Fonarev[16] spacetime of GR[17]

$$\begin{aligned} ds^2 = &-A(r)^{\frac{1}{\sqrt{1+4d^2}}(2d-\frac{1}{\sqrt{|2\omega+3|}})}\,\mathrm{e}^{4dat(2d-\frac{1}{\sqrt{|2\omega+3|}})}dt^2 \\ &+\mathrm{e}^{2at(1-\frac{2d}{\sqrt{|2\omega+3|}})}\Big[A(r)^{\frac{-1}{\sqrt{1+4d^2}}(2d+\frac{1}{\sqrt{|2\omega+3|}})}dr^2 \\ &+A(r)^{1-\frac{1}{\sqrt{1+4d^2}}(2d+\frac{1}{\sqrt{|2\omega+3|}})}r^2 d\Omega^2_{(2)}\Big]\,, \end{aligned} \tag{25}$$

$$\phi(t,r) = \phi_0\,\mathrm{e}^{\frac{4dat}{\sqrt{|2\omega+3|}}}A(r)^{\frac{1}{\sqrt{|2\omega+3|(1+4d^2)}}}\,, \tag{26}$$

where $A(r) = 1 - 2m/r$, $V(\phi) = V_0\phi^\beta$, $\beta = 2\left(1 - d\sqrt{|2\omega+3|}\right)$. Our "seed" is the special case with $a \neq 0$ and with time dependence eliminated by the parameter choice

$$d = \left(2\sqrt{|2\omega+3|}\right)^{-1} = \sqrt{|2\omega+3|}/2 \tag{27}$$

*simultaneously*, which gives $\omega = -1$ (this is the low-energy limit of the bosonic string, so presumably this solution has a stringy analogue). The scalar field remains time-dependent, $\beta = 1$, and $V(\phi) = V_0\phi$ (corresponding to a cosmological constant). Then

$$ds^2 = -dt^2 + A(r)^{-\sqrt{2}}dr^2 + A(r)^{1-\sqrt{2}}r^2 d\Omega^2_{(2)}\,, \tag{28}$$

$$\phi(t,r) = \phi_0\, \mathrm{e}^{2at} A(r)^{1/\sqrt{2}}\,, \tag{29}$$

which is a special case[17] of the Campanelli-Lousto geometry.[18] The symmetry transformation (3) applied to this seed now generates a new solution with

$$\tilde{V}(\tilde{\phi}) = V_0\, \tilde{\phi}^{\frac{1-4\alpha}{1-2\alpha}}\,, \qquad \tilde{\omega} = \frac{6\alpha(1-\alpha)-1}{(1-2\alpha)^2} \tag{30}$$

given by

$$\begin{aligned} d\tilde{s}^2 = &-\mathrm{e}^{4\alpha a t} A(r)^{\alpha\sqrt{2}} dt^2 + \mathrm{e}^{4\alpha a t}\left[A(r)^{-\sqrt{2}(1-\alpha)}dr^2\right. \\ &\left. + A(r)^{1-\sqrt{2}(1-\alpha)} r^2 d\Omega^2_{(2)}\right]\,, \end{aligned} \tag{31}$$

$$\tilde{\phi}(t,r) = \tilde{\phi}_0\, \mathrm{e}^{2a(1-2\alpha)t} A(r)^{\frac{1-2\alpha}{\sqrt{2}}}\,, \qquad \tilde{\phi}_0 = \phi_0^{1-2\alpha}\,. \tag{32}$$

If $a \neq 0$, we can define the new time $\tau = \frac{\mathrm{e}^{2\alpha a t}}{2\alpha a}$ to obtain

$$d\tilde{s}^2 = -A(r)^{\alpha\sqrt{2}}d\tau^2 + (2\alpha a\tau)^2\left[A(r)^{-\sqrt{2}(1-\alpha)}dr^2 + A(r)^{1-\sqrt{2}(1-\alpha)}r^2 d\Omega^2_{(2)}\right]\,, \tag{33}$$

$$\tilde{\phi}(\tau,r) = \phi_*\, \tau^{\frac{1-2\alpha}{\alpha}} A(r)^{\frac{1-2\alpha}{\sqrt{2}}}\,, \qquad \tilde{\phi}_* = \left[(2\alpha a)^{1/\alpha}\,\phi_0\right]^{1-2\alpha}\,. \tag{34}$$

If $m \to 0$, or for $r \gg m$, this geometry reduces to a spatially flat FLRW universe with linear scale factor $S(\tau) = 2\alpha a\tau$ and the scalar field

$$\tilde{\phi}(\tau,r) = \phi_*\, \tau^{\frac{1-2\alpha}{\alpha}} \tag{35}$$

acts asymptotically as a perfect fluid with $P = -\rho/3$.

## 5. Conclusions

The 1-parameter Abelian symmetry group formed by the transformations (2) and (3) as $\alpha$ varies offers a new solution-generating technique for (electro)vacuum BD gravity with a potential $V(\phi)$. The symmetry transformation (3) introduces one new parameter $\alpha$ in addition to those already present in the seed solution. We have

found a new 2-parameter family of spherical time-dependent, asymptotically FLRW solutions and also new FLRW solutions with power-law (or exponential[9]) scale factor. New cylindrical (cosmic string-like) solutions have also been found and they are reported in Ref.[9].

By using the BD representation of $f(R)$ gravity, it can be shown that these new solutions are also solutions of $f(R) = R^n$ theory.[9] The mathematical technique exposed does not, of course, guarantee that the new solutions are physically interesting, but it constitutes a new tool. Future work will explore new applications of the solution-generating technique presented here.

We apply *Relativistic Newtonian Dynamics* ($RND$), a Lagrangian-based, metric theory to a static, spherically symmetric gravitational field. Using a variational principle and conserved momenta, we construct several metrics, analytic everywhere except at $r = 0$, which have $g_{01} \neq 0$ yet still leads to the same trajectories as in the Schwarzschild model. These metrics passes all classical test of $GR$. However, this model and $GR$ predict different velocities on the trajectories, both for massive objects and massless particles. The total time for a radial round trip of light in $RND$ is the same as in the Schwarzschild model, but $RND$ allows for light rays to have different speeds propagating toward and away from the massive object. One of theses metrics keeps the speed of light toward the object to be $c$. We present possible experiments to test whether $g_{01}$=0. $RND$ extends to multiple non-static forces, each of which obeys an inverse square law and whose field propagates at the speed of light.

*Keywords*: Schwarzschild metric; Geometric dynamics; Spherically symmetric metric; One-way light speed.

## 1. Introduction

The *relativity of spacetime* means that spacetime is an object-dependent notion. The potential of an electric force depends on the charge of the particle, and the particle's acceleration depends on its charge-to-mass ratio. This was recognized in the geometric approach of [1]. Given a particle, we assume that there is a metric of the particle's spacetime, defined in a preferred inertial frame, which is a function of the total potential of the forces which affect the particle.

Moreover, we assert that the particle moves *freely* in its spacetime. In other words, the force field creates the geometry of the particle's spacetime in such a way that the particle's acceleration is *zero* in its spacetime. The basis for this assumption is the fact that an inanimate object has no internal mechanism with which to change its velocity. Thus, in its world, its acceleration is zero. Note that $GR$ makes the same claim about an object freely falling in a gravitational field.

The object moves along a *geodesic* and thus has zero acceleration. We generalize this idea from *GR* and claim that *every* object is in free fall in *its spacetime*. We call this principle the *Generalized Principle of Inertia (GPI)*. Explicitly, it states that an **inanimate object moves freely, that is, with uniform motion, in *its spacetime***.

Note that if gravity is the only force around, we do not perceive the relativity of spacetime. It is masked by the Equivalence Principle, which implies that a gravitational field is felt equally by all objects, independent of their mass. In the specific case of gravity, the landscape is the same for everybody, and spacetime is not object dependent. However, in light of our goal to extend our approach to *all* forces (in particular, the electromagnetic force), we must take the relativity of spacetime into account.

Since a geodesic has minimal length, it is advantageous to use a variational principle. Thus, we will derive Euler-Lagrange type equations and obtain conservation of certain momenta. With these tools we can compute the metric.

We always have a preferred frame of reference, in which we place an observer far away from the sources of the field, where the potential is zero. For example, if we are considering the motion of Mercury, we use a frame with the sun at the center and measure distances with respect to the background of fixed stars. If we are dealing with motion within a distant galaxy, we will use the frame represented by the microwave background radiation [2, 3].

## 2. The Variational Principle and Conserved Momenta

We present the preferred frame, Lagrangian approach to geometrize the motion of an object of mass $m$, obeying the $GPI$, in a force field. Let $ds^2 = g_{\alpha\beta}(q)dq^\alpha dq^\beta$ be the metric of the object's spacetime, where $q^\alpha, \alpha = 0, 1, 2, 3$ are the preferred-frame coordinates. In order to define the length of the trajectory, we introduce a Lagrangian: $L(q, \acute{q}) = \sqrt{g_{\alpha\beta}(q)\acute{q}^\alpha \acute{q}^\beta}$. By the $GPI$, the object's trajectory $q(\sigma)$ satisfies the Euler-Lagrange equations

$$\frac{\partial L}{\partial q^\mu} - \frac{d}{d\sigma}\frac{\partial L}{\partial \acute{q}^\mu} = 0, \tag{1}$$

where $\acute{q} = \frac{dq}{d\sigma}$. It is known that the length of the trajectory does not depend on the parametrization. We choose $\sigma$ to be $\sigma = \tau = c^{-1}s$, called *proper time*, which is proportional to $s$ and reduces to the coordinate time $t$ in the classical limit. Then equation (1) becomes

$$mc\frac{\partial L}{\partial q^\mu} = \frac{dp_\mu}{d\tau}, \quad \text{where} \quad p_\mu = mc\frac{\partial L}{\partial \dot{q}^\mu} = mg_{\mu\beta}\dot{q}^\beta \tag{2}$$

is the conjugate momentum and the dot denotes differentiation by $\tau$. This imply:
**Proposition 1** If the metric coefficients $g_{\alpha\beta}$ do not depend on the coordinate $q^\mu$, then the $\mu$ component $p_\mu$ of the conjugate momentum is conserved on the trajectory.

### 3. The metric of a static, spherically symmetric gravitational field

We consider the motion of an object of mass $m$ in a static, spherically symmetric gravitational field. We use spherical coordinates $ct, r, \theta, \varphi$ in our preferred inertial frame and place the origin of our frame at the center of the symmetry of the field. The Newtonian potential is $U(r) = -GmM/r$. Let

$$u(r) = -\frac{2U(r)}{mc^2} = \frac{r_s}{r} \tag{3}$$

denote the corresponding dimensionless potential, where $r_s = \frac{2GM}{c^2}$ is the Schwarzschild radius.

From spherical symmetry and conservation of angular momentum, the $RND$ metric in our preferred frame is of the form [4]

$$ds^2 = g_{00}(r)c^2dt^2 - g_{11}(r)dr^2 - 2cg_{01}(r)dtdr - r^2d\Omega^2, \tag{4}$$

where $d\Omega^2 = d\theta^2 + \sin^2\theta d\varphi^2$. The metric coefficient $g_{01}$ may differ from zero, since we do not assume that the speed of light toward the source is the same as the speed of light away from the source. From the symmetry of the problem, we may also assume, without loss of generality, that the motion is in the plane $\theta = \pi/2$. Hence, we may replace $d\Omega^2$ with $d\varphi^2$.

Using the Newtonian limit, we can show [5] that $g_{00}(r) = 1 - u$. Conservation of angular momentum implies $r^2\dot{\varphi} = J$. Since the metric is static, the conjugate momenta $p_t$ is conserved and

$$(1-u)c\dot{t} - g_{01}\dot{r} = K. \tag{5}$$

Introducing (the negative of) the determinant $g = g_{00}g_{11} + g_{01}^2$, the *RND evolution equation for massive and massless particles* is

$$g\dot{r}^2 = -(1-u)\left(c^2\varepsilon + \frac{J^2}{r^2}\right) + K^2, \tag{6}$$

where the symbol $\varepsilon$ is defined to equal 1 for massive objects and 0 for massless particles. If $g = 1$ (and only if), the $RND$ evolution equation (6) leads to the same trajectories as in Schwarzschild spacetime. Thus, in order to predict the correct anomalous precession of Mercury, we assume from now on that $g = 1$, and the $RND$ metric of a static, spherically symmetric gravitational field becomes

$$ds^2 = (1-u(r))c^2dt^2 - \frac{1-g_{01}^2(r)}{1-u(r)}dr^2 - 2cg_{01}(r)dtdr - r^2d\varphi^2, \tag{7}$$

with $u(r)$ defined by (3). Note that the dynamics based on the metric (7) predicts the observed precession of Mercury, periastron advance of a binary star and gravitational lensing, regardless of the value of $g_{01}$.

## 4. Same trajectories but different velocities

The $RND$ metric (7) produces the same values for $\dot{r} = \frac{dr}{d\tau}$ and the same trajectories as in Schwarzschild spacetime, for both massive and massless particles. However, $RND$ and the Schwarzschild model predict different velocities $dr/dt$ in the preferred frame. From (5), we obtain $\dot{t} = (K + g_{01}\dot{r})/(c(1-u))$, implying that the radial velocity $v = \dot{r}/\dot{t}$ depends on $g_{01}$.

Hence, we expect that the magnitude of the velocity when moving from perigee to apogee is not the same as when moving in the other direction. Since the difference depends on $\dot{r}$, this can be observed for orbits with high eccentricity, and, in order that $g_{01}$ not be too small, we must be close to the Schwarzschild radius. So we expect to observe this difference for stars with high eccentricity in the neighborhood of a black hole, like the stars $S2$ and $S14$ of Sagittarius A*.

Since for light $ds^2 = 0$, the speed of light $v_\downarrow(r) \leq 0$ toward the massive object and the speed of light $v_\uparrow(r) \geq 0$ away from the source, is, using (7),

$$v_\uparrow(r) = c\frac{1-u(r)}{1+g_{01}(r)},\ v_\downarrow(r) = -c\frac{1-u(r)}{1-g_{01}(r)}. \tag{8}$$

Having measured the two one-way speeds, one then computes

$$g_{01} = \frac{v_\downarrow + v_\uparrow}{v_\downarrow - v_\uparrow}. \tag{9}$$

Since the metric is, by assumption, asymptotically flat, we see that as $r$ approaches infinity, the magnitude of both $v_\downarrow(r)$ and $v_\uparrow(r)$ approach the inertial frame speed of light $c$, as expected.

$GR$ and $RND$ disagree on the one-way speeds, but the $RND$ time of a round trip for light is the same as in the Schwarzschild spacetime [4]. This means that a round-trip speed of light experiment cannot distinguish between $GR$ and $RND$. For this, we need an experiment which measures both one-way speeds of light. We have also shown that $RND$ predicts the observed the Shapiro time delay if $g_{01}(r) \ll 1$. Here, even though $g_{01} \neq 0$, the $RND$ prediction agrees with $GR$. The reason is that the trajectory of light as it passes the Sun is similar to a round trip, since the light first approaches the Sun and then travels away from the Sun.

Let $g_{01}(r) = u^n(r)$, for $n = 1, 2, 3, ....$ Then the metric coefficients are polynomials of degree $2n-1$, and the metric is analytic everywhere except at the origin. Of particular interest is the first-order polynomial metric, for which $g_{01}(r) = u(r)$. In this case $ds^2 = \eta_{\mu\nu}dx^\mu dx^\nu - u(cdt + dr)^2$. For this metric, the two directional radial light velocities are

$$v_\uparrow(r) = \frac{1-u(r)}{1+u(r)}c \quad \text{and} \quad v_\downarrow(r) = -c. \tag{10}$$

The speed of light $v_\uparrow$ vanishes at the Schwarzschild radius. However, unlike the Schwarzschild model, light travelling toward the source does not slow down. We see this as more natural than the Schwarzschild prediction.

## 5. Testing the $g_{01} = 0$ prediction of $GR$ for a spherically symmetric gravitational field

It can be shown that Einstein's field equations imply that $g_{01} = 0$. Here, we propose two experiments, one for massive bodies and one for light, to test the $GR$ prediction that $g_{01} = 0$ and to determine the value of $g_{01}$ in Nature.

The first experiment, as mentioned above, is to observe orbital velocities of stars with high eccentricity near black holes and calculate $g_{01}$ from equation (9).

The second experiment tests the influence of the gravitational field of the Earth on the one-way speed of light. We have designed an experiment using two $193nm$ sub-mW lasers [6] of Optica Photonics, with coherence length $> 150m$, see Figure 1. For the first-order polynomial metric, from (10), we would expect the "toward" light (a) and the "away from" light (b) from laser $A$ to produce different phase shifts at $d = 10m$ of $0.3\pi$, which should be detectable by interference with the laser $B$. The influence of the frequency of the light, caused by the gravitational redshift, predicted by $GR$ and tested in the Pound-Rebka experiment [7], should be negligible with respect to the effect we are testing.

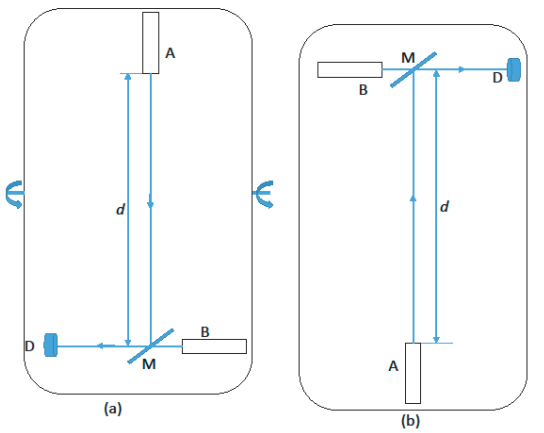

Fig. 1. Experimental setup.

## 6. More forces and more sources

First, we extend $RND$ to an arbitrary static, conservative force . Let $U(\mathbf{x})$ denote the potential of the field at the spatial point $\mathbf{x}$. Introduce, at each $\mathbf{x}$ where $\nabla U(\mathbf{x}) \neq \mathbf{0}$, a normalized vector $\mathbf{n}(\mathbf{x})$ in the direction of $\nabla U(\mathbf{x})$. Let $d\mathbf{x}_n = (d\mathbf{x} \cdot \mathbf{n})\mathbf{n}$ and $d\mathbf{x}_{tr} = d\mathbf{x} - (d\mathbf{x} \cdot \mathbf{n})\mathbf{n}$, respectively, denote the projections of the spatial increment

$d\mathbf{x}$ in the parallel and transverse directions to $\mathbf{n}(\mathbf{x})$. In this notation, as in (7), the $RND$ metric is

$$ds^2 = (1 - u(\mathbf{x}))c^2dt^2 - \frac{1 - g_{01}^2(\mathbf{x})}{1 - u(\mathbf{x})}d\mathbf{x}_n^2 - 2cg_{01(\mathbf{x})}dtd\mathbf{x}_n - d\mathbf{x}_{tr}^2. \tag{11}$$

It can be shown that the metric can be continuously extended to points where $\nabla U$ vanishes.

Consider now motion of an object in a field generated several sources affecting it. We assume that the field of each source $j$ obeys an inverse square law with potential $U(r) = -k_j/r$ in its comoving frame and propagates with the speed of light in our preferred frame. We use Lorentz covariance and an approach similar to that of the Liénard-Wiechert potentials (see, for example, [8], pp. 174-6) and [9]. We find that the four-potential per unit mass at space-time $x$ is

$$A_\alpha(x) = \Sigma_j \frac{-k_j(w_j)_\alpha}{(x_j'(\tau_j(x)) - x) \cdot w_j}, \tag{12}$$

where $x_j'(\tau_j(x)) - x$ is the relative position of the source $j$ at the retarded time $\tau_j(x)$, and $w_j$ is its four-velocity the source at that time. Note that this four-potential tends to 0 when $x$ is far removed from the sources.

Since each individual four-potential is a timelike vector, the total four-potential is also timelike. Therefore, we can apply a Lorentz transformation $\Lambda$ from $K$ to an inertial frame $K'$ such that $\Lambda(A) = (U, 0, 0, 0)$. In $K'$, the four-potential behaves like a "static" potential. Therefore, in $K'$, the metric is defined by formula (11), with $u$ defined by (3). To obtain the metric in $K$, apply the inverse Lorentz transformation $\Lambda^{-1}$ to the metric in $K'$.

# Doubly-foliable space-times and gauge-fixing of perturbations in scalar-tensor gravity theories

Cecília Gergely*, Zoltán Keresztes and László Árpád Gergely

*Institute of Physics, University of Szeged, Hungary*
** E-mail: lawrencesterne92@gmail.com*
*http://www.staff.u-szeged.hu/ gergely/group/group.html*

The direct detection of gravitational waves and gamma-ray counterparts has confirmed that gravitational waves propagate with the speed of light, disruling some of the scalar-tensor gravity models. A huge class of Horndeski theories (those with generic G2 and G3, and with G4 depending only of the scalar field) however survived the test. The study of perturbations of such models is important to establish the ghost-free and instability-free parameter regimes. This has been investigated for a wide range of scalar-tensor theories in the spherically symmetric setup, exploring a 2+1+1 decomposition of space-time based on an orthogonal double foliation. The orthogonality however consumed one gauge degree of freedom, allowing the discussion of only the odd sector of the scalar part of perturbations. In order to describe the even sector perturbations, we worked out a novel 2+1+1 decomposition of space-time and gravitational dynamics, based on a non-orthogonal double foliation. We explore this new formalism for the perturbations of both the spherically symmetric metric tensor and scalar field in generic scalar-tensor theories, achieving an unambiguous gauge-fixing. This opens up the way for the discussion of the full spectrum of perturbations of spherically symmetric scalar-tensor gravity, including both the odd and even sectors of the scalar part of perturbations.

*Keywords*: nonorthogonal 2+1+1 decomposition; scalar-tensor gravity, gauge-fixing.

## 1. Introduction

While General Relativity has been a temendously successful theory in establishing the compatibility of the gravitational interaction with the Special Relativistic constraint for signal propagation and has been tested successfully in all sorts of observations both on the Solar System scale and beyond, its extensions have been also systematically investigated.

Their necessity emerged due to A) the expectation to combine the geometric theory of gravity with quantum considerations, B) the need to understand the mysterious, yet at present dominating component of the Universe, dark energy, which drives its accelerating expansion, and C) the yet unsuccessful attempts to identify dark matter through its weak interaction, rending it at present entirely in the gravitational sector.

Possible extensions arise from both modifying the dynamics of the metric tensor and from including secondary fields. Such extensions could be tested, constrained, or falsified through precision cosmological observations or analysis of detected gravitational waves.

Indeed, the recent eleven-fold detection of gravitational waves by the LIGO Scientific Collaboration and Virgo Collaboration[1–7] confirmed the propagation speed of gravitational waves (tensorial perturbations) to be the speed of light within $-3 \times 10^{-15}$ and $+7 \times 10^{-16}$ accuracy.[8] The surviving theories could be

further subjected to stability analysis, demanding the avoidance of Ostrogradsky-instabilities, ghosts, Laplacian instabilities or tachyons.

In the framework of scalar-tensor gravity the Horndeski theories[9,10] are known to ensure second-order dynamics for both the metric tensor and the scalar field. Demanding the speed of light to be the speed of propagation of tensorial modes, the $L_5$ contribution to the Lagrangian has been disruled, together with the kinetic term dependence of $L_4$.[11–14] The latter could be kept for a class of the beyond Horndeski models,[15,16] which allow for higher-than-second order spatial derivatives, but no such time derivatives.

Both classes of theories were excessively analysed in a cosmological context. Black hole perturbations were also explored. For perturbations of spherically symmetric, static black holes the odd and even sector perturbations decouple. Both were analysed for the Horndeski class of models,[17,18] while for the beyond Horndeski models only the stability analysis of the odd sector has been carried on,[19] based on an orthogonal double foliation.[20,21] The orthogonality requirement however resulted in a gauge fixing, which was unambiguous for the odd sector, nevertheless generated an arbitrary function of all coordinates but the radial for the even sector, hampering the physical interpretation of the even sector perturbations.

In order to avoid this shortcoming we proposed[22] to develop another decomposition of space-time and all affected geometrical quantities along a nonorthogonal double foliation. The details of this work involve a quadruple set of embedding variables (extrinsic curvatures, normal fundamental forms and normal fundamental scalars).[23] These variables provide the set of velocity phase-space variables complementing the induced 2-metric, radial shift and radial lapse. A Hamiltonian analysis established the canonical coordinates and momenta in terms of these geometric variables in a General Relativistic setup, also the Hamiltonian and diffeomorphism constraints.[23] The complementary metric variables, the temporal shift and lapse are left arbitrary, hence an unambiguous gauge-fixing became possible.

## 2. The nonorthogonal double foliation

The space-time $\mathcal{B}$ is foliated with the 3-dimensional hypersurfaces $\mathcal{S}_t$ (spacelike, with normal $n^a$) and $\mathfrak{M}_\chi$ (timelike, with normal $l^a$) , their intersection being the 2-dimensional surface $\Sigma_{t\chi}$ (with $g_{ab}$ the induced metric, normals $k^a$ along $\mathfrak{M}_\chi$ and $m^a$ along $\mathcal{S}_t$). The 4-dimensional metric is 2+1+1 decomposed in two equivalent ways, employing the orthonormal bases $(n^a, m^a)$ and $(k^a, l^a)$:

$$\tilde{g}_{ab} = -n_a n_b + m_a m_b + g_{ab} \ , \tag{1}$$

$$\tilde{g}_{ab} = -k_a k_b + l_a l_b + g_{ab} \ . \tag{2}$$

The evolution vectors along a temporal coordinate $t$ and a spatial one $\chi$ running in $\mathfrak{M}_\chi$ can also be decomposed in these bases:

$$\left(\frac{\partial}{\partial t}\right)^a = N n^a + N^a + \mathcal{N} m^a = \frac{N}{\mathfrak{c}} k^a + N^a \ , \tag{3}$$

$$\left(\frac{\partial}{\partial\chi}\right)^a = Mm^a + M^a = M\left(-\mathfrak{s}k^a + \mathfrak{c}l^a\right) + M^a \ , \tag{4}$$

Here $N^a$ is a 2-dimensional shift, $M^a$ is a radial shift; $N$ and $M$ the lapse and radial lapse, $\mathfrak{s} = \sinh\phi$, $\mathfrak{c} = \cosh\phi$. The new element of the formalism is the third component $\mathcal{N} = N\tanh\phi$ of the 3-dimensional shift vector, which in the orthogonal limit vanishes.

The 2+1+1 decomposition of the covariant derivatives of the basis vectors

$$\tilde{\nabla}_a n_b = K_{ab} + 2m_{(a}\mathcal{K}_{b)} + m_a m_b\mathcal{K} + n_a m_b\mathcal{L}^* - n_a\mathfrak{a}_b \ , \tag{5}$$

$$\tilde{\nabla}_a l_b = L_{ab} + 2k_{(a}\mathcal{L}_{b)} + k_a k_b\mathcal{L} + l_a k_b\mathcal{K}^* + l_a\mathfrak{b}_b \ , \tag{6}$$

$$\tilde{\nabla}_a k_b = K^*_{ab} + l_a\mathcal{K}^*_b + l_b\mathcal{L}_a + l_a l_b\mathcal{K}^* + k_a l_b\mathcal{L} - k_a\mathfrak{a}^*_b \ , \tag{7}$$

$$\tilde{\nabla}_a m_b = L^*_{ab} + n_a\mathcal{L}^*_b + n_b\mathcal{K}_a + n_a n_b\mathcal{L}^* + m_a n_b\mathcal{K} + m_a\mathfrak{b}^*_b \ , \tag{8}$$

define a set of geometrical quantities, which caracterize the embedding of $\Sigma_{t\chi}$: extrinsic curvatures ($K_{ab},\ L_{ab},\ K^*_{ab},\ L^*_{ab}$); accelerations ($\mathfrak{a}_a,\ \mathfrak{a}^*_a$) of the timelike congruences ($n^a,\ k^a$), and similar "accelerations" ($\mathfrak{b}_a,\ \mathfrak{b}^*_a$) of the spacelike congruences ($l^a,\ m^a$); normal fundamental scalars ($\mathcal{K},\ \mathcal{L},\ \mathcal{K}^*,\ \mathcal{L}^*$); normal fundamental forms ($\mathcal{K}_a,\ \mathcal{L}_a$) and similarly defined quantities ($\mathcal{K}^*_a,\ \mathcal{L}^*_a$) for the basis vectors ($m^a,\ k^a$) with vorticities

$$\begin{aligned}\hat{\omega}^{(\mathbf{k})}_{ab} l^b &= \frac{1}{2}D_a\phi + \frac{\mathfrak{s}}{2\mathfrak{c}}\left(\mathfrak{a}_a + \mathfrak{b}_a\right) \ , \\ \check{\omega}^{(\mathbf{m})}_{ab} n^b &= \frac{1}{2}D_a\phi - \frac{\mathfrak{s}}{2\mathfrak{c}}\left(\mathfrak{a}_a + \mathfrak{b}_a\right) \ .\end{aligned} \tag{9}$$

These are all depicted on Fig. 1. They exhibit a complex set of interdependence relations, meticuously explored.[23]

## 3. Gauge fixing in scalar-tensor gravitational theories

In this section we summarize the main result[23] in the gauge-fixing of the perturbations of the spherically symmetric, static background in an unspecified scalar-tensor theory. Similarly to the unitary gauge in cosmology, here we aim to achieve a "radial unitary" gauge, thus to absorb the perturbation of the scalar field in a suitable choice of coordinates. On the spherically symmetric, static background (where quantities carry an overbar) Helmholtz-like theorems assure the decompositions

$$\delta N_a = \bar{D}_a P + E^b{}_a\bar{D}_b Q \, , \tag{10a}$$

$$\delta M_a = \bar{D}_a V + E^b{}_a\bar{D}_b W \, , \tag{10b}$$

$$\delta g_{ab} = \bar{g}_{ab}A + \bar{D}_a\bar{D}_b B + \frac{1}{2}\left(\, E^c{}_a\bar{D}_c\bar{D}_b + E^c{}_b\bar{D}_c\bar{D}_a\right) C \, , \tag{10c}$$

with $E_{ab} = \sqrt{\bar{g}}\,\varepsilon_{ab}$ the 2-dimensional Levi-Civita tensor and $\varepsilon_{\theta\varphi} = 1$. The scalars $(N, M, \mathcal{N}, P, V, A, B)$ and $(Q, W, C)$ form the even and odd sectors of the perturbations, respectively, and they decouple. The latter represent the tensor degrees of freedom.[17]

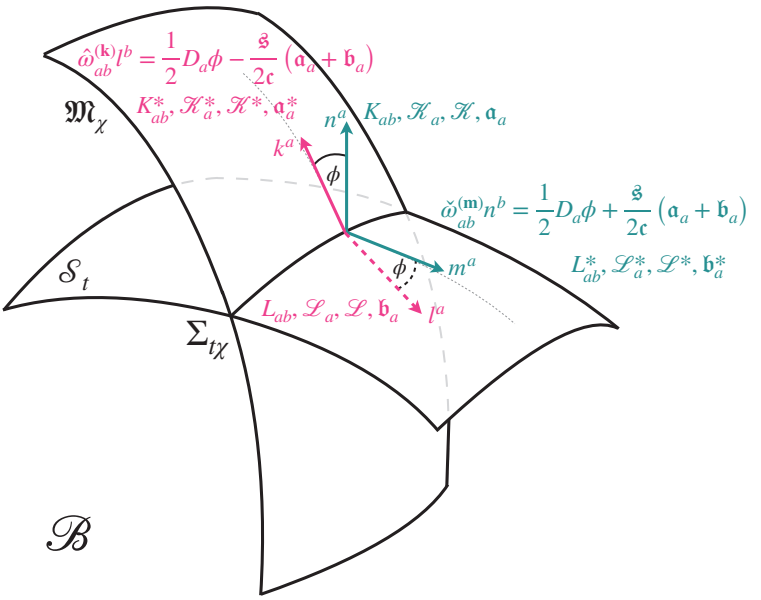

Fig. 1. The bases adapted to the two foliations, their embedding variables and the nonvanishing vorticities.

Next, we explore the diffeomorphism gauge freedom, with generators

$$\left(\xi^t, \xi^\chi, \xi^a = \bar{D}^a \xi + E^{ba} \bar{D}_b \eta\right) \quad , \qquad (a = \theta, \varphi) \tag{11}$$

also Helmholtz-decomposed. The initial metric and scalar perturbations are related to those (denoted by overhat) emerging after the diffeomorphism as

$$\mathfrak{L}_\xi \tilde{g}_{ab} = \delta\tilde{g}_{ab} - \widehat{\delta\tilde{g}_{ab}} \quad , \quad \mathfrak{L}_\xi \phi = \delta\phi - \widehat{\delta\phi} \quad , \tag{12}$$

which generate the respective variations of the even and odd sector variables.[19] In the framework of the nonorthogonal double foliation we managed to unambiguously fix the gauge through the choice

$$\xi^t = \frac{P + \dot{\xi}}{\bar{N}^2} , \qquad \xi^\chi = \frac{\delta\phi}{\bar{\phi}'} , \qquad \xi = -\frac{B}{2} , \qquad \eta = -\frac{C}{2} , \tag{13}$$

which ensure the radial unitary gauge $\widehat{\delta\phi} = 0$, the perturbation of the 2-metric being a conformal rescaling ($\widehat{B} = 0 = \widehat{C}$) and $\widehat{P} = 0$, a condition impossible to achieve in the ortogonal double foliation formalism, which consumed the respective degree of freedom.

Hence the odd sector consist of $\left(\widehat{Q}, \widehat{W}\right)$, while the even sector is formed by $\left(\widehat{N}, \widehat{M}, \widehat{\mathcal{N}}, \widehat{V}, \widehat{A}\right)$. The former has been extensively discussed,[19] while the study of the latter became possible with the unambiguous gauge choice emerging in the nonorthogonal double foliation formalism and will be presented elsewhere.

Propagating shock-waves can be discussed in terms of junction conditions between space-time regions separated by a hypersurface. Recent observations of gravitational waves and their electromagnetic counterparts established that the former also propagate with the speed of light. Hence energetic gravitational waves could be perceived as shock-waves on null hypersurfaces. The most generic scalar-tensor theories with at most second order dynamics, the Horndeski-theories were severely constrained. We derive junction conditions across a null hypersurface for the subclass of allowed Horndeski-theories with linear kinetic term dependence, exploring a formalism based on a transverse null vector. We obtain a 2+1 decomposed generalised Lanczos equation, with the jump of the transverse curvature induced by both the distributional energy-momentum tensor of the wavefront of the shock-wave, and by the jump in the transverse derivative of the scalar. The surface density, current and pressure of the distributional light-like shock-wave and the transverse derivative of the scalar are also constrained by a scalar junction equation.

*Keywords*: Scalar-tensor gravity; junction conditions; null-hypersurfaces.

## 1. Introduction

In general relativity, matching two solutions of the Einstein field equations accross a hypersurface separating them is realized through the Israel junction conditions, provided the hypersurface is timelike or spacelike.[1] Across a boundary hypersurface, they prescribe the continuity of the induced metric and of the extrinsic curvature. The discontinuity of the extrinsic curvature is also admissible for hypersurfaces referred to as thin shells. The Lanczos equation relates the jump of the extrinsic curvature to the distributional stress-energy tensor $\mathcal{T}^{\mu\nu}$ of the thin shell.

Israel's procedure breaks down if the hypersurface is null. This is a physically relevant case, as impulsive shock-waves traveling at the speed of light are described by null hypersurfaces, as are event horizons. The generalization of the Israel junction conditions to arbitrary hypersurfaces has been developed by Barrabés and Israel.[2] If the hypersurface is specified to be null, then in Poisson's reformulation, the junction conditions take a particularily simple form.[3]

The most general scalar-tensor theory with second order equations of motion for both the scalar and the metric tensor was given by Horndeski.[4,5] Recent gravitational wave observations[6–12] have severely constrained this class. The subclass guaranteeing the propagation of the tensorial modes with the speed of light[13–16] has a Lagrangian for the scalar field often referred to as kinetic gravity braiding theory.[17,18] The coupling of the curvature with the scalar can be through an unspecified function of the scalar field, in the Jordan frame. Adding these contributions together we get a generalised kinetic gravity braiding class of scalar-tensor theories.

Junction conditions across timelike and spacelike hypersurfaces in the full Horndeski class have been found,[19,20] but the null case has not been discussed. This case is important, as all electromagnetic and gravitational waves propagate on the light-cone.

In this work we address the junction conditions accross null hypersurfaces in a subset of the generalised kinetic gravity braiding class of theories, namely those in which the Lagrangian is linear in the kinetic term $X = -(\nabla\phi)^2/2$:

$$L = B(\phi)X + V(\phi) - 2\xi(\phi)\Box\phi X + \frac{1}{2}F(\phi)R \tag{1}$$

Here $B, V, \xi, F$ are arbitrary smooth functions of the dynamical scalar field $\phi$. In the following we denote by $\langle Q\rangle$ and $[Q]$ the average and jump of the quantity $Q$ across the null hypersurface. Greek and capital latin indices denote spacetime and two-dimensional spatial indices, respectively.

## 2. Junction conditions

Following Poisson,[3] we employ a pseudo-orthonormal basis with two null vectors $N^\mu$ and $L^\mu$, normalized as $L^\mu N_\mu = -1$. Here $N^\mu$ is the normal (surface gradient, which is also tangent), while $L^\mu$ plays the role of the transverse vector, with respect to which we perform a (2+1)+1 decomposition. Across the hypersurface, the continuity of both the metric tensor $g_{\mu\nu}$ and scalar $\phi$ are required. Their first derivatives can have jumps $c_{\mu\nu}$ and $\zeta$ given by

$$[\partial_\kappa g_{\mu\nu}] = -N_\kappa c_{\mu\nu}, \tag{2}$$

$$[\partial_\mu \phi] = -N_\mu \zeta, \tag{3}$$

hence the second order derivatives of the metric and scalar fields acquire distributional contributions along the thin shell. The distributional equations of motion take the form

$$\mathscr{E}^{\mu\nu} = \frac{1}{2}\mathscr{T}^{\mu\nu} \tag{4}$$

$$\mathscr{E}^{\phi} = 0, \tag{5}$$

where $\mathscr{E}^{\mu\nu}$ and $\mathscr{E}^{\phi}$ are the singular parts of the tensorial and scalar Euler-Lagrange expressions, respectively. The distributional stress-energy-momentum tensor of the shockwave may be decomposed with respect to the basis $\{L, N, e_2, e_3\}$ (where $e_2, e_3$ are spatial basis vectors orthogonal to both $L$ and $N$) as

$$\mathscr{T}^{\mu\nu} = \rho N^\mu N^\nu + j^A(N^\mu e^\nu_A + e^\mu_A N^\nu) + p^{AB} e^\mu_A e^\nu_B, \tag{6}$$

with the expressions $\rho, j^A, p^{AB}$ interpreted as surface energy density, surface current and surface stress, respectively. These quantities could entirely be given in terms of internal hypersurface coordinates, hence they are calculatable even if the bulk coordinates are discontinuous across the hypersurface.

The explicit form of these components for the Lagrangian (1) have been derived[21] as

$$\rho = F(\phi)[\mathcal{K}_{AB}]q^{AB} + F'(\phi)[\phi_L] - 2\xi(\phi)[\phi_L^2]\phi_N, \tag{7}$$

$$j^A = -F(\phi)[\mathcal{K}_N{}^A] + 2\xi(\phi)\phi_N\phi^A[\phi_L], \tag{8}$$

$$p^{AB} = pq^{AB}, \tag{9}$$

$$p = F(\phi)[\mathcal{K}_{NN}] - 2\xi(\phi)[\phi_L]\phi_N^2, \tag{10}$$

where $\phi_L, \phi_N$ are derivatives along $L^\mu$ and $N^\mu$ respectively, $\phi_A$ is the derivative along $e_A^\mu$, $q_{AB} = g(e_A, e_B)$ is the two-dimensional induced metric, $q^{AB}$ its inverse, capital latin indices are raised and lowered with the $q$ metrics, and $\mathcal{K}$ is the "transverse curvature" defined as

$$\mathcal{K}_{ab} = e_a^\mu e_b^\nu \nabla_\mu L_\nu, \tag{11}$$

where $a, b = 1, 2, 3$ and $e_1^\mu \equiv e_N^\mu = N^\mu$. The jump of the transverse curvature is related to the jump of the metric derivative as $[\mathcal{K}_{ab}] = \frac{1}{2}e_a^\mu e_b^\nu c_{\mu\nu}$ and the jump of the scalar field's transverse derivative is $[\phi_L] = \zeta$. Equations (7-10) represent the 2+1 decomposition of the tensorial equation (4), a generalization of the Lanczos equation.

The scalar equation (5) for the Lagrangian (1) becomes

$$\begin{aligned} 0 = {} & \xi(\phi)\phi_N^2 q^{AB}[\mathcal{K}_{AB}] - 2\xi(\phi)\phi_N\phi^A[\mathcal{K}_{NA}] + F'(\phi)[\mathcal{K}_{NN}] \\ & - 2\xi(\phi)[\phi_L]\phi_{NN} + 2\xi(\phi)\phi_N[\phi_L\mathcal{K}_{NN}] \end{aligned} \tag{12}$$

This equation contains the jumps of various components of the transverse curvature, which in principle are expressible[21] from the generalized Lanczos equations (7-10) in terms of the surface energy density, current, pressure and the jump of the transverse derivative of the scalar field. Hence, the scalar equation (12) could be perceived as a constraint on the distributional sources, mediated by the cubic derivative coupling $\xi$ and the jump of the transverse derivative of the scalar and of its square.

The expression $[\phi_L\mathcal{K}_{NN}]$ can be transformed away[21] by a suitable gauge in the tetrad choice. The normal vector field is autoparallel[3]

$$N^\nu\nabla_\nu N^\mu = \kappa N^\mu \tag{13}$$

with the *non-affinity parameter* $\kappa = \mathcal{K}_{NN}$. If the null fields are rescaled as $\bar{N}^\mu = e^\alpha N^\mu$ and $\bar{L}^\mu = e^{-\alpha}L^\mu$ with some function $\alpha$ defined on the hypersurface, the non-affinity parameter transforms as

$$\bar{\kappa} = e^\alpha \left(N^\nu\nabla_\nu\alpha + \kappa\right). \tag{14}$$

It is possible to set

$$[\phi_{\bar{L}}\bar{\kappa}] = 0 \tag{15}$$

by solving the differential equation

$$\frac{\partial \alpha}{\partial \lambda} = -\langle \kappa \rangle - \frac{\langle \phi_L \rangle}{[\phi_L]}[\kappa], \tag{16}$$

where $\lambda$ is a coordinate adapted to $N^\mu$. Therefore, with this choice of gauge, the last term of Eq. (12) vanishes.

## 3. Concluding remarks

We have presented generic tensorial and scalar junction conditions across null hypersurfaces in generalized kinetic gravity braiding theories with linear kinetic term dependence.

The tensorial equation emerges as a generalized Lanczos equation, with the 2+1 decomposition (7-10) based on a pseudo-orthonormal basis in which the null vector is the normal. The jump of the scalar derivative along a second null vector, which is transverse to the hypersurface, also enters the generalized Lanczos equation.

The scalar equation (12) further constrains the energy, current, pressure of the shock-wave and the jump of the transverse derivative of the scalar field. In the absence of the cubic derivative coupling $\xi$, this simply reduces to the condition of vanishing isotropic pressure of the shock-wave, a property already revealed in the case of Brans-Dicke theory in the Jordan frame.[22]

$f(T)$ gravity is a generalization of the teleparallel equivalent of general relativity (TEGR), where $T$ is the torsion scalar made up of the Weitzenböck connection. This connection describes a spacetime with zero curvature but with nonvanishing torsion, which fully encodes the gravitational phenomena. We will present recent results in $f(T)$ gravity related with the issue of the degrees of freedom of the theory. In particular, we discuss the recent finding that $f(T)$ gravity has one extra degree of freedom compared with TEGR, which was concluded through a detailed Hamiltonian analysis of the constraint structure of the theory. The physical interpretation of this result at the level of the trace of the equations of motion and its comparison with the $f(R)$ case is discussed.

*Keywords*: f(T) gravity; Teleparallel gravity; Constrained Hamiltonian systems.

## 1. Teleparallel gravity and the $f(T)$ paradigm

The teleparallel equivalent of general relativity is an alternative formulation of gravity that employs the tetrad field $\mathbf{e}_a = e_a^\mu \partial_\mu$ as a dynamical variable. Unlike general relativity, which is formulated in a Riemann spacetime equipped with the Levi-Civita connection, teleparallel theories of gravity are commonly defined in terms of the Weitzenböck connection. The Riemann tensor vanishes in this connection, therefore it describes a curvatureless spacetime with absolute parallelism (or *tele*-parallelism). However, the Weitzenböck connection $\Gamma^\rho{}_{\mu\nu} = e_a^\rho \partial_\mu E_\nu^a$ has nonvanishing torsion given by $T^\rho{}_{\mu\nu} = e_a^\rho(\partial_\mu E_\nu^a - \partial_\nu E_\mu^a)$, where $\mathbf{E}^a = E_\mu^a dx^\mu$ is the co-tetrad field. The action giving dynamical equations that are equivalent to Einstein equations is

$$S = \frac{1}{2\kappa}\int d^4x\; E\; T = \frac{1}{2\kappa}\int d^4x\; E S_\rho{}^{\mu\nu} T^\rho{}_{\mu\nu} \tag{1}$$

where $\kappa = 8\pi G$, $E = \det(E_\mu^a)$, and it is implicitly defined the torsion scalar $T$, and the so-called superpotential $S_\rho^{\mu\nu}$ is given by

$$S_\rho{}^{\mu\nu} = \frac{1}{4}(T_\rho{}^{\mu\nu} - T^{\mu\nu}{}_\rho + T^{\nu\mu}{}_\rho) + \frac{1}{2}T_\sigma{}^{\sigma\mu}\delta_\rho^\nu - \frac{1}{2}T_\sigma{}^{\sigma\nu}\delta_\rho^\mu. \tag{2}$$

The equations of motion for the action (1) are

$$4e\partial_\mu(E e_a^\lambda S_\lambda{}^{\mu\nu}) + 4e_a^\lambda T^\rho{}_{\mu\lambda} S_\rho{}^{\mu\nu} - e_a^\nu T = -2\kappa e_a^\sigma \mathcal{T}_\sigma{}^\nu, \tag{3}$$

where $\mathcal{T}_\sigma{}^\nu$ represents the energy-momentum tensor. The equivalence between GR and TEGR theories emerges, both at the levels of the equations of motion and

the Lagrangians, when the metric is expressed in terms of the co-tetrad as $g_{\mu\nu} = \eta_{ab}E^a_\mu E^b_\nu$, since it results

$$R = -T + 2\ e\ \partial_\mu(ET^\mu) \tag{4}$$

where $R$ is written in terms of the tetrad field and calculated with the Levi-Civita connection. Therefore, both Lagrangians only differ by a surface term that is integrated out when plugged into the action.

TEGR is a suitable framework for building deformations of GR, since its Lagrangian has only first order derivatives of the tetrad field, therefore any function of $T$ will give a gravitational theory with second order equations of motion. The first application of modified teleparallel gravities to high energy modifications of GR was through a Born-Infeld approach[1], where the main purpose was to obtain an early accelerated expansion of the Universe without resorting to an inflaton field. Later there were proposed low energy deformations to GR through the so-called $f(T)$ gravities, intended to be an alternative explanation of the late-time accelerated expansion of the Universe. The $f(T)$ gravity action is given by[2–4]

$$S = \frac{1}{2\kappa}\int d^4x\ E\ f(T), \tag{5}$$

and its equations of motion are

$$4e\partial_\mu(f'(T)Ee^\lambda_a S_\lambda{}^{\mu\nu}) + 4f'(T)e^\lambda_a T^\sigma_{\mu\lambda}S_\sigma{}^{\mu\nu} - e^\nu_a f(T) = -2\kappa e^\lambda_a \mathcal{T}_\lambda{}^\nu. \tag{6}$$

These dynamical equations have a very unusual peculiarity: they violate local Lorentz invariance. This happens in a very particular way: given a tetrad $\mathbf{E}^a$ that satisfies the equations (6), the local Lorentz transformed tetrad $\mathbf{E}^{a'} = \Lambda^{a'}_a\mathbf{E}^a$ does not necessarily satisfy them. This is commonly understood as the theory choosing a preferential frame that endows the spacetime with a determined parallelization. Other interpretations of the problem of Lorentz invariance and its relation with the additional degree(s) of freedom of the theory will be reviewed in the next section.

## 2. On local Lorentz invariance and Hamiltonian formalism

The issue about the number and nature of the additional degrees of freedom in modified teleparallel gravity theories is an open question, which has been faced through several approaches. One of the main strategies utilized is the study of the Hamiltonian formulation of $f(T)$ gravity. This has been studied in the past[5], with the outcome that the theory posesses $n-1$ extra d.o.f. when compared with TEGR. The authors suggested that the extra d.o.f. of $f(T)$ gravity would manifest in a kind of Higgs mechanism, through a massive vectorial field or a scalar field plus a massless vectorial field. So far, it has not been shown such physical equivalence between these hypotetical fields and the $f(T)$ Lagrangian. Moreover, no extra degrees of freedom appears at the level of cosmological perturbations[6–9]. This strongly suggests that the counting of degrees of freedom in[5] should be revised in the light of new work. Recently the issue about the Hamiltonian formalism of

$f(T)$ gravity has been revised by an independent Hamiltonian analysis [10], with the outcome that the theory possess only one extra degree of freedom compared with TEGR. This analysis was based in a Hamiltonian formulation of teleparallel gravity [11] built from a Lagrangian quadratic in first-order derivatives in the tetrad field and proportional to a *supermetric* [11] or *constitutive tensor* [12], a Lorentz invariant mathematical object that significantly simplifies the calculation of the Hamiltonian and the Poisson brackets. This formulation shows that the Hamiltonian structure of TEGR is very simple: the traditional Arnowitt-Deser-Misner constraint structure from general relativity has an additional subalgebra representing local Lorentz transformations that are gauge symmetries of the theory [11].

The Hamiltonian formulation of TEGR mentioned before has been used to develop the Hamiltonian formulation of $f(T)$ gravity in the Jordan frame representation of the theory [10]. This frame is obtained by defining the Legendre transform of the $f(T)$ action with the help of a scalar field, alike to the $f(R)$ gravity case. It is found a novel constraint structure where it appears a new constraint associated with the introduction of the scalar field, which does not commute with a subset of the constraints $\tilde{G}^{(1)}_{ab}$ associated with the Lorentz sector. In particular, the scalar field constraint $G^{(1)}_{\pi}$ has a nonvanishing Poisson bracket with only one linear combination of the $n(n-1)/2$ Lorentz constraints $\tilde{G}^{(1)}_{ab}$. Both constraints pair up to become second class, while the remaining constraints are first-class. This could be interpreted as a partial violation of Lorentz symmetry in a unique, undetermined combination of boosts and rotations. The counting of degrees of freedom gives that $f(T)$ gravity has $n(n-3)/2+1$ physical d.o.f., this means one additional d.o.f. when compared with TEGR [10].

Other meditations upon the degrees of freedom of $f(T)$ gravity can be found in the literature. For instance, the method of characteristics for hyperbolic partial differential equations has been applied for studying the qualitative behavior of the degrees of freedom [13]. The authors find evidence for an extra d.o.f., however they assume that the theory would have three extra d.o.f. [5]. The absence of the supposedly missing two extra d.o.f. leads to the authors to conclude that the theory would have superluminal modes and a bad posed Cauchy problem. It is mandatory to revisit these claims in the light of recent research. Other potentially helpful approaches in this respect must be explored, as the proposals of *covariant* approaches where the spin connection is taken different from zero [14–16]. Another helpful strategy could be the introduction of Lagrange multipliers that enforce the vanishment of the Riemann tensor, guaranteeing the null curvature condition [17]. Finally, considerations about remnant symmetries on the theory [18] and the search for solutions to $f(T)$ through a null tetrad approach [19,20] should be further addressed.

In what follows, we will explore one possible approach for understanding the nature of the extra d.o.f. in $f(T)$ gravity, through its comparison with the well known $f(R)$ gravity case. We will find convincing evidence for its existence in the trace of the equations of motion, however it is noteworthy to point out that the interpretation of the extra d.o.f. in both theories is radically different.

## 3. The nature of the extra d.o.f.

One of the most studied modifications of general relativity is $f(R)$ gravity. The action of this gravitational theory is given by

$$S_{f(R)} = \frac{1}{2\kappa}\int d^4x\ \sqrt{-g}f(R) + S_m(g_{\mu\nu}), \tag{7}$$

where $S_m$ is the action for matter minimally coupled to gravity. This action has fourth-order dynamical equations given by

$$f'(R)R_{\mu\nu} - \frac{1}{2}f(R)g_{\mu\nu} - [\nabla_\mu\nabla_\nu - g_{\mu\nu}\Box]f'(R) = \kappa T_{\mu\nu}. \tag{8}$$

By taking the trace of the equations of motion it is obtained a relation between the Ricci scalar $R$ and the trace $\mathcal{T}$ of the energy-momentum tensor that is algebraical, that is

$$f'(R)R - 2f(R) + 3\Box f'(R) = \kappa\mathcal{T}. \tag{9}$$

This equation shows the propagation of a new degree of freedom related with $f'(R)$ [22,23]. Moreover, it is possible to write (8) and (9) as second-order equations for the metric and the scalar object $f'(R)$ by changing the notation to

$$\phi \equiv f'(R), \qquad V(\phi) \equiv R\phi - f(R), \tag{10}$$

to rewrite Eq.(8) as

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = \frac{\kappa}{\phi}\mathcal{T}_{\mu\nu} - \frac{g_{\mu\nu}}{2\phi}V(\phi) + \frac{1}{\phi}[\nabla_\mu\nabla_\nu\phi - g_{\mu\nu}\Box\phi]. \tag{11}$$

We recognize in Eq.(10) the Legendre transform of $f(R)$, hence it is also obtained that $R = V'(\phi)$, which together with (11) are the dynamical equations associated with the action

$$S_{JF}[g_{\mu\nu},\phi] = -\frac{1}{2\kappa}\int d^4x\sqrt{-g}[\phi R - V(\phi)] + S_{\text{matter}}. \tag{12}$$

For completing the Legendre transformations it is needed that $\phi$ be a function of the scalar curvature $R$ and moreover, that the Lagrangian in (12) is equivalent to the Legendre transform of the function $V(\phi)$, therefore it can be rewritten as a function of $R$ by defining $f(R) = \phi R - V(\phi)$. The trace of Eq. (11) can be regarded as a wave equation for a self-interacting scalar field $\phi$, since it satisfies

$$3\Box\phi - \phi^3[\phi^{-2}V(\phi)]' = \kappa\mathcal{T}. \tag{13}$$

In this way, $\phi$ looks as a scalar field minimally coupled to the metric $g_{\mu\nu}$, but also coupled to the matter through the trace of the energy-momentum tensor. Meanwhile, Eq.(11) are Einstein equations, on which the source are the matter and the scalar field. The strategy used through the redefinition (10) allows to rephrase $f(R)$

gravity as a scalar-tensor theory with second-order dynamical equations. The equations (11) describe the dynamics of the metric field, therefore they encompass two d.o.f. in four dimensions. Additionally, there is one extra d.o.f. described by (13).

A reasonable approach would be to perform the same procedure to the equations of motion of $f(T)$ gravity, that is to say, to develop an analogous calculation of the trace of the equations of motion. The analogy is not complete, due to the fact that, while the equations of motion of $f(R)$ gravity are second-order on $f'(R)$, the dynamical equations for $f(T)$ gravity are first-order in the analog variable $f'(T)$. We can clearly see this feature if we rewrite the equations of motion (6) through the Legendre transform

$$\phi = f'(T), \qquad V(\phi) = T\phi - f(T), \tag{14}$$

to become

$$4\phi^{-1}e\partial_\mu(\phi E e_a^\lambda S_\lambda{}^{\mu\nu}) + 4e_a^\lambda T^\sigma{}_{\mu\lambda}S_\sigma{}^{\mu\nu} - e_a^\nu T = -\frac{2\kappa}{\phi}e_a^\lambda \mathcal{T}_\lambda{}^\nu + e_a^\nu \frac{V(\phi)}{\phi}. \tag{15}$$

These dynamical equations keep the structure of the TEGR equations, except for the renormalization of the volume $E$, the gravitational constant $\kappa$, and an additional term $\phi^{-1}V(\phi)$ that behaves as a local cosmological constant. Then the trace of (15) easily writes as

$$2T^\mu\partial_\mu\phi + 2\phi e\partial_\mu(ET^\mu) - T\phi + 2V(\phi) = -\kappa\mathcal{T}, \tag{16}$$

or alternatively as

$$2T^\mu\partial_\mu\phi + 2V(\phi) + \phi R = -\kappa\mathcal{T}, \tag{17}$$

when substituting $2e\partial_\mu(ET^\mu)$ by $R + T$, as stated in Eq.(4). We return to the TEGR case when $\phi = 1$ and $V(\phi) = 0$; in this case the equation (17) implies $R = -\kappa\mathcal{T}$, the classical result obtained in GR. Therefore, it is fair to say that (17) encodes more information than merely GR, and could be interpreted as the description of the propagation of an extra scalar degree of freedom that was not present in TEGR. It has been suggested that the existence of an extra d.o.f. in $f(T)$ is connected with the loss of a gauge symmetry. This can be seen in terms of the symmetries of $T$, which do not remain invariant under general local Lorentz transformations. Henceforth, $f(T)$ will inherit a remnant gauge symmetry, which has an on-shell character[21]. The implications of this remnant symmetry and its relevance in cosmological solutions deserves further research.

## 4. Conclusions and future work

In this work we have introduced teleparallel gravity and its simplest modification, the so-called $f(T)$ gravity, and briefly reviewed the important issue about the degrees of freedom in this theory. We have discussed several approaches on the counting of d.o.f., in particular some results obtained through the Dirac-Bergmann algorithm for constrained Hamiltonian systems. Recent work suggests that $f(T)$ gravity

would have only one extra d.o.f., in oposition to previous research. These claims are checked through the comparison with the $f(R)$ gravity case. In both theories the calculation of the trace of the equations of motion reveals an additional scalar d.o.f.. Nonetheless, its interpretation in the $f(T)$ case is qualitatively different, as it satisfies a first-order differential equation. This equation shows evidence that the additional scalar field could be related to the proper parallelization of spacetime. It is strongly encouraged further research about the characterization of the d.o.f. of more general teleparallel gravities and its implications in cosmology and compact objects.

*E-mail: sjana@prl.res.in*

In 2010, Banados and Ferreira (BF) constructed a variant of Born-Infeld (BI) gravity with a simple matter coupling and demonstrated how the standard background FRW cosmology could become free of curvature singularities (big-bang). Further investigations revealed many interesting consequences of this BF version of BI gravity. For a toy 3D version, we show a simple analytical solution exhibiting the removal of the big-bang singularity. Thereafter, we look at BI gravity coupled to scalar BI matter, where we are able to find non-singular (loitering and bounce types) background solutions with late as well as early time acceleration. Finally, we elevate the BI gravity parameter to a space-time dependent field (in a novel Brans-Dicke like way) and demonstrate how cosmologies without singularities and with late as well as early-time acceleration can indeed arise quite naturally.

## 1. The singularity problem

The fact that curvature singularities inevitably appear in many solutions of Einstein's field equations of General Relativity (GR) is well-known. Very general theorems on singularities (largely defined using geodesic incompleteness) with minimal assumptions (causal structure and energy conditions) were proven long ago by Penrose, Hawking and others. In electrodynamics too, a singular behaviour of the electric field at the location of the charge is known. It is not any huge embarrasment in electrodynamics. On the other hand a spacetime singularity (be it in the sense of diverging curvature scalars or geodesic incompleteness or both) is indeed problematic because one cannot extend the spacetime beyond that location. Apart from the fact that via Einstein equations, spacetime singularities corrrespond to infinities in energy density of matter, it is the inextendability of spacetime beyond such special points where some pathologies arise and/or curvature invariants diverge, which makes the theory unacceptable at those points.

It is believed that quantum gravity would cure classical GR of the singularity problem. And, indeed there are indications in various such attempts – i.e. in string theory and loop quantum gravity. On the other hand, it may be asked if any *other* classical theory of gravity can admit non-singular solutions. This is a valid question and it is along these lines we direct our presentation below.

## 2. Born-Infeld structures and Born-Infeld gravity

The appearance of a singularity at the location of the electric charge, is well known. A way out was sought in the work of Born and Infeld (BI)[1], which had links with earlier work due to Eddington[2]. BI proposed a nonlinear electrodynamics with an action given as:

$$S_{BI} = \int \frac{1}{\kappa^2}\left\{1 - \sqrt{-Det[\eta_{ij} + \kappa F_{ij}]}\right\} d^4x. \tag{1}$$

The field equations when solved for a point source lead to a resolution of the self-energy singularity in the electric field. $\kappa$ plays the role of a new parameter which yields an upper bound on the electric field of a point charge.

In 1998, Deser and Gibbons[3] first proposed a gravity action (in a metric formulation) building on BI electrodynamics and Eddington's old ideas (notably the *square root* and the *determinant* in the action). Later, in 2004, Vollick[4] worked out a Palatini formulation of the Deser-Gibbons theory, incorporating matter in a rather artificial way. More recently, Banados and Ferreira (BF)[5] have come up with a theory where the matter coupling is quite simple. The action proposed by BF is given as:

$$S_{BF}(g, \Gamma, \Psi) = \frac{1}{\kappa}\int d^4x \left[\sqrt{-|g_{ij} + \kappa R_{ij}|} - \lambda\sqrt{-g}\right] + S_M(g, \Psi), \tag{2}$$

where $|g_{ij}+\kappa R_{ij}| = Det[g_{ij}+\kappa R_{ij}]$ and $g = Det[g_{ij}]$. Note that the matter coupling here is standard, using the $g_{ij}$ and matter fields $\Psi$. For $\kappa R$ small we get back the Einstein-Hilbert action ($\Lambda = \frac{\lambda-1}{\kappa}$). When $\kappa R$ is large we recover the Eddington action[2]. Without matter, BF theory is equivalent to GR.

Variation w.r.t. $g_{ij}$ gives us the field equation:

$$\sqrt{-q}q^{ij} = \lambda\sqrt{-g}g^{ij} - \kappa\sqrt{-g}T^{ij}. \tag{3}$$

On varying w.r.t $\Gamma^i_{jk}$ we find that the $q_{ij}$ as obtained from solving the equation,

$$q_{ij} = g_{ij} + \kappa R_{ij}(q) \tag{4}$$

is a metric with a Christofel connection. The usual conservation law (covariant derivative using $g_{ij}$), $\nabla_j T^{ij} = 0$ holds. One may also consider the BF action as a bimetric gravity action where the two metrics are $q_{ij}$ and $g_{ij}$. $g_{ij}$ is the physical one while $q_{ij}$ is auxiliary.

The main problem in finding analytical solutions is in the inversion of the equation $q_{ij} = g_{ij}+R_{ij}(q)$. Since these equations cannot be *solved*, one needs to postulate $g_{ij}$ and $q_{ij}$ separately (with different unknown functions) and write down the field equations. Then only one may be able to find solutions.We shall now provide examples in cosmology. For more details on Born-Infeld inspired gravity theories and their consequences see a recent review[6].

### 2.1. *Cosmology*

We assume line elements of the form:

$$ds^2 = -dt^2 + a^2(t)\left(dx^2 + dy^2 + dz^2\right), \tag{5}$$

$$ds_q^2 = -U(t)dt^2 + a^2(t)V(t)\left(dx^2 + dy^2 + dz^2\right), \tag{6}$$

where $U(t)$, $V(t)$, $a(t)$ are three unknowns. The energy-momentum tensor $T^{ij}$ is that of a perfect fluid, i.e. $T^{00} = \rho$, $T^{\alpha\alpha} = p$ ($\alpha = 1, 2, 3$).

With these assumptions one writes down all the field equations stated earlier, for this case. Assuming $p = \frac{\rho}{3}$ one gets the Friedmann equation as:

$$3H^2(\bar{\rho}) = \frac{1}{\kappa}\left[\bar{\rho} - 1 + \frac{1}{3\sqrt{3}}\sqrt{(1+\bar{\rho})(3-\bar{\rho})^3}\right] \times \frac{(1+\bar{\rho})(3-\bar{\rho})^2}{(3+\bar{\rho}^2)^2} \tag{7}$$

where $\bar{\rho} = \kappa\rho$. For small $\bar{\rho}$ one gets get $H^2 \sim \frac{\rho}{3}$, which is the Friedmann equation in GR. Note that $H^2$ has zeros at $\bar{\rho} = 3$ and $\bar{\rho} = 0$ for $\kappa > 0$. For $\kappa < 0$ zeros are at $\bar{\rho} = 0$ and $\bar{\rho} = -1$. Note the difference with the usual FRW model where $3H^2 = \rho$ and the only zero is at $\rho = 0$.

One can find numerical solutions of the scale factor for $\kappa < 0$, $\kappa > 0$ (Fig. 1):

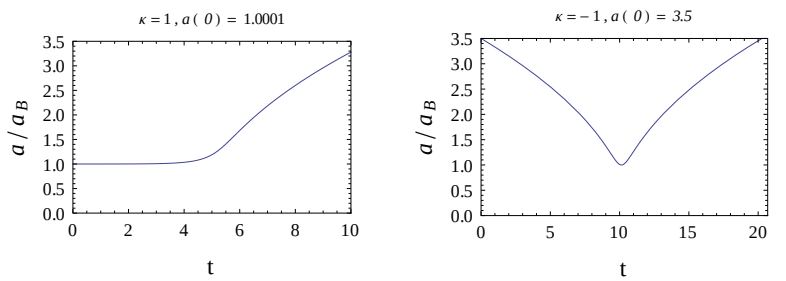

Fig. 1. Plot of the scale factor $a(t)$ for $\kappa = \pm 1$. $a_B$ is the nonzero minimum value of $a(t)$ corresponding to maximum density $\bar{\rho}_B$ and $t$ is an arbitrary time scale. $8\pi G = 1$, $c = 1$.

Note the nonzero minimum value of $a(t)$ which corresponds to the upper limit on $\rho$. There is no big-bang singularity or any singularity in the future. The absence of the singularity is largely controlled by the BI parameter $\kappa$ and the structure of BI gravity. In a toy $2+1$ dimensional model it is possible to find simple analytical solutions which exhibit non-singular features[7]. For example, in a $2+1$ version of the BF theory, the scale factor in the $2+1$ cosmology (with $\kappa < 0$ and $p = \frac{\rho}{2}$), has the form: $a(t) = \sqrt{\frac{t^2}{|\kappa|} + 1}$, which never vanishes and yields a toy, nonsingular universe.

## 3. BI gravity + BI matter: cosmologies

A useful question to ask is: what happens if there are BI structures in both the gravity and matter sectors in BF theory? We assume a simple scalar BI structure

which has been studied extensively as *tachyon matter* about a decade or so ago. The action we work with is $S = S_{BI}(g, \Gamma, \Psi) + S_M$, where

$$S_{BI} = \frac{c^3}{8\pi G\kappa} \int d^4x \left[ \sqrt{-|g_{\mu\nu} + \kappa R_{\mu\nu}(\Gamma)|} - \lambda\sqrt{-g} \right],$$

where $\lambda = \kappa\Lambda + 1$, and

$$S_M = -\frac{1}{c} \int \sqrt{-g}\alpha_T^2 \mathcal{V}(\phi) \sqrt{1 + \alpha_T^{-2} g^{\mu\nu} \partial_\mu\phi\partial_\nu\phi} d^4x,$$

where $\mathcal{V}(\phi)$ is the potential for the scalar field and $\alpha_T$ is the constant parameter. Analytical solutions are possible. More importantly, we ask: what are the features of the cosmological solutions? Here, in Fig. 2, the scale factor $a$ (for a constant negative pressure solution with the equivalent pressure and energy densities of the scalar field, $p_\phi = -\alpha_T^2 C_2 c^2$ and $\rho_\phi = C_2(a^{-3} + \alpha_T^2)$) is plotted as a function of the cosmological time ($\tau$). We choose $8\pi G = 1$, $c = 1$ and $\kappa = 0.5, \alpha_T^2 = 5.0, C_2 = 0.001$. Initial value of $a(\tau)$ is choosen as $a = 0.06$ at $\tau = 0.06$. Initial loitering is followed by deceleration and late-time acceleration. The zoomed version in Fig. 3 shows clearly the loitering phase and the transition into deceleration. The loitering phase also includes an acceleration, where the scale factor has an exponential growth ($a \sim a_0 \exp(2\sqrt{2}c\tau/\sqrt{3\kappa})$). For negative $\kappa$ we obtain a bounce solution (not shown).

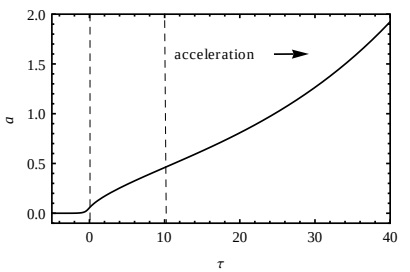

Fig. 2. Plot of scale factor $a(\tau)$.

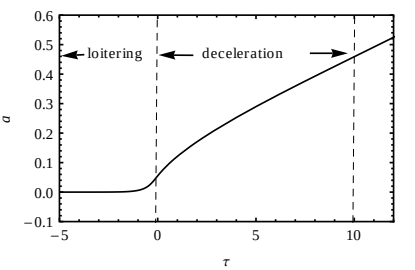

Fig. 3. Zoomed $a(\tau)$ near big-bang

We have fitted the late-time acceleration found in our solution, using Type Ia supernovae (Union2.1 compilation) data. The best fit values of the cosmological parameters for the positive $\kappa$ solution are given as:

$$q_0 = -0.605^{+0.026}_{-0.054} \; ; \; \Omega_{DM0} = 0.255^{+0.051}_{-0.021} \; ; \; \Omega_{DE0} = 0.745^{+0.016}_{-0.051}$$

Note that there is no separate dark matter or dark energy. We use a result due to Roy Chowdhury and Padmanabhan[9] to split the BI matter into a dark matter part and a dark energy part. This is characteristic of BI matter like the scalar BI used here. In summary, the BI matter coupled to BI gravity does produce a nonsingular universe with a late-time acceleration. More details are available in[8].

## 4. BI gravity with a Brans-Dicke scalar: cosmologies

Let us finally turn to another important issue which is related to the BI gravity parameter $\kappa$. From various proposals for tests of the BF theory one obtains various bounds on $\kappa$. This is rather problematic and we wish to avoid this in a Brans-Dicke like way. Recall that the original BD idea was to replace $G$ by a smooth field $\phi(x, y, z, t)$. Here we replace $\kappa$ with a smooth field $\kappa(x, y, z, t)$. The action is taken as:

$$S_{BI\kappa} = \int \left[\frac{1}{\kappa}\left(\sqrt{-|g_{\alpha\beta} + \kappa R_{\alpha\beta}(\Gamma)|} - \sqrt{-g}\right) - \sqrt{-g}\tilde{\omega}(\kappa) g^{\mu\nu}\partial_\mu\kappa\partial_\nu\kappa\right] d^4x + S_M\,(g, \Psi)\,. \quad (8)$$

Here, $\tilde{\omega}(\kappa)$ is a coupling function (like in scalar-tensor theories).

The three field equations ($\Gamma$, $g$ and $\kappa$ variation) are:

$$q_{\alpha\beta} = g_{\alpha\beta} + \kappa R_{\alpha\beta}(q), \quad (9)$$

$$\sqrt{-q}q^{\alpha\beta} - \sqrt{-g}g^{\alpha\beta} = -\kappa\sqrt{-g}\,T^{\alpha\beta}_{eff}, \quad (10)$$

where

$$T^{\alpha\beta}_{eff} = T^{\alpha\beta} - \tilde{\omega} g^{\alpha\beta} g^{\mu\nu}\partial_\mu\kappa\partial_\nu\kappa + 2\tilde{\omega} g^{\mu\alpha} g^{\nu\beta}\partial_\mu\kappa\partial_\nu\kappa, \quad (11)$$

$T^{\alpha\beta}$ is the usual stress-energy tensor, and finally,

$$2\kappa\tilde{\omega}(\kappa)\nabla_\mu\nabla^\mu\kappa + \kappa\tilde{\omega}'(\kappa)\nabla_\mu\kappa\nabla^\mu\kappa + \frac{1}{\kappa} + \frac{\sqrt{-q}}{\sqrt{-g}}\left(\frac{1}{2}q^{\alpha\beta}R_{\alpha\beta}(q) - \frac{1}{\kappa}\right) = 0. \quad (12)$$

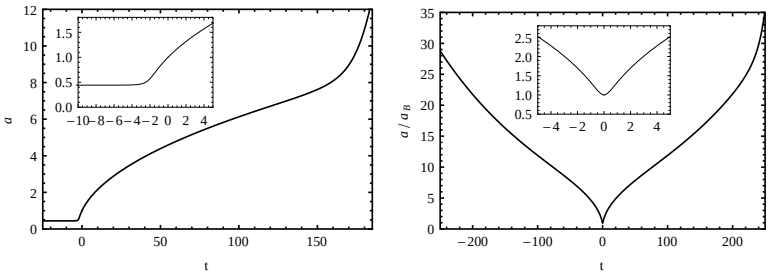
We now turn to FRW cosmologies. Assuming $\kappa(t) = \kappa_0 + \epsilon\, e^{\mu\, t}$ with $\kappa_0$, $\epsilon$, and $\mu$ as parameters, we consider several cases: $\rho, p = 0$ (vacuum); $p = 0$ (pressureless dust); $p = \frac{\rho}{3}$ (radiation). We investigate the nature of the scale factors for various ranges of $\kappa_0$, $\epsilon$ and $\mu$.

Let us illustrate this for the case of radiation: (a) $p = \frac{\rho}{3}$: $\kappa_0 > 0$, $\mu > 0$, $\epsilon < 0$ (Fig. 4(a)), (b) $p = \frac{\rho}{3}$ : $\kappa_0 < 0$, $\mu > 0$, $\epsilon < 0$ (Fig. 4(b)).

Generic features for $\kappa > 0$ (non-singular beginning), and $\kappa < 0$ (bounce) are retained in Figs. 4(a) and 4(b). Further details on this work is available in[10].

## 5. Concluding remarks

A recently proposed novel theory of gravity based on a Born–Infeld structure which matches with GR in vacuum is discussed with emphasis on its ability to resolve the cosmological singularity problem. We have first shown how the original BF version yields a nonsingular FRW universe. Incorporating BI structures in both the gravity and matter sectors we have analytically obtained non-singular FRW cosmologies with initial loitering and late time acceleration. We have also fitted the late-time cosmology with available Supernova data and obtained best-fit values for the cosmological parameters. Further, solutions with an initial bounce and late acceleration are found.



(a) (b)

Fig. 4. (a) plot of scale factor $a(t)$ for $\kappa_0 > 0$, $\mu > 0$, $\epsilon < 0$. The parameters used are $\kappa_0 = 1$, $\mu = 0.1$, and $\rho_0 = 0.1$ (in $\rho = \rho_0/a^4$). We choose $a(0) = 1$, $\kappa(0) = 0.999$ for the numerical solution. (b) plot of scale factor $a(t)$ for $\kappa_0 < 0$, $\mu > 0$, $\epsilon < 0$. The parameters used are $\kappa_0 = -1$, $\mu = 0.1$, and $\rho_0 = 0.01$. We choose $a(0) = (-\kappa_0\rho_0)^{1/4} = a_B$, $\kappa(0) = -1.00001$ for the numerical solution.

In the final part of this article, we have proposed a Brans-Dicke like modification of the BI gravity theory where the BI parameter is elevated to a scalar field. Analysing cosmological solutions we have observed that a nonsingular FRW universe is possible here too for $\kappa > 0$, while for $\kappa < 0$, we have an initial bounce.

Are these solutions useful as background cosmologies? Can we study cosmological perturbations, structure formation, early universe phenomenology, inflation, dark matter, CMB .... in the models we have discussed here? Unless that is done and more links with present-day cosmological observations are established, these models and solutions will merely remain elegant mathematical curiosities.

We present a novel theory of gravity, namely, an extension of symmetric teleparallel gravity. This is done by introducing a new class of theories where the nonmetricity $Q$ is coupled nonminimally to the matter Lagrangian. This nonminimal coupling entails the nonconservation of the energy-momentum tensor, and consequently the appearance of an extra force. We also present several cosmological applications.

*Keywords*: Modified gravity; nonmetricity; cosmology.

## 1. Introduction

The fact that general relativity (GR) is facing so many challenges, namely, (i) the difficulty in explaining particular observations, (ii) the incompatibility with other well established theories, (iii) and the lack of uniqueness, may be indicative of a need for new gravitational physics. Thus, a promising approach is to assume that at large scales GR breaks down, and a more general action describes the gravitational field[1–5]. The physical motivations for these modifications of gravity include the following: (i) the possibility of a more realistic representation of the gravitational fields near curvature singularities; (ii) and to create some first order approximation for the quantum theory of gravitational fields.

An interesting model that is related to this work is the nonminimal curvature-matter coupling[6–9], in which the Lagrangian density is of the form $L \sim f_1(R) + [1 + \lambda f_2(R)]\, L_m$, where $f_i(R)$ (with $i = 1, 2$) are arbitrary functions of the Ricci

scalar $R$ and $L_m$ is the matter Lagrangian density. Applications have been explored such as in an effective dark energy or dark matter[9–12]. An interesting feature of these theories is the non-conservation of the energy-momentum tensor, so that the coupling between the matter and the higher derivative curvature terms describes an exchange of energy and momentum between both.

Indeed, it is possible to tackle gravitation through several approaches, namely, with the metric formalism[1–3], which consists on varying the action with respect to the metric and setting the Levi-Civita connection, or through the metric-affine formalism[13], where the metric and the affine connection are regarded as independent variables, or even through a hybrid approach[9,14,15]. Note that the metric $g_{\mu\nu}$ may be thought of as a generalization of the gravitational potential and is used to define notions such as distances, volumes and angles. On the other hand, the affine connection $\Gamma^{\mu}{}_{\alpha\beta}$ defines parallel transport and covariant derivatives.

In fact, a basic result in differential geometry is that the general affine connection may be decomposed into the following 3 independent components:

$$\Gamma^{\lambda}{}_{\mu\nu} = \left\{{}^{\lambda}{}_{\mu\nu}\right\} + K^{\lambda}{}_{\mu\nu} + L^{\lambda}{}_{\mu\nu}\,, \tag{1}$$

where the first term is the Levi-Civita connection of the metric $g_{\mu\nu}$, defined as:

$$\left\{{}^{\lambda}{}_{\mu\nu}\right\} \equiv \frac{1}{2} g^{\lambda\beta}\left(\partial_{\mu} g_{\beta\nu} + \partial_{\nu} g_{\beta\mu} - \partial_{\beta} g_{\mu\nu}\right)\,. \tag{2}$$

The second term $K^{\lambda}{}_{\mu\nu}$ is the contortion, given by

$$K^{\lambda}{}_{\mu\nu} \equiv \frac{1}{2} T^{\lambda}{}_{\mu\nu} + T_{(\mu}{}^{\lambda}{}_{\nu)}\,, \tag{3}$$

with the torsion tensor defined as $T^{\lambda}{}_{\mu\nu} \equiv 2\Gamma^{\lambda}{}_{[\mu\nu]}$. The third term is the disformation

$$L^{\lambda}{}_{\mu\nu} \equiv \frac{1}{2} g^{\lambda\beta}\left(-Q_{\mu\beta\nu} - Q_{\nu\beta\mu} + Q_{\beta\mu\nu}\right)\,, \tag{4}$$

which is defined in terms of the nonmetricity tensor, given by $Q_{\rho\mu\nu} \equiv \nabla_{\rho} g_{\mu\nu}$.

This implies that by making assumptions on the affine connection, one is essentially specifying a metric-affine geometry[16]. For instance, the standard formulation of GR assumes a Levi-Civita connection, which implies vanishing torsion and nonmetricity, while its teleparallel equivalent (TEGR), uses the Weitzenböck connection, implying zero curvature and nonmetricity[17]. More recently, the symmetric teleparallel theories of gravity were analysed in[18–21], which possess remarkable features. Here, we present an extension of the symmetric teleparallel gravity, by introducing a new class of theories where a general function of the nonmetricity $Q$ is coupled nonminimally to the matter Lagrangian, in the framework of the metric-affine formalism[22].

This work is outlined in the following manner: In Section 2, we present the formalism of an extended symmetric teleparallel equivalent of general relativity. In Section 3, we consider some cosmological applications and conclude in Section 4.

## 2. Nonmetricity-matter coupling

### 2.1. *Action and gravitational field equations*

Consider the action defined by two functions of the nonmetricity $Q$, given by

$$S = \int \mathrm{d}^4x\sqrt{-g}\left[\frac{1}{2}f_1(Q) + f_2(Q)L_M\right], \tag{5}$$

where $L_M$ is a Lagrangian function for the matter fields.

We define the nonmetricity tensor and its two traces as follows:

$$Q_{\alpha\mu\nu} = \nabla_\alpha g_{\mu\nu}\,, \qquad Q_\alpha = Q_\alpha{}^\mu{}_\mu\,, \qquad \tilde{Q}_\alpha = Q^\mu{}_{\alpha\mu}\,. \tag{6}$$

It is also useful to introduce the superpotential

$$4P^\alpha{}_{\mu\nu} = -Q^\alpha{}_{\mu\nu} + 2Q_{(\mu\ \ \nu)}^{\ \ \alpha} - Q^\alpha g_{\mu\nu} - \tilde{Q}^\alpha g_{\mu\nu} - \delta^\alpha_{(\mu}Q_{\nu)}\,, \tag{7}$$

where one can readily check that $Q = -Q_{\alpha\mu\nu}P^{\alpha\mu\nu}$, which is a useful relation.

For notational simplicity, we introduce the following definitions

$$f = f_1(Q) + 2f_2(Q)L_M\,, \qquad F = f_1'(Q) + 2f_2'(Q)L_M\,, \tag{8}$$

and specify the following variations

$$T_{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\delta(\sqrt{-g}L_M)}{\delta g^{\mu\nu}}\,, \qquad H_\lambda{}^{\mu\nu} = -\frac{1}{2}\frac{\delta(\sqrt{-g}L_M)}{\delta\Gamma^\lambda{}_{\mu\nu}}\,, \tag{9}$$

as the energy-momentum tensor and the hyper-momentum tensor density, respectively.

Varying the action (5) with respect to the metric, one obtains the gravitational field equations given by

$$\frac{2}{\sqrt{-g}}\nabla_\alpha\left(\sqrt{-g}FP^\alpha{}_{\mu\nu}\right) + \frac{1}{2}g_{\mu\nu}f_1 + F\left(P_{\mu\alpha\beta}Q_\nu{}^{\alpha\beta} - 2Q_{\alpha\beta\mu}P^{\alpha\beta}{}_\nu\right) = -f_2T_{\mu\nu}\,. \tag{10}$$

and the variation with respect to the connection, yields the following relation

$$\nabla_\mu\nabla_\nu\left(\sqrt{-g}FP^{\mu\nu}{}_\alpha - f_2H_\alpha{}^{\mu\nu}\right) = 0\,. \tag{11}$$

### 2.2. *Divergence of the energy-momentum tensor*

The divergence of the energy-momentum tensor is given by:

$$\begin{aligned}\mathcal{D}_\mu T^\mu{}_\nu + \frac{2}{\sqrt{-g}}\nabla_\alpha\nabla_\beta H_\nu{}^{\alpha\beta} = &-\frac{2}{\sqrt{-g}f_2}\left[\left(\nabla_\alpha\nabla_\beta f_2\right)H_\nu{}^{\alpha\beta} + 2f_{2,(\alpha}\nabla_{\beta)}H_\nu{}^{\alpha\beta}\right]\\ &-\left(T^\mu{}_\nu - \delta^\mu_\nu L_M\right)\nabla_\mu\log f_2\,,\end{aligned} \tag{12}$$

where $\mathcal{D}_\alpha$ denoted the metric covariant derivative with respect to the symbols (2). This shows that due to the coupling between the nonmetricity $Q$ and the matter fields, the matter energy-momentum tensor is no longer conserved. The first term of the right-hand-side line is due to the nonminimal coupling of the hypermomentum, and the second term is related to the nonminimal coupling of the energy-momentum tensor.

Consider a perfect fluid, given by the energy-energy tensor, $T_{\mu\nu} = (\rho + p)\, u_\mu u_\nu + p g_{\mu\nu}$, so that the energy and momentum balance equations gives

$$\dot{\rho} + 3\mathcal{H}\,(\rho + p) = \mathcal{S}, \tag{13}$$

where $\dot{} = u_\mu \mathcal{D}^\mu$, and $\mathcal{H} = (1/3)\mathcal{D}^\mu u_\mu$. For simplicity, one can decompose the energy source term as $\mathcal{S} = \mathcal{S}_\mathcal{T} + \mathcal{S}_\mathcal{H}$, where $\mathcal{S}_\mathcal{T}$ is defined by

$$\mathcal{S}_\mathcal{T} = (\rho + L_M)\,\frac{\dot{f}_2}{f_2}\,,$$

which vanishes when we adopt the Lagrangian $L_M = -\rho$, and the hypersource is given as

$$\mathcal{S}_\mathcal{H} = -\frac{2}{\sqrt{-g}} u^\nu \Big[\nabla_\alpha \nabla_\beta H_\nu{}^{\alpha\beta} + \frac{1}{f_2}\,(\nabla_\alpha \nabla_\beta f_2)\, H_\nu{}^{\alpha\beta} + \frac{1}{f_2} f_{2,(\alpha} \nabla_{\beta)} H_\nu{}^{\alpha\beta}\Big]\,.$$

Note that the non-conservation of the energy-momentum tensor implies non-geodesic motion, where an extra-force $\mathcal{F}^\lambda$ arises due to the $Q$-matter coupling

$$\frac{d^2 x^\lambda}{ds^2} + \left\{{}^{\lambda}_{\mu\nu}\right\} u^\mu u^\nu = \mathcal{F}^\lambda. \tag{14}$$

The extra-force can be decomposed as

$$\mathcal{F}^\lambda = -\frac{h^{\alpha\lambda}\nabla_\alpha p}{\rho + p} + \mathcal{F}^\lambda_\mathcal{T} + \mathcal{F}^\lambda_\mathcal{H}\,, \tag{15}$$

where the first term on the right-hand-side is the usual general relativistic contribution of the pressure gradient. The extra force $\mathcal{F}^\lambda$ consists of the term $\mathcal{F}^\lambda_\mathcal{T}$, defined as

$$\mathcal{F}^\lambda_\mathcal{T} = (-p + L_M)\, h^\lambda_\nu \nabla^\nu \log f_2\,, \tag{16}$$

and the hyperforce $\mathcal{F}^\lambda_\mathcal{H}$ is given by

$$\mathcal{S}_\mathcal{H} = -\frac{2}{\sqrt{-g}} u^\nu \Big[\nabla_\alpha \nabla_\beta H_\nu{}^{\alpha\beta} \frac{1}{f_2}\,(\nabla_\alpha \nabla_\beta f_2)\, H_\nu{}^{\alpha\beta} + \frac{1}{f_2} f_{2,(\alpha} \nabla_{\beta)} H_\nu{}^{\alpha\beta}\Big]\,. \tag{17}$$

It is interesting that the extra force (16) vanishes identically for a perfect fluid if we adopt the Lagrangian prescription $L_M = p$.

## 3. Cosmological applications

In the framework of standard Friedman-Robertson-Walker (FRW) geometry, we have $Q = 6H^2$. Introducing the effective energy density $\rho_{\rm eff}$ and effective pressure $p_{\rm eff}$ of the cosmological fluid, defined as

$$\rho_{\rm eff} = -\frac{f_2}{2F}\left(\rho - \frac{f_1}{2f_2}\right), \qquad p_{\rm eff} = \frac{2\dot{F}}{F} H - \frac{f_2}{2F}\left(\rho + 2p + \frac{f_1}{2f_2}\right), \tag{18}$$

we can write the gravitational field equations in a form similar to the Friedmann equations of GR as

$$3H^2 = \rho_{\rm eff}, \qquad 2\dot{H} + 3H^2 = -p_{\rm eff}. \tag{19}$$

To describe cosmological evolution, and the possible transition to an accelerated phase, we also introduce the parameter $w$ of the dark energy equation of state, defined as

$$w=\frac{p_{\rm eff}}{\rho_{\rm eff}}=\frac{-4\dot{F}H+f_2\left(\rho+2p+\frac{f_1}{2f_2}\right)}{f_2\left(\rho-\frac{f_1}{2f_2}\right)}. \tag{20}$$

The deceleration parameter can be written as

$$q=\frac{1}{2}\left(1+3w\right)=2+\frac{3\left(4\dot{F}H-f_1-2f_2p\right)}{f_1-2f_2\rho}\,. \tag{21}$$

Thus, as a first step in this direction we have obtained the generalized Friedmann equations describing the cosmological evolution in flat FRW type geometry. The coupling between matter and the $Q$ field introduces two types of corrections. The first is the presence of a term of the form $f_2/2F$ multiplying the components of the energy-momentum tensor (energy density and pressure) in both Friedmann equations. Secondly, an additive term of the form $f_1/4F$ also appears in the generalized Friedmann equations. The basic equations describing the cosmological dynamics can then be reformulated in terms of an effective energy density and pressure, which both depend on the standard components of the energy-momentum tensor, and on the functions $f_i(Q)$, $i=1,2$, and on $F$. In the vacuum case $\rho=p=0$, the deceleration parameter takes the form $q=-1+12\dot{F}H/f_1$, showing that, depending on the mathematical forms of the coupling functions, a large number of cosmological evolutionary scenarios can be obtained. Generally, we have shown explicitly that for late times, the Universe attains an exponentially accelerating de Sitter phase[22].

## 4. Conclusions

In this work, we have explored an extension of the symmetric teleparallel gravity, by considering a new class of theories where the nonmetricity $Q$ is coupled nonminimally to the matter Lagrangian, in the framework of the metric-affine formalism. As in the standard curvature-matter couplings, this nonminimal $Q$-matter coupling entails the nonconservation of the energy-momentum tensor, and consequently the appearance of an extra force. Thus, in summary, we have established the theoretical consistency and motivations on these extensions of $f(Q)$ family of theories. Furthermore, we considered cosmological applications, in which the presented approach provides gravitational alternatives to dark energy. As future avenues of research, one should aim in characterizing the phenomenology predicted by these theories with a nonmetricity-matter coupling, in order to find constraints arising from observations.

In this talk we discuss some classical aspects of general polynomial higher-derivative gravity. In particular, we describe the behaviour of the weak-field solutions associated to a point-like mass at small distances and provide necessary and sufficient conditions for the metric to be regular. We also consider the metric for a collapsing thick null shell, and verify that it is regular if the aforementioned conditions are valid.

*Keywords*: Higher-derivative gravity; Lee-Wick gravity; Spacetime singularities.

## 1. Introduction

Higher-derivative theories of gravity possess interesting features from both quantum and classical point of views. Indeed, the inclusion of higher-derivative terms in the Lagrangian can make the theory perturbatively renormalizable,[1,2] while they can also smooth out classical singularities.[3–6] Owed to these good properties, higher derivatives are often considered in the search for a fundamental theory of gravity. One of the main difficulties of this approach to quantum gravity, nonetheless, is the presence of ghost-like degrees of freedom, which classically generate instabilities in the solutions and, in the quantum perspective, violate unitarity. For example, consider the model defined by the action[2]

$$S = \frac{1}{4\kappa}\int d^4x\sqrt{-g}\left(2R + RF_1(\Box)R + R_{\mu\nu}F_2(\Box)R^{\mu\nu}\right), \tag{1}$$

where $F_j(\Box)$ is a real polynomial of degree $\delta_j$ of the d'Alembert operator. The propagator associated this model, in the Landau gauge, is given by

$$G_{\mu\nu,\alpha\beta}(k) = \frac{P^{(2)}_{\mu\nu,\alpha\beta}}{k^2 f_2(-k^2)} - \frac{P^{(0-s)}_{\mu\nu,\alpha\beta}}{2k^2 f_0(-k^2)}, \tag{2}$$

where $f_0$ and $f_2$ are polynomial functions of degree $d_0 = \max\{\delta_1, \delta_2\} + 1$ and $d_2 = \delta_2 + 1$, respectively, defined as

$$f_0(\Box) = 1 - [F_2(\Box) + 3F_1(\Box)]\,\Box\,, \quad f_2(\Box) = 1 + \frac{1}{2}F_2(\Box)\,\Box\,. \tag{3}$$

Hence, if the polynomial $f_s(z)$ has $N_s$ distinct real roots $z = -m^2_{(s)i}$ with multiplicity $n_{(s)i}$, then the propagator has $N_0 + N_2$ massive poles. In Ref. 2 it was shown that half of these excitations correspond to ghost modes.

Recently there have been some proposals for dealing with these ghosts still in the framework of higher-derivative gravity (HDG). For example, in the Lee-Wick HDG[7,8] the ghost-like poles of the propagator are associated to complex masses. Such modes can then appear as virtual states only, yielding an unitary scattering matrix.[7] Another approach to avoid ghosts is to make a non-local extension of the polynomial HDG by using non-polynomial functions $F_j$ such that the propagator has no other degrees of freedom besides the graviton.[9–13]

In this talk we present some classical aspects of the general polynomial-derivative gravity model (1), namely, we discuss the avoidance of Newtonian singularities. We remark that, in the weak field approximation, the local model (1) is the most general one with higher derivatives, and it contains the case of Lee-Wick gravity as particular case. The original results presented here were published in Ref. 14. Using similar arguments it is possible to extend considerations to some classes of non-local gravity theories, as carried out in a more general manner in Ref. 15.

## 2. Singularities in the Newtonian limit

In order to evaluate the field generated by a point-like source in the static non-relativistic weak-field approximation we consider metric fluctuations around the Minkowski spacetime, $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$, sourced by the energy-momentum tensor $T_{\mu\nu} = M\,\delta^3(\mathbf{r})\,\delta^0_\mu\,\delta^0_\nu$. In this case the metric can be written in the isotropic form

$$ds^2 = -\left[1 + \frac{2}{3}(2\chi_2 + \chi_0)\right] dt^2 + \left[1 - \frac{2}{3}(\chi_2 - \chi_0)\right](dx^2 + dy^2 + dz^2) \qquad (4)$$

and one can show that the (linearised) equations of motion for the potentials $\chi_s$ $(s = 0, 2)$ are equivalent to solving[14]

$$f_s(\Delta)\Delta\chi_s = \kappa_s\, M\, \delta^3(\mathbf{r})\,, \qquad (5)$$

with $\kappa_0 = -\kappa/2$, $\kappa_2 = \kappa$. We remark that the decomposition of the usual Newtonian potentials into $\varphi = \frac{1}{3}(2\chi_2 + \chi_0)$ and $\psi = \frac{1}{3}(\chi_2 - \chi_0)$ allows a great simplification in the notation and considerations, as it splits the contribution of the scalar and spin-2 modes, through $\chi_0$ and $\chi_2$, respectively.

The solution of (5) can be obtained by the Laplace[14,16] or Fourier[15] transform technique and reads

$$\chi_s(r) = -\frac{\kappa_s M}{4\pi r} + \frac{\kappa_s M}{4\pi^{3/2}} \sum_{i=1}^{N_s} \sum_{j=1}^{n_{(s)i}} \frac{a_{(s)i,j}}{(j-1)!} \left(\frac{r}{2m_{(s)i}}\right)^{j-\frac{3}{2}} K_{j-\frac{3}{2}}(m_{(s)i} r)\,, \qquad (6)$$

where $K_\nu$ is the modified Bessel function of the second kind. Also, $z = -m^2_{(s)i}$ is one of the $N_s$ distinct roots of the equation $f_s(-z) = 0$ and $n_{(s)i}$ is its multiplicity. Of course, if $d_s$ is the degree of $f_s(z)$, then $\sum_i n_{(s)i} = d_s$. The coefficient $a_{(s)i,j}$ can

be obtained by the Heaviside residue method, and follows from the partial fraction decomposition of $[zf_s(-z)]^{-1}$.

The solution above can be expanded in power series around $r = 0$, which gives

$$\chi_s(r) = -\frac{\kappa_s M}{4\pi r}\left(1 - S_s^{(0)}\right) + c_s + \frac{\kappa_s M}{8\pi}\sum_{i=1}^{N_s}\left(S_s^{(1)} - S_s^{(2)}\right) r + O(r^2)\,, \qquad (7)$$

where $c_s$ is a constant and

$$S_s^{(0)} = \sum_{i=1}^{N_s} a_{(s)i,1}\,, \qquad S_s^{(1)} = \sum_{i=1}^{N_s} m_{(s)i}^2 a_{(s)i,1}\,, \qquad S_s^{(2)} = \sum_{i=1}^{N_s} a_{(s)i,2}. \qquad (8)$$

It is possible to show[5,14] that $S_s^{(0)} = 1$ for any $d_s \geqslant 1$, which means that all the theories which have at least four derivatives in the spin-$s$ sector have a finite potential $\chi_s(r)$ at $r = 0$. Moreover, one can prove[14,15] that $S_s^{(1)} = S_s^{(2)}$ if and only if $d_s \geqslant 2$ — in other words, $\chi_s'(0) = 0$ in all theories with more than four derivatives in the spin-$s$ sector. It can be shown that, for these models, the condition $\chi_0'(0) = \chi_2'(0) = 0$ is necessary and sufficient to have regular curvature invariants.[14,16] Thus, it follows that the metric (4) is regular in all theories which have at least six derivatives in both spin-0 and spin-2 sectors.[14,15]

## 3. Singularities in the ultrarelativistic limit

The static Newtonian solution presented in the previous section can be used to construct the metric of a non-spinning gyraton (see, *e.g.*, Refs. 17, 18). The general idea is to apply a boost to the non-relativistic metric and then take the Penrose limit. With this solution one can consider a homogeneous spherical shell distribution of gyratons with total mass $M$ imploding towards its centre, and analyse the occurrence of singularities and the formation of mini black holes.[16,17,19]

In Ref. 14 it was shown that the Kretschmann scalar associated to the $\mathcal{I}$ domain[a] of the collapsing thick null shell in a general polynomial theory is

$$R^2_{\mu\nu\alpha\beta} \;=\; \frac{32G^2M^2}{3\tau^2}\left[4\Delta^2(\ln r)^2 + c'\Delta\ln r \;+\; c''\Delta + \left(S_2^{(0)} - S_2^{(1)}\right)^2\right] + O(r^2)\,, \qquad (9)$$

where $\tau > 0$ is the thickness of the shell, $\Delta \equiv S_2^{(1)} - S_2^{(2)}$ and $c'$ and $c''$ are constants which depend on the massive parameters of the theory. Inasmuch as $\Delta = 0$ for the theories with more than four derivatives in the spin-2 sector, the collapse of the thick null shell does not generate a singularity. On the other hand, the Kretschmann invariant diverges for models with less than six derivatives.

[a]The $\mathcal{I}$ domain, defined by the locus of the spacetime points for which $r+|t| < \tau/2$, is characterized by the intersection of the in-coming and the out-coming fluxes of null fluid. In this domain the shell assumes its highest density, favouring the mini black hole formation and the emergence of singularities.

The solution for the collapsing shell can also be used to verify the existence of mass gap for the formation of mini black holes. This is related to the occurrence of apparent horizons in the solution, *i.e.*, regions such that $g \equiv (\nabla\varrho)^2 = 0$, where $\varrho$ is the component $g_{\theta\theta}$ of the spherically symmetric metric. In fact, one can show that the invariant $g$ reads

$$g(r) \,=\, 1 + \frac{2GM(S_2^{(0)} - S_2^{(2)})r^2}{3\tau} \,+\, O(r^4) \tag{10}$$

for the collapsing thick null shell in any polynomial gravity theory.[14] Since $r < \tau$ on the domain $\mathcal{I}$, it follows that

$$\frac{2GM|S_2^{(0)} - S_2^{(2)}|r^2}{3\tau} < \frac{2GM|S_2^{(0)} - S_2^{(2)}|\tau}{3}\,. \tag{11}$$

In other words, given any $\tau$ it is possible to avoid the existence of an apparent horizon on $\mathcal{I}$ provided that the total mass $M$ of the shell is sufficiently small. This result was obtained for the first time in Ref. 19 for the theory with only four derivatives; in Refs. 17 and 16 it was extended for the ghost-free gravity and polynomial gravity with only real and non-degenerate masses, while in Ref. 14 general polynomial theories were considered, including the case of Lee-Wick gravity.

## 4. Conclusions

The results presented here show that there is a significant difference of the HDG theories with four and more derivatives. Even though the modified Newtonian potential is finite in both cases (if there are at least four derivatives in the spin-2 and spin-0 sectors), the former always contains curvature singularities in the solution associated to a point-like mass. On the other hand, these singularities are regularized in the models with more than four derivatives. The same situation occurs for the collapsing thick null shell, for which curvature singularities are avoided only in the models with six or more derivatives.

These results bring more motivations for further studies on the occurrence of singularities in the spherically symmetric static solutions in the full non-linear regime of HDG models. For example, the numerical searches for solutions in theories with 6, 8 and 10 derivatives reported in Ref. 20 only found regular solutions. In what concerns the fourth-derivative gravity, it is known that singularities are present in both regimes.[3,21,22] This subject certainly deserves more investigation.

## Acknowledgments

We construct a two-dimensional action that is an extension of spherically symmetric Lovelock gravity. In spite that the action contains arbitrary functions of the areal radius and the norm squared of its gradient, the field equations are second order and obey the Birkhoff's theorem. Similar to the spherically symmetric Lovelock gravity, the field equations admit the generalized Misner-Sharp mass that determines the form of the vacuum solution. The arbitrary functions in the action allow for vacuum solutions that describe a larger class of nonsingular black-hole spacetimes than previously available.

*Keywords*: Nonsingular black hole; Two-dimensional effective theory.

## 1. 2D effective actions for spherically symmetric spacetimes

The metric for $n(\geq 3)$-dimensional spherically symmetric spacetimes is given by

$$\begin{aligned} \mathrm{d}s^2_{(n)} &= g_{\mu\nu}(x)\mathrm{d}x^\mu \mathrm{d}x^\nu \\ &= \bar{g}_{AB}(y)\mathrm{d}y^A \mathrm{d}y^B + R(y)^2 \mathrm{d}\Omega^2_{(n-2)}, \end{aligned} \tag{1}$$

where $\bar{g}_{AB}(y)$ $(A, B = 0, 1)$ is the general two-dimensional (2D) Lorentzian metric, $\mathrm{d}\Omega^2_{(n-2)}$ is the line-element on the unit $(n-2)$-sphere, and $R$ is the areal radius.

After imposing spherical symmetry and integrating out the angular variables, the general $n(\geq 3)$-dimensional gravitational action,

$$I_n = \frac{1}{16\pi G_{(n)}} \int \mathrm{d}^n x \sqrt{-g}\mathcal{L}(\mathcal{R}, \mathcal{R}_{\mu\nu}, \mathcal{R}_{\mu\nu\rho\sigma}), \tag{2}$$

reduces to a 2D effective action. The variation of this effective 2D action will give the same equations of motion for the original action (2)[1–3].

We adopt units such that $c = \hbar = 1$ and $G_{(n)}$ denotes the $n$-dimensional gravitational constant. In the following, $D_A$ and $\mathcal{R}[\bar{g}]$ denote the covariant derivative and the Ricci scalar with respect to $\bar{g}_{AB}$, respectively. We also define $(DR)^2 := (D_A R)(D^A R)$ and a length parameter $l$ proportional to the Planck length as $l^{n-2} := 16\pi G_{(n)}/\mathcal{A}_{(n-2)}$, where $\mathcal{A}_{(n-2)}$ is the volume of a unit $(n-2)$-sphere. The complete analysis for the results presented here is available in Ref. 4.

### 1.1. *Effective 2D action for Einstein gravity and its generalization*

The Einstein-Hilbert action for general relativity corresponds to $\mathcal{L} = \mathcal{R}$ in the action (2) and its effective 2D action takes the form

$$I_{\mathrm{EH}(2)} = \frac{1}{l^{n-2}} \int \mathrm{d}^2y\sqrt{-\bar{g}}\Big\{ R^{n-2}\mathcal{R}[\bar{g}] + (n-2)(n-3)R^{n-4}(DR)^2 + (n-2)(n-3)R^{n-4}\Big\}. \tag{3}$$

By the Birkhoff's theorem, the unique vacuum solution with spherical symmetry is the well-known Schwarzschild-Tangherlini solution.

A natural way to generalize the spherically symmetric action (3) in Einstein gravity is the following 2D dilaton gravity:

$$I_{(2)} = \frac{1}{l^{n-2}} \int \mathrm{d}^2y\sqrt{-\bar{g}}\Big\{ \phi(R)\mathcal{R}[\bar{g}] + h(R)(DR)^2 + V(R)\Big\}, \tag{4}$$

where $\phi(R)$, $h(R)$, and $V(R)$ are arbitrary functions of a scalar field $R$. (See Ref. 5 for a review on this class of 2D gravity.) This standard 2D dilaton gravity theory (4) obeys the Birkhoff's theorem[6]. Namely, the general vacuum solution has the following form:

$$\mathrm{d}s^2 = -f(R)\mathrm{d}t^2 + f(R)^{-1}\mathrm{d}R^2. \tag{5}$$

If one chooses $h(R) = V(R) = \phi_{,RR}(R)$, the metric function is given by

$$f(R) = 1 - \frac{l^{n-2}M}{j(R)}, \quad \Big(j(R) := \int V(R)\mathrm{d}R\Big). \tag{6}$$

Especially, in the case with $n = 4$ and $\phi_{,R} = j(R) = (R^2+l^2)^{3/2}/R^2$, the general vacuum solution is the well-known Bardeen metric[7]:

$$\mathrm{d}s^2_{(4)} = -\left(1 - \frac{l^2MR^2}{(R^2+l^2)^{3/2}}\right)\mathrm{d}t^2 + \left(1 - \frac{l^2MR^2}{(R^2+l^2)^{3/2}}\right)^{-1}\mathrm{d}R^2 + R^2\mathrm{d}\Omega^2_{(2)}. \tag{7}$$

The Bardeen spacetime (7) is certainly nonsingular everywhere, however, this class of nonsingular black holes are considered to be unphysical. This is because the metric (7) violates the *limiting curvature conjecture*, which asserts that the curvature invariants are bounded by some fundamental value in a viable fundamental theory[8]. In fact, to the best of our knowledge, this limiting curvature condition cannot be fulfilled within the framework of the action for pure 2D dilaton gravity (4). This is the main reason why we consider a more general class of 2D dilaton gravity.

### 1.2. *Effective 2D action for Lovelock gravity and its generalization*

Lovelock gravity is a natural generalization of general relativity in arbitrary dimensions as a second-order quasilinear theory of gravity[9]. The second-order field equations ensure the ghost-free nature of the theory and Lovelock gravity reduces to general relativity with a cosmological constant in four dimensions.

In the action (2), Lovelock gravity in vacuum corresponds to

$$\mathcal{L}=\sum_{p=0}^{[n/2]}2^{-p}\alpha_{(p)}\delta^{\mu_1\cdots\mu_p\nu_1\cdots\nu_p}_{\rho_1\cdots\rho_p\sigma_1\cdots\sigma_p}\mathcal{R}_{\mu_1\nu_1}{}^{\rho_1\sigma_1}\cdots\mathcal{R}_{\mu_p\nu_p}{}^{\rho_p\sigma_p}, \tag{8}$$

where $\delta^{\mu_1\cdots\mu_p}_{\rho_1\cdots\rho_p}:=p!\delta^{\mu_1}_{[\rho_1}\cdots\delta^{\mu_p}_{\rho_p]}$, and its effective 2D action was obtained[10,11] as

$$\begin{aligned}I_{\mathrm{L}(2)}=&\frac{1}{l^{n-2}}\int \mathrm{d}^2y\sqrt{-\bar{g}}R^{n-2}\sum_{p=0}^{[n/2]}\frac{(n-2)!}{(n-2p)!}\alpha_{(p)}\\&\times\Bigg[p\mathcal{R}[\bar{g}]R^{2-2p}+(n-2p)(n-2p-1)\Big\{(1-Z)^p+2pZ\Big\}R^{-2p}\\&+p(n-2p)R^{1-2p}\Big\{1-(1-Z)^{p-1}\Big\}(D_AR)\frac{(D^AZ)}{Z}\Bigg],\end{aligned} \tag{9}$$

where we have defined $Z:=(DR)^2$. The Birkhoff's theorem in Lovelock gravity shows that, under several technical assumptions, the unique vacuum solution is given by the Schwarzschild-Tangherlini-type solution[12,13].

In analogy with the action (4), we now propose[4] the following natural extension of the spherically symmetric Lovelock action (9)

$$I_{\mathrm{XL}}=\frac{1}{l^{n-2}}\int \mathrm{d}^2y\sqrt{-\bar{g}}\Big\{\phi(R)\mathcal{R}[\bar{g}]+\eta(R,Z)+\chi(R,Z)(D_AR)\frac{(D^AZ)}{Z}\Big\}, \tag{10}$$

where $\eta(R,Z)$ and $\chi(R,Z)$ are as yet arbitrary functions of a scalar field $R$ and $Z$. For any given $\phi(R)$ and $\chi(R,Z)$, one can choose the function $\eta(R,Z)$ as

$$\phi_{,RR}=\eta_{,Z}-\chi_{,R}, \tag{11}$$

where a comma denotes the partial derivative, so that the field equations obey the Birkhoff's theorem for $Z=(DR)^2\neq 0$ and $\chi-\phi_{,R}\neq 0$. Then the resulting general vacuum solution has the following form:

$$\mathrm{d}s^2=-f(R)\mathrm{d}t^2+f(R)^{-1}\mathrm{d}R^2. \tag{12}$$

Actually, the condition (11) ensures the existence of the generalized Misner-Sharp mass which satisfies the unified first law. Under the condition (11), the existence of Minkowski vacuum requires

$$\eta(R,1)=2\phi_{,RR}. \tag{13}$$

## 2. Designing nonsingular black holes

Now we show how to construct specific nonsingular black holes as exact solutions by making appropriate choices for the functions in the action (10). We are interested in constructing nonsingular black holes that satisfy the limiting curvature condition, namely curvature invariants are everywhere bounded for arbitrarily large $M$.

Such an example is the following Hayward nonsingular black hole[14]:

$$f(R) = 1 - \frac{l^2 M R^2}{R^3 + l^4 M}, \tag{14}$$

of which generalization in $n$ dimensions is given by[4]

$$f(R) = 1 - \frac{l^{n-2} M R^2}{R^{n-1} + l^n M}. \tag{15}$$

This $n$-dimensional Hayward black hole (15) is the unique vacuum solution in the theory with

$$\eta(R, Z) = 2\phi_{,RR} Z + \frac{(n-3) l^{n-2} R^n (1-Z) - (n-1) l^n R^{n-2} (1-Z)^2}{\{l^{n-2} R^2 - l^n (1-Z)\}^2},$$
$$\chi(R, Z) = \phi_{,R} - \frac{l^{n-2} R^{n+1}}{\{l^{n-2} R^2 - l^n (1-Z)\}^2}. \tag{16}$$

Also, the following Bardeen-type nonsingular black hole[4]

$$f(R) = 1 - \frac{l^{n-2} M R^2}{(R^2 + M^{2/(n-1)} l^{2n/(n-1)})^{(n-1)/2}} \tag{17}$$

or new nonsingular black hole[4]

$$f(R) = 1 + \frac{R^{n+1}}{2 l^{n+2} M} \left( 1 - \sqrt{1 + \frac{4 l^{2n} M^2}{R^{2(n-1)}}} \right) \tag{18}$$

can be the unique vacuum solution in the theory with a suitable choice of $\eta(R, Z)$ and $\chi(R, Z)$.

We analyze the propagation of gravitational waves in a molecular matter medium: our findings demonstrate that dispersion only is expected, together with the emergence of three extra polarizations, able to induce longitudinal stresses. We also give quantitative estimates of the predicted effects.

*Keywords*: Macroscopic gravity, gravitational wave dispersion, extra polarizations, longitudinal stress, multi-messenger astronomy.

## 1. Introduction

The Theory of General Relativity provides us a very accurate and elegant theoretical framework from which forecast on all natural phenomena dominated by gravity. One of the most fascinating features of the theory is the prediction of the fact that the gravitational field is radiative: curvature can propagate through spacetime with the speed of light. With the first direct measurement of a gravitational wave, in 2015, we are witnessing the birth of a new era in the fields of astronomy, astrophysics and cosmology. The major part of theoretical studies have dealt with the asymptotic properties of gravitational waves, far from bounded sources, Refs. 1, 2, 3, 4. Many other authors have dealt with the problem of the propagation of gravitational waves in a matter medium: the case of a dissipative fluid is considered in Refs. 5, 6, whilst a collisionless kinetic gas is studied in Refs. 7, 8, 9, 10, 11; the interaction between gravitational waves and neutrinos is analyzed in Refs. 12, 13, 14 whereas the case of spinning particles is investigated in Ref. 15.

Our aim is to analyze the propagation of gravitational wave in a matter medium described as a set of point-like masses, grouped into molecules: it has been shown, Ref. 16 that such a medium can be modelled, through the application of Kaufman molecular moments averaging method, Ref. 17 (whose application is denoted by $\langle\cdot\rangle$), as

$$\langle T_{\mu\nu}\rangle = T^{(f)}_{\mu\nu} + \frac{c^2}{2}\,\partial^\rho\partial^\sigma Q_{\mu\rho\nu\sigma}, \tag{1}$$

where $T^{(f)}_{\mu\nu}$ is the stress energy tensor that describes a set of free particles, *i.e.* the centers of mass of the molecules, and $Q_{\mu\rho\nu\sigma}$ is the quadrupole polarization tensor, that gives account of the molecular structure, characterized by the same set of symmetries of Riemann tensor.

We find, through a direct calculation performed via the geodesic deviation equation, that the quadrupole tensor is generated, on a static level, by the tensor of the second spatial derivatives of the Newtonian potential of the molecule. Moreover, if the molecule is perturbed with a vacuum gravitational wave we find that the latter is source of an induced contribution to the quadrupole moment of the molecule: the alteration in the structure of the molecules causes the fact that the medium reacts to the gravitational wave with a mean field that modifies the propagation of the wave inside the medium itself.

We show that only dispersion is expected, along with the appearance of three extra degrees of freedom able to induce longitudinal stresses on test particles. We also give some quantitative estimates of the predicted effects, by assuming the medium to be either similar to our own galaxy or to a more exotic object.

## 2. Constitutive relation and modified wave equation

The derivation of the constitutive relation is made under the hypothesis of slow motion of the point-like masses composing the molecule and small departure from Minkowski background metric. Moreover, the molecule is imagined as a sphere of constant mass density, characterized by a definite macroscopic radius $L$: the reduced wavelength $\lambda\!\!\!^{-}$ of the gravitational radiation interacting with the molecule must be greater than the molecular size. We perturb the molecule with a vacuum, plus polarized gravitational wave and we express the quadrupole tensor in terms of the amplitudes of the wave. It can be checked that the following constitutive relation comes out:

$$Q_{i0j0} = \epsilon_g \left( \frac{2}{c^2}\, \phi_{,ij} + \frac{1}{2}\, h_{ij,00} \right) \qquad , \qquad Q_{0ijk} = Q_{ijkl} = 0. \tag{2}$$

Here $\phi$ is the Newtonian potential of the molecule and $h_{\mu\nu}$ is the small departure from Minkowski background, the dynamical metric perturbation called gravitational wave. The constant $\epsilon_g$ is a real gravitational dielectric constant and can be calculated as

$$\epsilon_g = \frac{N L^5 c^2}{4G}, \tag{3}$$

being $N$ the density of molecules inside the medium. We write the macroscopic form of Einstein field equation

$$G_{\mu\nu} = \chi \left( T^{(f)}_{\mu\nu} + \frac{c^2}{2}\, \partial^\rho \partial^\sigma Q_{\mu\rho\nu\sigma} \right) \qquad , \qquad \chi = \frac{8\pi G}{c^4} \tag{4}$$

at first order in $h_{\mu\nu}$, implementing the constitutive relation (2): we find a set of fourth order partial differential equation for the wave inside the medium. We write

the problem in terms of the trace reversed matrix $\bar{h}_{\mu\nu}$ on which we are allowed to activate Hilbert gauge fixing, given the diffeomorphism invariance of the theory:

$$\bar{h}_{\mu\nu} = h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h \qquad , \qquad \partial^\mu \bar{h}_{\mu\nu} = 0. \tag{5}$$

We find that the trace $\bar{h}$ solves

$$\Box\left(\partial_0^2 + m^2\right)\bar{h} = 0, \tag{6}$$

where $\Box$ is d'Alembert wave operator and $m^2 = \dfrac{c^2}{4\pi G\epsilon_g}$: hence $\bar{h}$ is a superposition of an harmonic part, solution of d'Alembert equation, that can be canceled out with a further gauge transformation that preserves Hilbert gauge, plus a solution of the harmonic oscillator $\partial_0^2 + m^2$ that does not propagate. This means that we can set $\bar{h}$ to zero: the remaining five degrees of freedom solve the fourth order PDE

$$\partial_0^4 \bar{h}_{\mu\nu} + m^2\Box\bar{h}_{\mu\nu} = 0. \tag{7}$$

We search for plane wave solutions of (7), choosing the $z$ axis to be coincident with the direction of propagation of the wave, $\bar{h}_{\mu\nu} \propto e^{i(\omega(k)t - kz)}$ and we calculate the dispersion relation:

$$\omega_\pm^2(k) = c^2\left(-\frac{m^2}{2} \pm \sqrt{\frac{m^4}{4} + m^2k^2}\right). \tag{8}$$

It can be shown that only the plus signed solution has a physical significance, because it goes back to be the standard vacuum dispersion relation $\omega(k) = ck$ when the material medium is removed, in the limit $\epsilon_g \to 0$, or $m^2 \to \infty$, in contrast to the minus signed, that shows a divergence in the same limit. It is also easy to show that $\omega_+(k)$ is real for any value of the wavenumber: dispersion only is expected. We calculate the group velocity

$$v_g(k) = \frac{m^2kc}{2\sqrt{\left(\sqrt{m^2k^2 + \dfrac{m^4}{4}} - \dfrac{m^2}{2}\right)\left(m^2k^2 + \dfrac{m^4}{4}\right)}} \xrightarrow[k \ll m]{} c\left(1 - \frac{3k^2}{2m^2}\right). \tag{9}$$

We will show that the condition $\lambda\!\!\!^{-} \gg L$ always implies $k \ll m$.

## 3. Polarizations

We exploit the gauge freedom, fixing

$$\bar{h} = \bar{h}_{11} + \bar{h}_{22} + \left(1 - \frac{c^2k^2}{\omega^2}\right)\bar{h}_{33} = 0, \tag{10}$$

via the following equations:

$$\begin{aligned} \bar{h}_{11} &= \bar{h}_+ + \bar{h}^* \\ \bar{h}_{22} &= -\bar{h}_+ + \bar{h}^* \\ \bar{h}_{33} &= \frac{2\omega^2}{c^2k^2 - \omega^2}\bar{h}^*. \end{aligned} \tag{11}$$

In order to analyze which kind of deformation is induced by each component on a sphere of test particles, we calculate the geodesic deviation equation, taken in the comoving frame

$$\frac{1}{c^2}\frac{d^2\xi^\mu}{dt^2} = R^\mu_{\nu\rho\sigma}u^\nu u^\rho \xi^\sigma = R^\mu_{00i}\xi^i, \tag{12}$$

where $\xi^\mu = (0, \xi^x, \xi^y, \xi^z)$ is a vector denoting the separation between two nearby geodesics and the Riemann tensor is constructed up to the first order in $\bar{h}_{\mu\nu}$. We fix the vector $\xi^\mu$ as

$$\xi^\mu = \left(0, \xi^x_{(0)} + \delta\xi^x, \xi^y_{(0)} + \delta\xi^y, \xi^z_{(0)} + \delta\xi^z\right), \tag{13}$$

being $\xi^i_{(0)}$ the initial positions and $\delta\xi^i$ the displacements of order $O(h)$ induced by the gravitational wave. We compute (12) up to order $h$ separately for each component of $\bar{h}_{\mu\nu}$, finding that:

(1) $\bar{h}_+$ is a standard plus mode in the $xy$ plane,
(2) $\bar{h}_{12}$ is a standard cross mode in the $xy$ plane,
(3) $\bar{h}_{13}$ is a cross mode in the $xz$ plane,
(4) $\bar{h}_{23}$ is a cross mode in the $yz$ plane,
(5) $\bar{h}^*$ is a superposition of two pure modes: a breathing mode (Refs. 18, 19, 20) in the $xy$ plane and a longitudinal mode along the $z$ direction.

The ratio between the amplitudes of the anomalous polarizations and the standard ones (plus and cross polarization in the transverse plane) are found to be of order $k^2/m^2$.

## 4. Models of macroscopic media

Now we will give some quantitative estimates of $\epsilon_g$, without any intention of being too accurate, but merely realistic, in the characterization of the involved parameters. Let us begin with the case of a medium composed by molecules whose size is roughly the typical size of a binary system, Refs. 21, 22, 23: we will set $L = 30\,AU = 4.4 \cdot 10^{12}\,m$. In terms of the wavenumber, the condition $\lambda \gg L$ reads as $kL \ll 1$: we will fix $kL = 0.05$, *i.e.* $k = 1.14 \cdot 10^{-14}\,m^{-1}$. The parameter $N$ changes considerably in different regions of the Galaxy, therefore we calculate $\epsilon_g$ for three different values of $N$: in $(i)$ we set $N = 1\,pc^{-3}$ (our neighborhood), in $(ii)$ we choose the value $N = 100\,pc^{-3}$ (inner region) and in $(iii)$ we fix $N = 10^5\,pc^{-3}$ (Galaxy core). We report the results obtained for $\epsilon_g$ and for the ratio $k^2/m^2$, that gives the entity of the deviation from $c$ in the group velocity and the ratio between the amplitudes of the anomalous polarizations and the standard ones:

$(i)$ $\epsilon_g = 1.89 \cdot 10^{40}\,kg\,m$ $\qquad$ $k^2/m^2 = 2.27 \cdot 10^{-14}$
$(ii)$ $\epsilon_g = 1.89 \cdot 10^{42}\,kg\,m$ $\qquad$ $k^2/m^2 = 2.27 \cdot 10^{-12}$
$(iii)$ $\epsilon_g = 1.89 \cdot 10^{45}\,kg\,m$ $\qquad$ $k^2/m^2 = 2.27 \cdot 10^{-9}$.

Now we consider the case of a material medium composed by molecules whose size is roughly comparable with the size of an open cluster, Refs. 24, 25: we set for $L$ the value $L = 3\,pc = 9.26{\cdot}10^{16}\,m$. As before, we fix $kL = 0.05$, *i.e.* $k = 5.40{\cdot}10^{-19}\,m^{-1}$. Our galaxy is estimated to contain about $100,000$ open clusters, mainly located in the central disc. We will calculate the density of molecules as the number of molecules ($10^5$) divided by the volume of the Galaxy, assuming it to be a disc with diameter of $45\,kpc$ and thickness of the disc of about $0.6\,kpc$ (roughly the size of the Milky Way, Ref. 26). We obtain the value $N = 3.55 \cdot 10^{-57}\,m^{-3}$. We calculate $\epsilon_g$ and $k^2/m^2$:

$$\epsilon_g = 8.13 \cdot 10^{54}\,kg\,m \qquad\qquad k^2/m^2 = 2.21 \cdot 10^{-8}.$$

One can imagine a medium in which the density of clusters is 5 or 50 times greater than in our Galaxy: being the ratio $k^2/m^2$ linear in $N$, we expect for such a medium a magnitude of Macroscopic Gravity effects of order $10^{-7} \div 10^{-6}$.

## 5. Conclusions

In this work we have demonstrated that the propagation of a gravitational wave in a molecular medium shows remarkable differences with respect to the vacuum case. By establishing a constitutive relation between the quadrupole tensor and the perturbative fields acting on the molecule, namely a vacuum gravitational wave $h_{\mu\nu}$ and the Newtonian potential of the molecule itself $\phi$, we have derived the law of motion for the wave inside the medium, a fourth order PDE: we have ruled out the possibility of damped and growing modes and determined that dispersion only occurs. We have outlined the fact that only the trace of the gravitational wave is still solution of d'Alembert equation, hence erasable with a gauge transformation. The remaining five degrees of freedom are not harmonic: they cannot be canceled out by a gauge transformation that preserves Hilbert gauge. This finding demonstrates that a gravitational wave in a matter medium possesses five degrees of freedom and it is able to induce longitudinal stresses in a sphere of test particles. We have showed that the quantity $k^2/m^2$ acts as a quantifier of two different observables: the deviation from $c$ in the group velocity and the ratio between the amplitudes of the anomalous polarizations and the standard ones. Lastly we have established some models of molecular medium, varying the values of the parameters $L$ and $N$: we have estimated the entity of Macroscopic Gravity effects, obtaining for $k^2/m^2$ values in the range $10^{-14} \div 10^{-6}$. We focused our analysis on two specific regions of wavelengths. In the first case (binaries) the signal is characterized by $\lambda \simeq 10^{13}\,m$, that is comparable with the scale of lengths to which the space interferometer LISA will be sensitive, Refs. 27, 28. In the second case (clusters) the wavelength of the signal is in the region $\lambda \simeq 10^{18}\,m$ and it is, in principle, detectable by experiments like IPTA, Refs. 29, 30. Despite the modest entity of the expected deviation from vacuum General Relativity, the integrated effect over very large distances can become significant and the propagation of gravitational waves can

be considerably different from that of an electromagnetic counterpart, in a typical "follow up" scenario of multi-messenger astronomy.

# Ring paradigm as quantum gravity

Jan Novák

*Department of physics, Technical University in Liberec,*
*Liberec, Czech Republic*
** E-mail: jan.novak@johnynewman.com*
*www.tul.cz*

Construction of a model of Quantum Gravity, which will be some day in concordance with experiments, is one of the most fascinating tasks we have in modern theoretical physics. There are a plethora of common problems, which must be solved to find a viable candidate for Quantum Gravity. We introduce the concept of the nonlinear graviton and we end with possible experimental evidence for our approach.

*Keywords*: String Theory; Loop Quantum Gravity; Causal Set Approach; Causal Dynamical Triangulation;non-locality; background independence; dimensional reduction; arrow of time; determinism, Wheeler delayed choice experiment; EPR paradox.

## 1. Introduction

We have two main branches in theoretical physics, which describe the Universe at very small and very large scales. These are called General Relativity (GR) and Quantum Mechanics (QM). QM and GR passed many experimental tests and they seem to be fundamental theories of Nature except very high energies.

There are a plethora of reasons, why we should try to build a theory, which would reduce to QM and GR in certain limits. One of the reasons is the unification and the other argument is the existence of singularities. There are many common issues, which must be solved, when we want to unify QM with GR,[1]. We need to make the theory non-local[2] and background independent[3]. We must also deal with dimensional reduction at high energies[4]. We disscused other issues, which are connected to this problematics in[1]. Let us mention, for example, problem of arrow of time[5], determinism or indeterminism of the theory[6], connections with particle physics[7], dark matter[8], dark energy[9], Wheeler delayed choice experiment and EPR paradox[10,11].

Already many attempts have been made during the 20th century to reconcile QM and GR. Let us mention String Theory (ST[3]), Loop Quantum Gravity (LQG[3]), Causal Dynamical Triangulation (CDT[3]), Causal Set Approach (CSA[3]), Group Field Theory,[3] and many others. We present a distinct approach in this article. We claim that, the mathematical apparatus for this theory is hidden in parts of algebraic geometry[12], and algebraic topology.

## 2. First remarks about a new paradigm

We want to show that there is hidden a new philosophical concept that could lead to a new theory in the physical foundations of previously mentioned theories. We will use the knowledge that particles are not point-like objects. But the spacetime will be not continuous for us. So, ST will be for us just a toy model.

Fig. 1. The Universe could be modeled as a finite structure of intersection of Hopf-linked rings, on which are traveling other rings. We suppose that there was one ring in the Big Bang and further rings were created after, which are the trajectories on which could travel particles and fields. Particle and fields could be described as vibrating rings traveling around other rings.

We will not use deep knowledge from LQG. But the investigations are connected to studies of the following set, where the basic objects are topologically circles, and they are Hopf-linked, Figure 1. The formulation of the paradigm, which will follow leads to a mathematical investigation of this set.

Space (not spacetime!) will be discretized to objects, which are called rings. These will be deformable circles, which could be Hopf-linked. We want to argue that points are not the mathematical abstraction, which we will need. When we would discretize to points, the singularities of the type of black holes and initial singularities would be unavoidable. A motivation to this discretization comes from a philosophical branch called finitism, which avoids completed infinities altogether. And this effort to discretize to these rings is well motivated by discrete causal set theory, where we want to put particles, fields, and spacetime on equal footing. Let's stop for a moment on this key point of this paradigm.

We all know very well that GR is perturbatively non-renormalizable. This means that when we try to construct Feynman diagrams and deal with gravitons similarly as in QM the theory diverges.

Another fact from a different area of physics is that the notion of particles is non-unique in quantum field theory in curved background. This serves us as an inspiration for our construction of graviton on the fundamentally nonlinear level.

Our paradigm will come with the existence of a new object, which will be the ring, as we already said. It is a finite deformable circle, which has a finite circumference of 1 Planck length and could stretch from 2 Planck lengths to possibly macroscopic distances. Why we need this object and why it is useful to have particles, fields, and rings? The answer is that we would be possible to put particles, fields, and spacetime on the equal level. Now we will always keep any particle and field together with some trajectory, which will be part of the ring. This will enable us at the end to model particle and fields in a unique description.

The first thing what we need to do is to prove that our discretization is correct according to a deep principle, the so-called holographical principle. It states that the area of any surface $S$ enclosing a volume $V$ measures the information content of the underlying theory in the volume $V$. Our discretization is in concordance with this principle. The number of rings scales as the area of the enclosed volume.

An urgent question comes to our mind. Is this discretization just a mathematical tool or a real physical object? We claim that it is not a mathematical abstraction.

**A keynote about nonlinear graviton**

What we have done so far is an artificial discretization. So what does it have to do with gravity? We need to mention the standard picture of GR and QM. According to GR is a matter moving in 4- dimensional continuous spacetime $(M, g)$ described by topological variety $M$ with a metric $g$. As was quoted by J.A.Wheeler, matter says spacetime how to curve, and spacetime says to matter how to move.

On the other hand, particles jump up on this manifold according to the quantum field theory and are interacting with each other by exchanging the elementary particles of fields. They locally curve the spacetime. These two pictures are incompatible.

What we have in our minds as a picture for a description of gravity are some elementary particles exchanging gravitons. Do we have any experimental evidence that gravitons really exist? It is interesting that detection of the inflationary gravitational wave backgroun, would provide us with direct observational confirmation of the fact that gravity must be quantized. While on the purely theoretical level there is no doubt that it should be so, in particular, if one treats gravity as a low-energy effective QFT, there is so far no evidence for the quantum nature of gravity. Discovery of the inflationary gravitational wave background would be revolutionary. We could always pose a question, is it possible to observe just one graviton in some apparatus as we could observe just one photon? It is only an academic question because one graviton has the too tiny effect to be observable in any possible experiment with interferometers. But we want to indicate that the answer is no. It is not possible to observe the effect of just one graviton, because the picture we have in our mind from the standard QM, is incorrect.

Let's consider Figure 2. We have two particles (we don't say now, how we want to model them) and we switch on the gravity. Then a ring (trajectory or element of space) is created between these two particles, which links it. This link will create an attractive force between these two particles. We could think about it as a spring between them, although it does not have properties of a linear spring. It simultaneously creates a trajectory for exchanging other fields and particles, so a creation of other three interactions.

One question immediately comes to our minds. Is it not a contradiction with the basic principles of QM? We do not say that a particle has a trajectory in QM. We speak about probabilities. But this trajectory creates in Planck time from 2 Planck

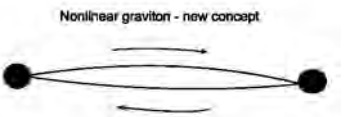

Fig. 2. The old picture of particles exchanging gravitons is incorrect according to RP (Ring Paradigm). When we switch on the extragravity (which is the unification of all 4 interations ), an element of space - ring - is created between these two particles. Other particles could then travel on this trajectories. The important thing is that these trajectories are created in Planck time.

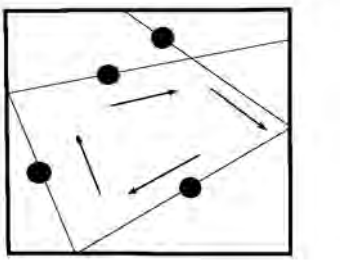

Fig. 3. There is a particle knocked in a box at the figure. It jumps from one trajectory to other trajectory. The trajectories are parts of rings, which are created between the walls of the box and they are changing in Planck time.

lengths to possibly arbitrary distances, and it is changing in Planck time. So, let's consider some particle knocked in the box as in Figure 3.

It is a well-known fact that we could not localize it. There are randomly created trajectories in the box, and the particle jumps from one trajectory to other as we depicted it.

We now just move forward. What we want to draw ultimately is a more advanced version of a Feynman diagram as in Figure 4.

There are two trajectories with opposite orientation, then a trajectory is created in Planck time between these two trajectories. Particles (vibrating rings) are coming on the first ring, then a vibrating ring is traveling in-between, and two particles originate on the second ring.

It is immediately clear that we will need to make this picture of vibrating rings traveling around other rings dynamical. We will need the process of creating a ring, the process of absorption of rings and breaking of rings, Figure 5. We wish to model the false vacuum (creation and absorption) at the end and also accelerated expansion (breaking). We said that we could talk about the ring as a very strange spring between the two particles. We can stretch it, the force is increasing first, and then it is decreasing as $\frac{1}{r^2}$ with the distance $r$ between these two rings.

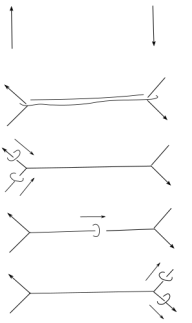

Fig. 4. We need to draw an advanced version of the Feynman diagram in RP. We switch on extragravity at the beginning, then a ring is created in Planck time between these two rings. Particles collide on these rings on the left, then a particle is propagating on the ring between these two rings, and finally, two new particles are created on these rings on the right.

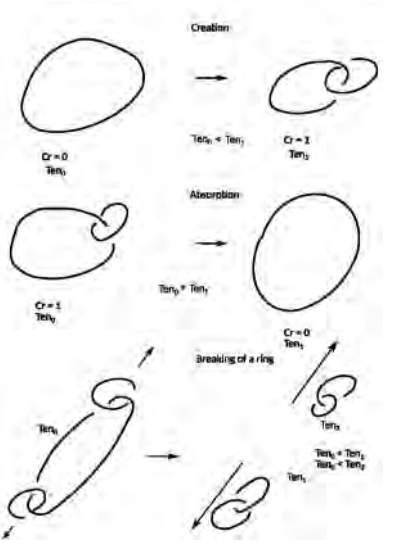

Fig. 5. The basic processes with rings are creation, absorption and breaking of a ring.

## Conclusion

We introduced a concept of nonlinear graviton in this short article. We claim that graviton is not a particle. It is a ring (element of space, trajectory), which connects other rings, and which produces force between them.

One immediate result is the limit velocity, by which we are able to send information in our Universe. Particles and fields of the standard model could travel only with maximal velocity of light in vacuum. If we will find other particles outside

standard model, they will still maximally travel with velocity of light. But the ring is created in Planck time on possibly arbitrary distances in the Universe. Could we send some information by it? Could it have some technical applications? These are the important questions, on which we need to find answers in future research.

The equation of state of an ultrarelativistic perfect fluid is obtained as a necessary condition for a perfect fluid space-time in Rastall's cosmology.

*Keywords*: perfect fluid space-time; Rastall's cosmology; ultrarelativistic fluid

## 1. Introduction

It is well known the importance of a perfect fluid description of gravitational sources in General Relativity[3]. It has been also stressed the relevance of compatibility of perfect-fluid solutions with modified or extended theories of gravity[1].

In this note we point out some cosmological features emerging from the request that the Rastall model[11] describe a perfect fluid geometry of space-time.

We shortly recall some features of the model introduced by Rastall in 1972; we refer to this paper for the relevant issues and stress that the chosen signature for the underling Lorentzian manifold will be $(-,+,+,+)$, in accordance with such a source.

Let then $Lor\boldsymbol{X}$ be the open submanifold of the subbundle of symmetric tensors constituted by regular metrics with the above choice of the Lorentzian signature. An induced fibered chart on $J^2Lor\boldsymbol{X}$ has local coordinates $(x^\alpha, g_{\alpha\beta}, g_{\alpha\beta,\gamma}, g_{\alpha\beta,\gamma\nu})$ and we can define other local coordinates $g^{\mu\nu}$ and so on by the relation $g_{\alpha\mu}g^{\mu\nu} = \delta^\nu_\alpha$.

As well known Einstein equations read

$$G_{\mu\nu} \doteq R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = \kappa_{GR}T_{\mu\nu}\,,$$

where $\kappa_{GR} = \frac{8\pi G}{c^4}$; the Ricci tensor is obtained from a metric connection, so that $R_{\mu\nu} = R_{\mu\nu}(j^2g)$ and the scalar curvature $R$ has to be intended as $R(j^2g) = g^{\alpha\beta}R_{\alpha\beta}(j^2g)$. These equations naturally imply the conservation of energy-momentum tensor as a consequence of the Bianchi identities.

The Rastall model for gravity coupled with matter governed by an energy-momentum tensor satisfying (with $\lambda$ a suitable non-null dimensional constant)

$$\hat{T}^\mu_{\nu;\mu} = \lambda R_{,\nu}$$

where the comma denotes the partial derivative, and by field equations

$$R_{\mu\nu} - \frac{1}{2}\left(1 - 2\kappa_r\lambda\right)Rg_{\mu\nu} = \kappa_r\hat{T}_{\mu\nu}\,, \tag{1}$$

*Corresponding Author

where $\kappa_r$ is a dimensional constant to be determined in order to give the right Poisson equation in the static weak-field limit. This model introduces an energy-momentum tensor fulfilling the requirement $\nabla_\mu \hat{T}^\mu_\nu \doteq \hat{T}^\mu_{\nu;\mu} \neq 0$ without violating the Bianchi identities; for a 4-vector, say $a_\nu$, $\hat{T}^\mu_{\nu;\mu} = a_\nu$ and $a_\nu \neq 0$ on curved spacetime, but $a_\mu = 0$ on flat spacetime (in agreement with Special Relativity). Of course, in general, $\kappa_r \neq \kappa_{GR}$. Taking the trace of Eqs.(1) gives us the so-called structural or master equation $(4\kappa_r\lambda - 1)\, R = \kappa_r \hat{T}$ $(\kappa_r\lambda \neq \frac{1}{4})$.

By this relation the Rastall equations (1) can be recast in the form of Einstein equations. Indeed, one can immediately write $G_{\mu\nu} = \kappa_r S_{\mu\nu}$, where $S_{\mu\nu} \doteq \hat{T}_{\mu\nu} - \frac{\kappa_r\lambda}{4\kappa_r\lambda - 1} g_{\mu\nu}\hat{T}$. By construction, this new energy-momentum tensor is conserved, *i.e.* $S^\mu_{\nu;\mu} = 0$. Furthermore, (if $u_\mu$ is a 4-velocity with $g^{\mu\nu}u_\mu u_\nu = -1$) by assuming $\hat{T}_{\mu\nu} = -(\rho + p)u_\mu u_\nu - p g_{\mu\nu}$, *i.e.* the source is a perfect isentropic fluid with energy density $\rho$ and pressure $p$, we can explicitly work out an expression for $S_{\mu\nu}$. The source turns out to be still a perfect fluid, provided we redefine its energy density and pressure.[11]

## 2. Perfect fluid space-times in Rastall's cosmology

Rastall's cosmology has been recently object of attention in scientific community; some papers are concerned with the querelle whether Rastall's stress-energy tensor corresponds to an artificially isolated part of the physical conserved stress-energy or not[2,7,10,15], some others are concerned with the derivation of a related variational principle (*i.e.* with the question how to get a - eventually modified - Rastall model which could be derived by a Lagrangian and physically different from Einstein gravity), see *e.g.* Refs. 12, 14, 13.

We study this model from the point of view of the compatibility of its geometry with a perfect fluid description of space-time. Indeed, as a gravity model it provides a non minimal coupling between metric and matter and we try to understand how this is related with this compatibility requirement.

Indeed it is well known that by suitably introducing a matter density $\mu$, the energy density of space-time $\bar{\rho}$ can be defined as a function of $\mu$ satisfying $\bar{p} = \mu\bar{\rho}' - \bar{\rho}$ where the prime denotes derivation with respect to $\mu$; (this is equivalent with asking whether we can derive the tensor $R_{\mu\nu} \equiv \tilde{T}_{\mu\nu}$ from a variational principle, *i.e.* with looking for a Lagrangian density depending on $\rho(\mu)$ from which $\tilde{T}_{\mu\nu}$ can be derived variationally; such kind of space-times appear *e.g.* in the dual Lagrangian description of the Ricci tensor for barotropic perfect relativistic fluids[6], see also Refs. 4, 5, 8).

We therefore have

$$\tilde{T}_{\alpha\beta} = \bar{\rho}(\mu) g_{\alpha\beta} - \mu\bar{\rho}'(\mu)[g_{\alpha\beta} + u_\alpha u_\beta]\,,$$

with trace $\tilde{T} = 4\bar{\rho} - 3\mu\bar{\rho}'$; moreover $\bar{p} = \mu^2 \frac{d}{d\mu}(\frac{\bar{\rho}}{\mu}) = \mu\bar{\rho}' - \bar{\rho}$.

### 2.1. *Ultrarelativistic equation of state from a perfect fluid geometry*

By requiring the perfect fluid Ricci tensor to be *also* a Rastall's geometry the following identity should hold true.

$$\begin{aligned}\tilde{T}_{\alpha\beta} &\equiv \hat{T}_{\alpha\beta} - \frac{1}{2}\frac{2\tilde{\lambda}-1}{4\tilde{\lambda}-1} g_{\alpha\beta}\hat{T} \\ &= [\rho - \mu\rho' - \frac{1}{2}\frac{2\tilde{\lambda}-1}{4\tilde{\lambda}-1}(4\rho - 3\mu\rho')]g_{\alpha\beta} - \mu\rho' u_\alpha u_\beta \\ &\equiv (\bar{\rho} - \mu\bar{\rho}')g_{\alpha\beta} - \mu\bar{\rho}' u_\alpha u_\beta = -\bar{p}g_{\alpha\beta} - (\bar{\rho}+\bar{p})u_\alpha u_\beta \,. \end{aligned} \tag{2}$$

The above identity leads to

$$\rho' = \bar{\rho}' \,.$$

By inserting this and deriving with respect to $\mu$ we get

$$\frac{2\tilde{\lambda}-1}{4\tilde{\lambda}-1}(4\rho' - 3(\mu\rho')') = 0 \,.$$

Let us now exclude the case $2\tilde{\lambda} - 1 = 0$. We see that a necessary condition for the Ricci tensor of a nontrivial Rastall's geometry of matter to be a perfect fluid is

$$4\rho' - 3(\mu\rho')' = 0 \,.$$

*i.e.*

$$\rho' - 3p' = 0 \,.$$

the equation of state is therefore

$$p = \frac{1}{3}\rho + const.(\mu) \,,$$

*i.e.* if we denote $\alpha$ the integration constant (a constant function of $\mu$) (uniquely determined by initial data)

$$p - \alpha = \frac{1}{3}\rho$$

In particular it is easy to get that $-3\alpha = \rho - 3p = \tilde{T}$, *i.e.* $\alpha = -\frac{1}{3}\tilde{T}$

By redefining the pressure $\pi = p - \alpha = p + \frac{1}{3}\tilde{T}$ the equation of state is the one of an ultrarelativistic perfect fluid with pressure $\pi$ and energy density $\rho$.

$$\pi = \frac{1}{3}\rho \iff p = \frac{1}{3}(\rho - \tilde{T})$$

*i.e.* with a rescaled pressure or equivalently a *energy density rescaled by the trace of the energy-momentum tensor*. This relation gives us a model with constant (with respect to the matter density $\mu$) energy-tensor trace $\tilde{T}$ and consequently constant (with respect to $\mu$) scalar curvature.

# How to use unimodular quantum cosmology for the prediction of a late-time classical universe?

Natascha Riahi

*University of Vienna, Faculty of Physics, Gravitational Physics*
*Boltzmanng. 5, 1090 Vienna, Austria*
*E-mail: natascha.riahi@gmx.at*

Unimodular quantum cosmology admits wavepacket solutions that evolve according to a kind of Schrödinger equation. Though this theory is equivalent to general relativity on the classical level, its canonical structure is different and the problem of time does not occur. We present an Ehrenfest theorem for the long term evolution of the expectation value of the scale factor for a spatially flat Friedmann universe with a scalar field. We find that the classical and the quantum behavior in the asymptotic future coincide for the special case of a massless scalar field. We examine the general behavior of uncertainties in order to single out models that can lead to a classical universe.

## 1. Introduction

The canonical quantization of general relativity leads to the so-called problem of time (see[1] and references therein). In most non-perturbative approaches of quantum gravity time has disappeared from the theory and is seen as an artifact of the classical limit. Here we investigate quantum cosmology in the framework of unimodular gravity. This theory is practically equivalent to general relativity at the classical level, but since it has a different canonical structure time does not disappear from the quantum theory[2] and the quantization of unimodular theory yields different results compared to the quantization of general relativity[3]. In[4] we constructed a class of unitarily evolving solutions with a negative expectation value of the Hamiltonian for the special case of a spatially flat universe with a massless scalar field. Investigating a special example, we found that the classical and quantum dynamics of the scale factor coincide for the asymptotic future (though with significant spread). Here we compare the expectation value of the scale factor to the evolution of its classical counterpart for solutions of the spatially flat Friedmann universe with an arbitrary scalar field which yields an Ehrenfest theorem for the late time behavior. We examine the evolution of the uncertainties in order to single out models that can lead to a classical universe in the asymptotic future.

## 2. About Unimodular Gravity

We start with the Einstein Hilbert action (1)

$$S_{EH} = \frac{1}{2\kappa}\int_{\mathcal{M}} d^4x\,\sqrt{-g}\,(R-2\Lambda) - \frac{1}{\kappa}\int_{\partial\mathcal{M}} d^3x\,\sqrt{h}\,K\,, \tag{1}$$

where

$$\kappa = \frac{8\pi G}{c^4}$$

contains the velocity of light $c$ and the gravitational constant $G$. We also take into account the matter action $S_m$ that describes the fields. If we vary the action $S = S_m + S_{EH}$ with respect to the metric $g_{\mu\nu}$ under the restriction $-g = 1$, we obtain Einsteins equations with an arbitrary additional constant $\Lambda$ , that can be identified with the cosmological constant of general relativity ([2]).

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R = \kappa\, T_{\mu\nu} - \Lambda\, g_{\mu\nu}, \quad \sqrt{-g} - 1 = 0\,. \tag{2}$$

This theory is called unimodular gravity. Any solution of unimodular gravity (2) is also a solution of general relativity for a specific cosmological constant and vice versa. The only difference between the two theories is, that $\Lambda$ is a natural constant in general relativity while it is a conserved quantity in unimodular gravity. But since in both theories the cosmological constant can not vary over the whole universe, we would have to investigate different universes to determine if solutions with different $\Lambda$ exist (unimodular theory) or if $\Lambda$ is a "true" natural constant. So the two theories are practically indistinguishable on the classical level.

## 3. The Unimodular Hamiltonian of a spatially flat Friedmann Universe

The metric of a homogeneous and isotropic spacetime (Friedmann universe)

$$ds^2 = -N^2(t) c^2 dt^2 + a^2(t) d\Omega_3^2 \tag{3}$$

is characterized by the lapse function N(t) and the scale factor $a(t)$. If the spatial curvature is zero, $d\Omega_3^2$ is the line element of three-dimensional flat space.

Inserting the metric into the Einstein-Hilbert action (1) with $\Lambda = 0$ yields ([1])

$$S_{EH} = \frac{3}{\kappa} \int dt\, N \left( -\frac{\dot{a}^2 a}{c^2 N^2} \right) v_0\,,$$

where $v_0$ is is the volume of the spacelike slices according to (3).

The action of a scalar field in a Friedmann universe (3) reads

$$S_m = \int dt\, N a^3 \left( \frac{\dot{\phi}^2}{2N^2 c^2} - V(\phi) \right) v_0\,. \tag{4}$$

Using the unimodular condition for the lapse function $N = a^{-3}$, we find for the Hamiltonian ([4]) of the unimodular theory

$$H_{uni} = \frac{c^2}{2} \frac{p_\phi^2}{a^6} - \frac{c^2}{4\epsilon} \frac{p_a^2}{a^4} + V(\phi) \tag{5}$$

The Hamiltonian is a conserved quantity and not a constraint as in general relativity

The canonical quantization of this Hamiltonian yields

$$\hat{p}_a = -i\hbar \frac{\partial}{\partial a}\,, \quad \hat{p}_\phi = -i\hbar \frac{\partial}{\partial \phi}\,, \tag{6}$$

$$\widehat{H} = \frac{\hbar^2 c^2}{4\epsilon}\frac{1}{a^5}\frac{\partial}{\partial a}a\frac{\partial}{\partial a} - \frac{\hbar^2 c^2}{2}\frac{1}{a^6}\frac{\partial^2}{\partial \phi^2} + V(\phi)\,. \tag{7}$$

Here we have chosen the factor ordering that gives the part of the Hamiltonian that is quadratic in the momenta the form of a Laplace Beltrami operator ([1]).

The evolution of the wavefunction $\psi(a,\phi,t)$ is determined by

$$\widehat{H}\psi = i\hbar\frac{\partial}{\partial t}\psi\,. \tag{8}$$

The Hamiltonian is symmetric with respect to the inner product defined by the measure $a^5 da d\phi$, where $a \in (0,\infty)$ and $\phi \in (-\infty,\infty)$.

Applying the coordinate transformations

$$A = a^3/3 \qquad B = \frac{3}{\sqrt{2\epsilon}}\phi \tag{9a}$$

and

$$u = Ae^{-B} \qquad v = Ae^{B}\,, \tag{9b}$$

we obtain for the Hamilton operator

$$\widehat{H} = \frac{\hbar^2 c^2}{\epsilon}\frac{\partial^2}{\partial u \partial v} + V\left(\frac{u}{v}\right) \tag{10}$$

The volume element is given by $dudv$ and $u \in (0,\infty)$, $v \in (0,\infty)$.

The classical unimodular Hamiltonian then reads

$$H = -\frac{c^2}{\epsilon}p_u\, p_v + V\left(\frac{u}{v}\right)\,.$$

The Laplace-Beltrami factor ordering ensures that the quantization of the Hamiltonian commutes with the coordinate transformation if we understand classical transformations as canonical point transformations (see also[5]).

## 4. General properties of the time evolution

In[4] we have derived a class of unitarily evolving wavepacket solutions of (8) for the special case of a massless scalar field ($V = 0$). We found that these solutions fulfill in the late phase of time evolution

$$\lim_{t\to\infty}\,\psi(0,v,t) = \lim_{t\to\infty}\,\psi(u,0,t) = 0\,. \tag{11}$$

Now we assume that a wavepacket solution for a general scalar field can be found and that it also fulfills (11). We investigate the physical behaviour of these solutions compared to the evolution of the classical quantities.

As in ordinary quantum mechanics, the evolution of the expectation values of an observable $\widehat{O}$ with respect to a solution $\psi(u,v,t)$ of the Schrödinger equation (8) is given by

$$\frac{d}{dt}\langle\psi|\widehat{O}|\psi\rangle = -\frac{i}{\hbar}\left(\langle\psi|\widehat{O}\widehat{H}|\psi\rangle - \langle\widehat{H}\psi|\widehat{O}\psi\rangle\right)\,. \tag{12}$$

This implies the equation

$$\frac{d}{dt}\langle\psi|\widehat{O}|\psi\rangle = -\frac{i}{\hbar}\left\langle\psi\left[\widehat{O},\widehat{H}\right]\psi\right\rangle\,, \tag{13}$$

only if $\widehat{O}\psi$ obeys

$$\langle\widehat{H}\psi|\widehat{O}\psi\rangle \stackrel{!}{=} \langle\psi|\widehat{H}\widehat{O}|\psi\rangle\,. \tag{14}$$

In the case of the Hamiltonian(10), this condition reads

$$\int_0^\infty \psi^*(u,v,t)\frac{\partial}{\partial v}\widehat{O}\psi(u,v,t)dv\,\Big|_{u=0} - \int_0^\infty\left(\frac{\partial}{\partial u}\psi^*(u,v,t)\right)\widehat{O}\psi(u,v,t)du\,\Big|_{v=0} = 0\,. \tag{15}$$

We find that this condition is fulfilled in the limit $t\to\infty$ for wavepackets with the property (11). This means that the time evolution that we derive by the application of (13), gives the correct result for the limit $t\to\infty$, and is approximately valid in the late phase of time evolution.

We find for the variable $uv$, related to the scalefactor by $A^2 = uv = \frac{a^6}{9}$

$$\lim_{t\to\infty}\frac{d^2}{dt^2}\langle A^2\rangle = \frac{c^2}{\epsilon}\left\langle -2\,\widehat{H} + V + u\frac{\partial V}{\partial u} + v\frac{\partial V}{\partial v}\right\rangle\,, \tag{16a}$$

whereas the classical time evolution reads

$$\lim_{t\to\infty}\frac{d^2}{dt^2}A^2 = \frac{c^2}{\epsilon}\left(-2\,H + V + u\frac{\partial V}{\partial u} + v\frac{\partial V}{\partial v}\right)\,. \tag{16b}$$

So we see that in the special case of a massless scalar field the late time behavior of the classical scalefactor and its expectation value according to unimodular quantum cosmology are the same. In general (16) represents the Ehrenfest theorem for unimodular quantum cosmology.

The result for the uncertainty $\Delta(A^2)$ in the special case of a massless scalar field reads

$$\lim_{t\to\infty}\frac{d^4}{dt^4}(\Delta(A^2))^2 = \frac{24c^2}{\epsilon^2}(\Delta H)^2\,,$$

which implies that the uncertainty $\Delta(A^2)$ is monotonically growing with $t^2$ in the late phase of time evolution.

## 5. Evolution of uncertainties for general matter models

All dynamical equations in this section are derived under the assumption (11) using (13) and are therefore valid for late times. We find for the dynamics of the expectation values

$$\frac{d}{dt}\langle v\rangle = -\mu\,\langle\widehat{p_u}\rangle\,,\ \frac{d}{dt}\langle u\rangle = -\mu\,\langle\widehat{p_v}\rangle\,,\ \frac{d}{dt}\langle\widehat{p_u}\rangle = -\left\langle\frac{\partial V}{\partial v}\right\rangle\,,\ \frac{d}{dt}\langle\widehat{p_v}\rangle = -\left\langle\frac{\partial V}{\partial u}\right\rangle\,, \tag{17}$$

where $\mu = c^2/\epsilon = 2\pi G/(3c^2)$.

If $\frac{\partial V}{\partial v}, \frac{\partial V}{\partial u}$ fulfill

$$\langle F(u,v)\rangle \approx F(\langle u\rangle, \langle v\rangle) \tag{18}$$

the equations constitute a closed system of ordinary differential equations for the expectation values, which coincide with the classical evolution equations according to (7).

The four observables $\hat{u}, \hat{v}, \widehat{p_v}, \widehat{p_u}$ give rise to ten uncertainties $(\Delta u)^2, (\Delta v)^2$, $(\Delta p_u)^2, \Delta(p_v)^2$, $\Delta(u,v), \Delta(u,p_u)$, $\Delta(v,p_v)$, $\Delta(u,p_v)$, $\Delta(v,p_u)$, $\Delta(p_u,p_v)$, where the mixed uncertainties of two observables are defined by

$$\Delta(v_1,v_2) = \frac{1}{2}\left\langle \widehat{v_1}\widehat{v_2} + \widehat{v_2}\widehat{v_1} - 2\left\langle \widehat{v_1}\right\rangle \left\langle \widehat{v_1}\right\rangle \right\rangle$$

The application of (13) yields the evolution equations that contain expectation values of partial derivatives of $V$ as for instance

$$\frac{d}{dt}\Delta(u,p_v) = -\mu\Delta(p_v)^2 - \left\langle \frac{\partial V}{\partial v}u \right\rangle + \left\langle \frac{\partial V}{\partial v} \right\rangle \langle u\rangle \ . \tag{19}$$

Expanding the occurring derivatives of $V$ around the expectation values given by (17)and neglecting all stochastic moments of higher than second order yields a closed system of linear differential equations for the variances (quadratic uncertainties):

$$\begin{aligned}
&\frac{d}{dt}(\Delta u)^2 = -2\mu(\Delta(u,p_v)\,, \quad \frac{d}{dt}(\Delta v)^2 = -2\mu(\Delta(v,p_u))\,, \\
&\frac{d}{dt}\Delta(u,p_v) = -\mu\Delta(p_v)^2 - V_{22}\Delta(u,v) - V_{12}(\Delta u)^2\,, \\
&\frac{d}{dt}\Delta(v,p_u) = -\mu\Delta(p_u)^2 - V_{11}\Delta(u,v) - V_{12}(\Delta v)^2\,, \\
&\frac{d}{dt}\Delta(u,v) = -\mu\Delta(v,p_v) - \mu\Delta(u,p_u)\,, \\
&\frac{d}{dt}(p_u)^2 = -2V_{11}(\Delta(u,p_u) - 2V_{12}(\Delta(v,p_u)\,, \\
&\frac{d}{dt}(p_v)^2 = -2V_{22}(\Delta(v,p_v) - 2V_{12}(\Delta(u,p_v)\,, \\
&\frac{d}{dt}\Delta(p_u,p_v) = -V_{11}\Delta(u,p_v) - V_{12}\Delta(p_v,v) - V_{22}\Delta(v,p_u) - V_{12}\Delta(p_u,u)\,, \\
&\frac{d}{dt}\Delta(u,p_u) = -\mu\Delta(p_u,p_v) - V_{11}(\Delta u)^2 - V_{12}\Delta(u,v)\,, \\
&\frac{d}{dt}\Delta(v,p_v) = -\mu\Delta(p_u,p_v) - V_{22}(\Delta v)^2 - V_{12}\Delta(u,v)\,,
\end{aligned} \tag{20}$$

where we have chosen the abbreviations

$$V_{11} = \frac{\partial^2 V}{\partial v^2}\,, \quad V_{22} = \frac{\partial^2 V}{\partial u^2} \quad V_{12} = \frac{\partial^2 V}{\partial v \partial u}\,.$$

Given that all contributions of higher moments can be neglected, all uncertainties remain bounded if the system (20) is stable. This is especially the case if $V_{11}, V_{22}, V_{12}$

converge to fixed values for late times and fulfill

$$|V_{12}| < \sqrt{V_{11}V_{22}}\,, \quad V_{12} < 0$$

since then all characteristic roots of (20) have zero real part and are of simple type (see for instance[6]).

If we neglect deviations from the classical dynamics which would be of the order of magnitudes of variances (see (18)) we can evaluate (20) inserting the classical solutions for $\langle u\rangle\,, \langle v\rangle\,, \langle\widehat{p_u}\rangle\,, \langle\widehat{p_v}\rangle$ and verify if the initial assumption of small uncertainties (variances) is justified.

# Newton gauge cosmological perturbations for static spherically symmetric modifications of the de Sitter metric

Antonio Enea Romano[1,2],Camilo Santa Vélez[2]

[1]*King's College London, Strand, London, WC2R 2LS, United Kingdom*
[2]*Instituto de Fisica, Universidad de Antioquia, A.A.1226, Medellin, Colombia*

Static coordinates can be convenient to solve the vacuum Einstein's equations in presence of spherical symmetry, but for cosmological applications comoving coordinates are more suitable to describe an expanding Universe, especially in the framework of cosmological perturbation theory (CPT). Using CPT we develop a general method to transform in the weak field limit any static spherically symmetric (SSS) metric from static coordinates to the Newton gauge. We apply the method to the Schwarzschild de Sitter (SDS) metric to a SSS solution of the Brans-Dicke theory, confirming the results obtained independently by solving the perturbation equations in the Newton gauge. We then consider different classes of SSS metrics obtained by modifying the SDS metric and compute the corresponding Bardeen potentials. Using the gauge invariance of the Bardeen potentials we obtain a gauge invariant definition of the turn around radius, checking it is consistent with the result obtained in static coordinates for the SDS metric and for other SSS metrics.

## 1. Introduction

Spherically symmetric solutions are important because they allow to compute different observables within the solar system or to study the stability of large scale structure[1,2]. They can consequently provide a very important tool to test modified gravity theories[3]. In general relativity the most general spherically symmetric vacuum solution of the Einstein's field equations with a cosmological constant, the Schwarzschild-De-Sitter solution, can be written in static coordinates[4]. This is a consequence of the Birkhoff's theorem, but for a general modified theory of gravity such a coordinate system may not be possible. For a modified gravity theory in fact the most general spherically symmetric solution may not be expressed in static coordinates, but only a subclass of the general solutions. This is the consequence of the fact that the Birkhoff's theorem may not hold in modified gravity theories[5].

In cosmology comoving coordinates are more convenient to describe an expanding Universe, especially in the framework of cosmological perturbation theory (CPT), and it is therefore useful to find the coordinate transformation from static to comoving coordinates. In this paper we develop a general method to transform in the weak field limit any spherically symmetric metric from static coordinates to the Newton gauge and apply it to different known and new cases. We first apply the method to the Schwarzschild de Sitter (SDS) metric, confirming it does indeed allow to compute correctly the Newtonian potential due to a point mass in an expanding Universe. We then compute the Newtonian potentials for a spherically symmetric solution of the Brans-Dicke theory in static coordinates, confirming the results obtained independently by solving the Brans-Dicke field equations in the Newton gauge[3]. Using the gauge invariance of the Bardeen potentials we obtain a gauge

invariant definition of the turn around radius, checking it is consistent with the result obtained in static coordinates for the SDS metric and for other static spherically symmetric (SSS) metrics. We finally consider different generalized classes of SSS metrics and using the same method we transform them to the Newton gauge.

## 2. Static Coordinates

Assuming a general spherically symmetric metric ansatz of the type

$$ds^2 = F(t,R)dt^2 - H(t,R)dR^2 - R^2 d\Omega^2, \tag{1}$$

one of the Einstein's equations gives $\partial_t f = 0$, implying the existence of the well known static coordinates solution

$$F(t,R) = H(t,R)^{-1} = \left(1 - \frac{2m}{R} - \frac{R^2}{l^2}\right), \tag{2}$$

where have defined $l^2 = 3/\Lambda$. Substituting the same general ansatz in the field equation of a different gravity theory the equation $\partial_t f = 0$ may not hold anymore, and a general spherically symmetric solution may not be written in static coordinates anymore. The de-Sitter metric, i.e. the $m = 0$ limit of the SDS metric, can also be written in isotropic coordinates

$$R = e^{t/l} r \tag{3}$$

$$t = \tilde{t} - \frac{l}{2}\log(r^2 e^{2t/l} - l^2) \tag{4}$$

$$ds^2 = d\tilde{t}^2 - a^2(t)(dr^2 + r^2 d\Omega^2), \tag{5}$$

where $a(\tilde{t}) = e^{\tilde{t}/l}$. These coordinates are called comoving coordinates in cosmology because they are interpreted as the coordinates of the observer comoving with the Hubble flow, and for this reason we will use this terminology in the rest of this paper. We will use a similar coordinate transformation from static to comoving coordinates to re-write the SDS metric far from the Schwarzschild radius, i.e. for $m \ll r$ in terms of cosmological perturbations respect to the FRW background.

## 3. Cosmological perturbations in a spherically symmetric space and their relation with static coordinates

For cosmological applications it is useful to re-write the SSS metrics in comoving coordinates. The the most general scalar perturbations respect to the flat FRW background can be written as[6]

$$ds^2 = a^2\Big\{(1+2\psi)d\tau^2 - 2\partial_i\omega d\tau dx^i - [(1-2\phi)\delta_{ij} + D_{ij}\chi]\, dx^i dx^j\Big\}, \tag{6}$$

where $D_{ij} = \partial_i\partial_j - \frac{1}{3}\delta_{ij}\nabla^2$.

Assuming spherical symmetry the metric can be written as[7]

$$ds^2 = a^2\Big[(1+2\psi)d\tau^2 - \left(1-2\phi+\frac{2}{3}\mathcal{E}\right)dr^2 - 2\omega' d\tau dr - \left(1-2\phi-\frac{1}{3}\mathcal{E}\right)r^2 d\Omega^2\Big], \tag{7}$$

where

$$\mathcal{E} = \chi'' - \frac{\chi'}{r}\,, \tag{8}$$

and the prime $'$ denotes derivative respect to $r$.

Static coordinates are not commonly used in cosmology, where the comoving coordinate are normally preferred, but can be useful to solve different problems such as the estimation of the maximum size of gravitationally bounded structures. This is due to the fact that in static coordinates it is more convenient to define the turn around radius[3]. For this reason it can be interesting to understand what cosmological perturbations metrics can be written in static coordinates. In general it is difficult to establish if static coordinates exist for a generic metric written in the form in eq.(7), so we will to approach the problem from the opposite direction and look for an answer to this question : what form does it take in terms of cosmological perturbations theory a metric which can be written in static coordinates?

## 4. SDS metric in the Newton gauge

After substituting $R = e^{t/l}r$ in the SDS metric in static coordinates, far from the cosmological and Schwarzschild horizon , i.e. for $m \ll r \ll l$, at leading order we get

$$ds^2 = \left(1-\frac{2m}{ar}\right)dt^2 - 4m\dot{a}\,dtdr - a^2\left(1+\frac{2m}{ar}\right)dr^2 - a^2r^2d\Omega^2\,, \tag{9}$$

where $\dot{a} = da/dt$. Introducing conformal time $d\tau = dt/a(t)$ we then get

$$ds^2 = a^2\left[\left(1-\frac{2m}{ar}\right)d\tau^2 - 4m\frac{a_\tau}{a^2}d\tau dr - \left(1+\frac{2m}{ar}\right)dr^2 - r^2d\Omega^2\right], \tag{10}$$

and comparing with equation (7) we get

$$\psi = -\frac{m}{ar}\,, \tag{11}$$

$$\phi = -\frac{m}{3ar}\,, \tag{12}$$

$$\omega' = \frac{2ma_\tau}{a^2} \tag{13}$$

$$\mathcal{E} = \frac{2m}{ar}. \tag{14}$$

After integrating eq.(8) and $\omega'$ we finally get

$$\omega = \frac{2ma_\tau}{a^2}r \tag{15}$$

$$\chi = -\frac{2mr}{a} + \frac{1}{2}r^2C(\tau) + D(\tau)\,, \tag{16}$$

where $C$ and $D$ are functional constants of integration. Since we are only interested in perturbations which should vanish in a limit in which the mass vanishes, the physically interesting solutions correspond to $C = D = 0$.

Using cosmological perturbation theory (CPT) we can derive explicitly the gauge transformation between the static coordinates and the Newton gauge. Under an infinitesimal space-time translation of the form

$$\tilde{x}^0 = x^0 + \zeta, \tag{17}$$
$$\tilde{x}^i = x^i + \partial^i \beta, \tag{18}$$

the gauge transformations are

$$\tilde{\phi} = \phi - \frac{1}{3}\nabla^2\beta + \frac{a_\tau}{a}\zeta, \tag{19}$$
$$\tilde{\omega} = \omega + \zeta + \beta_\tau, \tag{20}$$
$$\tilde{\psi} = \psi - \zeta_\tau - \frac{a_\tau}{a}\zeta, \tag{21}$$
$$\tilde{\chi} = \chi + 2\beta. \tag{22}$$

Imposing the Newton gauge condition

$$\omega_N = \chi_N = 0, \tag{23}$$

after solving the differential equations (19) we get

$$\beta = \frac{mr}{a}, \tag{24}$$
$$\zeta = -\frac{mra_\tau}{a^2}. \tag{25}$$

We can then use the gauge transformations to calculate the perturbations in the Newton gauge up to leading order

$$\Psi_N = -\frac{m}{ar}, \tag{26}$$
$$\Phi_N = -\frac{m}{ar}. \tag{27}$$

Instead of finding the transformation taking to the Newton gauge we could have also computed the Bardeen potentials[8] directly from eq.(11) up to leading order:

$$\Psi_B = \psi - \frac{1}{a}\left[a\left(\frac{\chi_\tau}{2} - \omega\right)\right]_\tau = -\tfrac{m}{ar}, \tag{28}$$
$$\Phi_B = \phi + \frac{1}{6}\nabla^2\chi - \frac{a_\tau}{a}\left(\omega - \frac{\chi_\tau}{2}\right) = -\tfrac{m}{ar}\,. \tag{29}$$

As expected the the Bardeen potentials reduce to the Newton gauge potentials obtained in eq.(27) and eq.(26), and the metric takes the form

$$ds^2 = a^2\left[\left(1 - \frac{2m}{ar}\right)d\tau^2 - \left(1 + \frac{2m}{ar}\right)\left(dr^2 + r^2 d\Omega^2\right)\right]. \tag{30}$$

## 5. Spherically symmetric solutions in Brans-Dicke theory in static coordinates and in the Newton gauge

In Brans-Dicke (BD) theory the the Jebsen-Birkhoff theorem[5] is valid if the scalar field is time independent. As a consequence under the the assumption of a static scalar field also the static ansatz for the metric adopted in[3] should give the most general spherically symmetric solution. Applying a perturbative approach the solution of the field equations can be written as[9]

$$ds^2 = \left[1-(1+\epsilon)\frac{2m}{R}-(1-2\epsilon)\frac{\Lambda R^2}{3}\right]dt^2 - \left[1-(1-\epsilon)\frac{2m}{R}-(1-4\epsilon)\frac{\Lambda R^2}{3}\right]dR^2 - R^2 d\Omega^2, \tag{31}$$

where $\epsilon = \frac{1}{2\omega+3}$. The SDS solution is recovered in the limit $\epsilon \to 0$, which is also the limit in which the BD theory reduced to GR.

Adopting comoving coordinate defined as $R = ar$ the metric takes the form

$$ds^2 = \left[1-(1+\epsilon)\frac{2m}{ar}-(1-2\epsilon)\frac{\Lambda (ar)^2}{3}\right]dt^2 - \left[1-(1-\epsilon)\frac{2m}{ar}-(1-4\epsilon)\frac{\Lambda (ar)^2}{3}\right](adr+a'rdt)^2 - (ar)^2 d\Omega^2, \tag{32}$$

and after introducing conformal time $dt = ad\tau$

$$ds^2 = a^2\left\{\left[1-(1+\epsilon)\frac{2m}{ar}-(1-2\epsilon)\frac{\Lambda a^2 r^2}{3}\right]d\tau^2 - \left[1-(1-\epsilon)\frac{2m}{ar}-(1-4\epsilon)\frac{\Lambda a^2 r^2}{3}\right]\left(dr^2+2\frac{a'r}{a}drd\tau+\frac{r^2a'^2}{a^2}d\tau^2\right) - r^2 d\Omega^2\right\}, \tag{33}$$

we obtain the Bardeen potentials from the perturbations in the gauge given

$$\Psi_B = -\frac{m}{ar}(1+\epsilon), \tag{34}$$

$$\Phi_B = -\frac{m}{ar}(1-\epsilon), \tag{35}$$

which coincide with the Newton gauge result as expected, due to the gauge invariance of $\Psi_B$ and $\Phi_B$. These potentials reduce to the GR result $\Phi_N = \Psi_N = -\frac{m}{ar}$ in eq.(26,27) when $\epsilon \to 0$.

In general relativity the absence of anisotropic pressure perturbations in the vacuum implies that $\Phi_N = \Psi_N$ while in BD theory the field equations do imply this anymore, and they can be different. Note we have recovered, far form the cosmological horizon, the metric computed in[3] solving the perturbation equations in the Newton gauge. This shows explicitly what is the coordinate transformation between the solution in static and comoving coordinates, and that the solutions are indeed the same. The advantage of this approach is that it allows to derive the metric as a Newton gauge perturbation of the FRW solution directly from the

metric in static coordinates, without the need to solve again the perturbed field equations as it was done in[3].

# Scalar-nonmetricity theory

Margus Saal*, Laur Järv, Mihkel Rünkla and Ott Vilson

*Institute of Physics, University of Tartu,*
*W. Ostwaldi 1, 50411 Tartu, Estonia*
**E-mail: margus.saal@ut.ee*

Motivated by the symmetric teleparallel equivalent of general relativity we present a class of extended gravity theories where a scalar field is nonminimally coupled to nonmetricity $Q$. The Lagrange multipliers ensure that the connection is torsion free and flat. As a consequence, there exists a coordinate system where the connection coefficients vanish globally. We give the field equations for the metric, connection, and scalar field, and then briefly discuss cosmology, conformal invariance, and the relation with $f(Q)$ theory.

*Keywords*: symmetric teleparallel gravity, scalar-nonmetricity gravity

## 1. Introduction

General relativity (GR) as a geometric theory of gravity is based on metric Levi-Civita connection endowed with curvature $R$. However, by invoking alternative assumptions about the connection, one may reformulate the theory as teleparallel equivalent of general relativity (TEGR) based on torsion $T$, or symmetric teleparallel equivalent of general relativity (STEGR) based on nonmetricity $Q$.[1] Very recently the latter was generalized to $f(Q)$ gravity[2] in analogy with $f(R)$ theories. In the present note we review our work on constructing a scalar-nonmetricity theory,[3,4] in analogy with the scalar-tensor gravity based on curvature.

## 2. Triality of gravitational theories

### 2.1. *Connections*

On metric-affine spacetimes no constraints are imposed on the metric $g_{\mu\nu}$ and on the connection $\Gamma^{\lambda}{}_{\mu\nu}$ so that they are completely independent variables. The most general affine connection can be decomposed into three parts

$$\Gamma^{\lambda}{}_{\mu\nu} = \left\{{}^{\lambda}{}_{\mu\nu}\right\} + K^{\lambda}{}_{\mu\nu} + L^{\lambda}{}_{\mu\nu} \tag{1}$$

given by the Levi-Civita connection $\left\{{}^{\lambda}{}_{\mu\nu}\right\}$ of the metric $g_{\mu\nu}$, contortion

$$K^{\lambda}{}_{\mu\nu} \equiv \frac{1}{2} g^{\lambda\beta} \left(T_{\mu\beta\nu} + T_{\nu\beta\mu} + T_{\beta\mu\nu}\right) = -K_{\nu\mu}{}^{\lambda}\,, \tag{2}$$

and disformation

$$L^{\lambda}{}_{\mu\nu} \equiv \frac{1}{2} g^{\lambda\beta} \left(-Q_{\mu\beta\nu} - Q_{\nu\beta\mu} + Q_{\beta\mu\nu}\right) = L^{\lambda}{}_{\nu\mu}\,. \tag{3}$$

The contortion tensor can be defined via torsion,

$$T^{\lambda}{}_{\mu\nu} \equiv 2\Gamma^{\lambda}{}_{[\mu\nu]} = \Gamma^{\lambda}{}_{\mu\nu} - \Gamma^{\lambda}{}_{\nu\mu}\,, \tag{4}$$

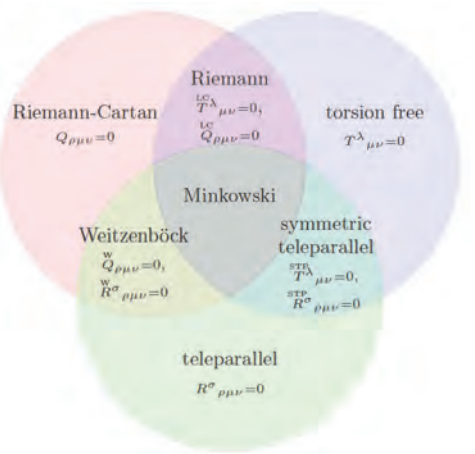

Fig. 1. Restrictions to connection defines different geometries.[3]

and the disformation tensor via nonmetricity,

$$Q_{\rho\mu\nu} \equiv \nabla_\rho g_{\mu\nu} = \partial_\rho g_{\mu\nu} - \Gamma^\beta{}_{\rho\mu} g_{\beta\nu} - \Gamma^\beta{}_{\rho\nu} g_{\mu\beta} \,. \tag{5}$$

Let us recall, that the torsion measures the non-closure of the parallelogram if two vectors are parallel transported along to each other, and the nonmetricity is associated with the change in length of a vector upon parallel transport.

Strictly speaking, nonmetricity, torsion, as well as curvature

$$R^\sigma{}_{\rho\mu\nu} \equiv \partial_\mu \Gamma^\sigma{}_{\nu\rho} - \partial_\nu \Gamma^\sigma{}_{\mu\rho} + \Gamma^\alpha{}_{\nu\rho}\Gamma^\sigma{}_{\mu\alpha} - \Gamma^\alpha{}_{\mu\rho}\Gamma^\sigma{}_{\nu\alpha} \tag{6}$$

are all properties of the connection. Restricting the connection we can define different geometries, see Fig. 1. In the present note we focus our attention to the case, when torsion and curvature are zero, i.e. the symmetric teleparallel (STP) connection. To denote a situation where a particular property is imposed on the connection, and consequently on the covariant derivative, curvature, etc, we use overset labels, e.g., $\overset{\text{STP}}{\Gamma}{}^{\lambda}{}_{\mu\nu}$, $\overset{\text{W}}{\nabla}_\mu$, $\overset{\text{LC}}{R}{}^{\sigma}{}_{\rho\mu\nu}$.

In what follows we shall utilize the symmetric teleparallel connection, $\overset{\text{STP}}{\Gamma}{}^{\lambda}{}_{\mu\nu} = \overset{\text{STP}}{\Gamma}{}^{\lambda}{}_{(\mu\nu)}$, which is torsion free, $\overset{\text{STP}}{T}{}^{\sigma}{}_{\mu\nu} = 0$, and flat, $\overset{\text{STP}}{R}{}^{\sigma}{}_{\rho\mu\nu} = 0$. In that case there exists a coordinate system $\{\xi^\sigma\}$ where the connection coefficients $\overset{\text{STP}}{\Gamma}{}^{\lambda}{}_{\mu\nu}$ vanish globally, $\overset{\text{STP}}{\Gamma}{}^{\lambda}{}_{\mu\nu}(\xi^\sigma) = 0$.

The result leads to corollaries. First, the covariant derivatives commute[1] $\overset{\text{STP}}{\nabla}_\mu \overset{\text{STP}}{\nabla}_\nu \mathbb{T}\Big|_{\{\xi^\sigma\}} = \partial_\mu\partial_\nu \mathbb{T} = \partial_\nu\partial_\mu \mathbb{T} = \overset{\text{STP}}{\nabla}_\nu \overset{\text{STP}}{\nabla}_\mu \mathbb{T}\Big|_{\{\xi^\sigma\}}$, where $\mathbb{T}$ is a tensor (density) of arbitrary rank (and weight). Secondly, in an arbitrary coordinate system $\{x^\mu\}$, the connection coefficients read[2]

$$\overset{\text{STP}}{\Gamma}{}^{\lambda}{}_{\mu\nu} = \frac{\partial x^\lambda}{\partial \xi^\sigma} \frac{\partial}{\partial x^\mu} \left( \frac{\partial \xi^\sigma}{\partial x^\nu} \right) , \tag{7}$$

where $\{\xi^\sigma\}$ are the coordinates for which the connection vanishes.

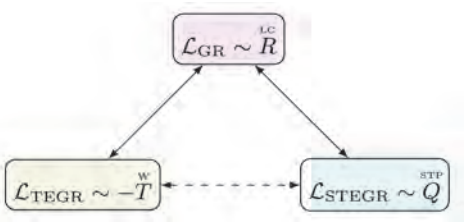

Fig. 2. Triple equivalence of gravitational theories: general relativity (GR) based on connection with vanishing nonmetricity and torsion, teleparallel equivalent of general relativity (TEGR) based on connection with vanishing nonmetricity and curvature, and symmetric teleparallel equivalent of general relativity (STEGR) based on connection with vanishing curvature and torsion.[3]

### 2.2. *Equivalent formulations of general relativity*

The curvature scalar for general connection reads

$$R = \overset{\rm LC}{R} + M^{\lambda}{}_{\nu\rho} M^{\mu}{}_{\mu\lambda} g^{\nu\rho} - M^{\lambda}{}_{\mu\rho} M^{\mu}{}_{\nu\lambda} g^{\nu\rho} + \overset{\rm LC}{\nabla}_{\mu} \left( M^{\mu}{}_{\nu\rho} g^{\nu\rho} - M^{\nu}{}_{\nu\rho} g^{\mu\rho} \right) , \tag{8}$$

where we have used the notation $M^{\lambda}{}_{\mu\nu} = K^{\lambda}{}_{\mu\nu} + L^{\lambda}{}_{\mu\nu}$. If we restrict the geometry to have vanishing torsion and nonmetricity, hence $M^{\lambda}{}_{\nu\rho} = 0$, and the curvature scalar (8) is simply $R = \overset{\rm LC}{R}$ which is the case of GR. If we choose a Weitzenbck connection whereby the curvature and the nonmetricity are zero, thus $\overset{\rm W}{R} = 0$, $M^{\lambda}{}_{\nu\rho} = \overset{\rm W}{K}{}^{\lambda}{}_{\nu\rho}$, then Eq. (8) yields $\overset{\rm LC}{R} = -\overset{\rm W}{T} - 2\overset{\rm LC}{\nabla}_{\rho} \overset{\rm W}{T}{}^{\rho}$, where we introduced the torsion scalar $T$ and its trace $T^{\rho}$. The action given by $\overset{\rm W}{T}$ differs from the one of GR by just a total divergence term and thus provides an equivalent theory (TEGR).

A third possibility is to impose vanishing curvature and torsion, which is the case of symmetric teleparallel connection. Plugging $\overset{\rm STP}{R} = 0$ and $M^{\lambda}{}_{\nu\rho} = \overset{\rm STP}{L}{}^{\lambda}{}_{\nu\rho}$ into (8) now yields

$$\overset{\rm LC}{R} = \overset{\rm STP}{Q} - \overset{\rm LC}{\nabla}_{\rho} (\overset{\rm STP}{Q}{}^{\rho} - \overset{\rm STP}{\tilde{Q}}{}^{\rho}) , \tag{9}$$

where we introduced the nonmetricity scalar $Q$ as

$$Q = -\frac{1}{4} Q_{\alpha\beta\gamma} Q^{\alpha\beta\gamma} + \frac{1}{2} Q_{\alpha\beta\gamma} Q^{\beta\gamma\alpha} + \frac{1}{4} Q_{\alpha} Q^{\alpha} - \frac{1}{2} Q_{\alpha} \tilde{Q}^{\alpha} , \tag{10}$$

and two independent contractions,

$$Q_{\alpha} \equiv Q_{\alpha}{}^{\beta}{}_{\beta} , \qquad \tilde{Q}^{\alpha} \equiv Q_{\beta}{}^{\beta\alpha} . \tag{11}$$

As the action constructed with the nonmetricity scalar (10) restricted to symmetric teleparallel connection would differ from the GR action only by a total divergence term, and the latter does not contribute to the equations of motion, we get another formulation of Einstein's gravity, i.e. STEGR. The three equivalent formulations are summarized on Fig. 2.

## 3. Scalar-nonmetricity theory

Let us introduce the action

$$S = \frac{1}{2}\int \mathrm{d}^4x\sqrt{-g}\,(\mathcal{L}_\mathrm{g} + \mathcal{L}_\ell) + S_\mathrm{m}\,, \tag{12}$$

with gravitational Lagrangian of a scalar $\Phi$ coupled to nonmetricity $Q$,

$$\mathcal{L}_\mathrm{g} = \mathcal{A}(\Phi)Q - \mathcal{B}(\Phi)g^{\mu\nu}\partial_\mu\Phi\partial_\nu\Phi - 2\mathcal{V}(\Phi)\,, \tag{13}$$

and Lagrange multipliers terms that impose vanishing curvature and torsion,

$$\mathcal{L}_\ell = 2\lambda_\sigma{}^{\nu\mu\rho}R^\sigma{}_{\nu\mu\rho} + 2\lambda_\sigma{}^{\mu\nu}T^\sigma{}_{\mu\nu}\,. \tag{14}$$

Here $S_\mathrm{m}$ denotes the action of matter fields (not directly coupled to the scalar field $\Phi$). The general action contains three functions describing the nonminimal coupling, kinetic term, and potential of the scalar field $\mathcal{A}(\Phi), \mathcal{B}(\Phi), \mathcal{V}(\Phi)$. The nonmetricity scalar $Q$ is given by (10). In the case when $\mathcal{A} = 1$ and $\mathcal{B} = \mathcal{V} = 0$ the theory reduces to plain STEGR.

Variation of the action (12) with respect to the metric gives symmetric field equations

$$\begin{aligned}&\frac{2}{\sqrt{-g}}\overset{\mathrm{STP}}{\nabla}_\sigma\left(\sqrt{-g}\mathcal{A}\overset{\mathrm{STP}}{P}{}^\sigma{}_{\mu\nu}\right) - \frac{1}{2}g_{\mu\nu}\mathcal{A}\overset{\mathrm{STP}}{Q} + \mathcal{A}\left(\overset{\mathrm{STP}}{P}{}_{\mu\sigma\rho}\overset{\mathrm{STP}}{Q}{}_\nu{}^{\sigma\rho} - 2\overset{\mathrm{STP}}{Q}{}_{\sigma\rho\mu}\overset{\mathrm{STP}}{P}{}^{\sigma\rho}{}_\nu\right) + \\ &+\frac{1}{2}g_{\mu\nu}\left(\mathcal{B}g^{\sigma\rho}\partial_\sigma\Phi\partial_\rho\Phi + 2\mathcal{V}\right) - \mathcal{B}\partial_\mu\Phi\partial_\nu\Phi = \mathcal{T}_{\mu\nu}\,.\end{aligned} \tag{15}$$

Here $\overset{\mathrm{STP}}{P}{}_{\mu\sigma\rho}$ is the nonmetricity conjugate (or superpotential)

$$\overset{\mathrm{STP}}{P}{}^\sigma{}_{\mu\nu} = -\frac{1}{2}\overset{\mathrm{STP}}{L}{}^\sigma{}_{\mu\nu} + \frac{1}{4}\overset{\mathrm{STP}}{Q}{}^\sigma g_{\mu\nu} - \frac{1}{4}\left(\overset{\mathrm{STP}}{\tilde{Q}}{}^\sigma g_{\mu\nu} + \delta^\sigma_{(\mu}\overset{\mathrm{STP}}{Q}{}_{\nu)}\right) \tag{16}$$

which satisfies $\overset{\mathrm{STP}}{Q} = \overset{\mathrm{STP}}{Q}{}_\sigma{}^{\mu\nu}\overset{\mathrm{STP}}{P}{}^\sigma{}_{\mu\nu}$ and the matter energy-momentum tensor $\mathcal{T}_{\mu\nu}$ is defined as usual.

Variation with respect to the scalar field $\Phi$ gives

$$2\mathcal{B}\overset{\mathrm{LC}}{\nabla}_\alpha\overset{\mathrm{LC}}{\nabla}{}^\alpha\Phi + \mathcal{B}'\,g^{\mu\nu}\partial_\mu\Phi\partial_\nu\Phi + \mathcal{A}'\overset{\mathrm{STP}}{Q} - 2\mathcal{V}' = 0\,, \tag{17}$$

where the primes mean derivative with respect to the scalar field. The equation for the metric does not contain second derivatives of the scalar field, and analogously the equation for the scalar field does not contain second derivatives of the metric. Hence the equations are naturally "debraided". On the other hand, the scalar field is not sourced by ordinary matter, as it would be in the scalar-curvature-tensor case.

Variation of the action (12) with respect to connection yields an equation containing Lagrange multipliers

$$\overset{\mathrm{STP}}{\nabla}_\rho\left(\sqrt{-g}\lambda_\sigma{}^{\nu\mu\rho}\right) + \sqrt{-g}\lambda_\sigma{}^{\mu\nu} = \sqrt{-g}\mathcal{A}\overset{\mathrm{STP}}{P}{}^{\mu\nu}{}_\sigma\,. \tag{18}$$

Due to the symmetric teleparallel connection the covariant derivatives commute and it is possible to eliminate the Lagrange multipliers, which are antisymmetric with

respect to their last indices, from (18) by acting on it with $\overset{\text{STP}}{\nabla}_\mu \overset{\text{STP}}{\nabla}_\nu$. The result can be simplified further by using the equivalent of Bianchi identity, $\overset{\text{STP}}{\nabla}_\alpha \overset{\text{STP}}{\nabla}_\beta (\sqrt{-g}\overset{\text{STP}}{P}{}^{(\alpha\beta)}{}_\mu) = 0$, to give

$$\overset{\text{STP}}{\nabla}_\mu \left[ \left(\partial_{[\nu}\mathcal{A}\right) \overset{\text{STP}}{\nabla}_{\lambda]} \left(\sqrt{-g}g^{\mu\nu}\right)\right] = 0\,. \tag{19}$$

The equation for the connection (19) is not trivially satisfied and in order to find a solution we must solve the three equations simultaneously. In addition, we have the continuity equation for matter, which follows from the three above mentioned equations and can be used as a separate consistency check.

## 4. Remarks

### 4.1. *Example: flat FRLW cosmology*

Let us consider the spatially (Levi-Civita) flat line element $\mathrm{d}s^2 = -\mathrm{d}t^2 + a(t)^2\delta_{ij}\mathrm{d}x^i\mathrm{d}x^j$. From the equation for the connection (19) we observe that if the metric and the scalar field depend on one and the same variable $t$, then the coincident gauge $\overset{\text{STP}}{\Gamma}{}^\lambda{}_{\mu\nu} = 0$ is a consistent choice, because the anti-symmetrization vanishes for $[0,0]$ case. Calculating the Lagrangian $\overset{\text{STP}}{Q}$ in these coordinates yields $\overset{\text{STP}}{Q} = -6(\dot{a}/a)^2 = -6H^2$ and the corresponding Friedmann equations read

$$H^2 = \frac{1}{3\mathcal{A}}\Big(\rho + \frac{1}{2}\mathcal{B}\dot{\Phi}^2 + \mathcal{V}\Big)\,, \tag{20}$$

$$2\dot{H} + 3H^2 = \frac{1}{\mathcal{A}}\Big(-2\mathcal{A}'H\dot{\Phi} - \frac{1}{2}\mathcal{B}\dot{\Phi}^2 + \mathcal{V} - p\Big)\,, \tag{21}$$

$$\mathcal{B}\ddot{\Phi} + (3\mathcal{B}H + \frac{1}{2}\dot{\mathcal{B}})\dot{\Phi} + \mathcal{V}' + 3\mathcal{A}'H^2 = 0\,. \tag{22}$$

Here $\rho$ is the energy density and $p$ is the pressure of the matter fluid. By combining the equations we arrive at $\dot{\rho} + 3H(\rho + p) = 0$, thus checking once more that the coincident gauge $\overset{\text{STP}}{\Gamma}{}^\lambda{}_{\mu\nu} = 0$ is a suitable choice. These equations coincide with those obtained in the scalar-torsion case, and hence describe both early and late time accelerating phase equally well.

### 4.2. *Conformal transformations*

The nonmetricity scalar transforms under the conformal transformation $\bar{g}_{\mu\nu} = \mathrm{e}^{\Omega(\Phi)}g_{\mu\nu}$ as follows:

$$\bar{Q} = \mathrm{e}^{-\Omega}\Big(Q + \frac{3}{2}g^{\mu\nu}\partial_\mu\Omega\partial_\nu\Omega + (Q^\alpha - \tilde{Q}^\alpha)\partial_\alpha\Omega\Big). \tag{23}$$

The term $g^{\mu\nu}\partial_\mu\Omega\partial_\nu\Omega$ can be absorbed into the redefinition of the kinetic term of the scalar field, however the term $(Q^\alpha - \tilde{Q}^\alpha)\partial_\alpha\Omega$ does not appear in the original action and causes the action (12) not to preserve its structure under conformal transformations. However, if we add a term $\frac{1}{2}(Q^\alpha - \tilde{Q}^\alpha)\partial_\alpha\mathcal{A}(\Phi)$ to the original

Lagrangian, we obtain the exact equivalent to the familiar scalar-curvature theory, which is covariant under the conformal transformations and scalar field redefinitions.

### 4.3. *Equivalence with $f(Q)$*

Following the standard procedure it is possible to show that $f(Q)$ theories[2] where $\mathcal{L}_{\mathrm{g},f(Q)} = f(Q)$ form a subclass of scalar-nonmetricity theories. Utilizing an auxiliary field $\Phi$ we can write

$$\mathcal{L}_{\mathrm{g},aux} = f'(\Phi)\,Q - (f'(\Phi)\,\Phi - f(\Phi))\ . \tag{24}$$

By varying the action (24) with respect to $\Phi$ yields $f''(\Phi)(\Phi - Q) = 0$. By varying the action (24) with respect to $\Phi$ one gets $f''(\Phi)(\Phi - Q) = 0$. As $f''(\Phi) \neq 0$, the equation of motion gives $Q = \Phi$ and we restore the original action. After identifications $\mathcal{A}(\Phi) = f'(\Phi)$ and $2\mathcal{V}(\Phi) = f'(\Phi)\,\Phi - f(\Phi)$ we get scalar-nonmetricity action without a kinetic term for the scalar field (i.e $\mathcal{B}(\Phi) = 0$).

## 5. Summary

Of the three alternative geometric reformulations of general relativity, the symmetric teleparallel gravity and its extensions have received the least attention so far. In our work we endeavor to explore the ground by considering a generic setting where a scalar field is nonminimally coupled to the nonmetricity scalar in the symmetric teleparallel framework. A lot of research waits ahead, most obviously constructing solutions and clarifying their features, but also understanding the relations between the theories established in different geometric settings.

# Anisotropic universe with power law $f(R)$ gravity

M. Farasat Shamir*

*Department of Humanities and Sciences,*
*National University of Computer and Emerging Sciences, Lahore Campus, Pakistan*
**E-mail: farasat.shamir@nu.edu.pk*

This study highlights the dynamics of anisotropic universe in modified gravity. To meet this aim, locally rotationally symmetric Bianchi type $I$ spacetime is studied in the metric theory of $f(R)$ gravity. Anisotropic fluid is considered to study the exact solutions of modified field equations. In particular, a general solution metric is reported using the well-known power law $f(R)$ gravity model. The graphical analysis of equation of state parameter is given which includes the corresponding values predicted for cosmic expansion. The energy conditions are also discussed for a range of specific model parameter. It is shown that anisotropic universe in modified gravity anticipate some interesting solutions and viable power law $f(R)$ gravity models can be reconstructed using suitable values of model parameter.

*Keywords*: Modified Gravity; $f(R)$ Gravity; Expansion of Universe.

## 1. Introduction

Sufficient experimental evidence in the recent decade have unveiled a mysterious picture of accelerated expansion of universe[1]. It is also believed that universe is currently exhibiting a transient phase of cosmic expansion with $\omega = -1$ and ultimately it will collapse sometime in the future[2]. This interesting phenomenon of late time acceleration and dark energy is somehow justified by modification of gravity. The $f(R)$ theory of gravity has been debated seriously with some fruitful results[3]. Interesting reviews[4] may be helpful for a better comprehension of the theory.

The involvement of a general function of Ricci scalar in the theory predicts many solutions of modified field equations as compared to ordinary general relativity. However, one can also recover already known solutions. The simplest example is the existence of de Sitter solution when dealing with the vacuum case and power law $f(R)$ gravity model[5]. Similarly, Einstein static universe does exist in $f(R)$ theory with barotropic perfect fluid[6]. Thus investigating modified gravity, in particular, using power law model with anisotropic background seems interesting. In this study, locally rotationally symmetric (LRS) Bianchi type $I$ spacetime is investigated by considering anisotropic fluid and power law $f(R)$ gravity model.

## 2. Field Equations in $f(R)$ Gravity

The $f(R)$ gravity field equations are

$$f_R(R)R_{\mu\nu} - \frac{1}{2}f(R)g_{\mu\nu} - \nabla_\mu\nabla_\nu f_R(R) + g_{\mu\nu}\Box f_R(R) = \kappa T_{\mu\nu}, \tag{1}$$

where $f_R(R)$ is the derivative of $f(R)$ with respect to $R$ and the other notations have their usual meanings. Moreover, we consider LRS Bianchi type $I$ spacetime

$$ds^2 = dt^2 - X^2(t)dx^2 - Y^2(t)[dy^2 + dz^2], \tag{2}$$

and assume that the universe is filled with anisotropic fluid

$$T^{\mu}_{\nu} = diag[\rho, -p_x, -p_y, -p_z]. \tag{3}$$

We further characterize the anisotropic fluid as

$$T^{\mu}_{\nu} = diag[1, -\omega, -(\omega+\delta), -(\omega+\delta)]\rho, \tag{4}$$

where $\omega$ and $\delta$ are equation of state and skewness parameters respectively. Since $f(R)$ gravity field equations are highly non-linear in nature, so we adopt a conventional physical assumption of proportionality of shear scalar and expansion scalar which gives

$$X = Y^s, \qquad s \in \mathbb{R}. \tag{5}$$

Using, Eqs. (2), (4) and (5), the modified field equations simplify to

$$(2s+1)\frac{\dot{Y}^2}{Y^2}f_R - \frac{f}{2} - \tilde{Y}f_R + (s+2)\frac{\dot{Y}}{Y}\dot{f}_R = \kappa\rho, \tag{6}$$

$$-\left(\frac{2\ddot{Y}}{Y} + \frac{\dot{Y}^2}{Y^2}\right)f_R + \frac{f}{2} + \tilde{Y}f_R - \frac{2\dot{Y}}{Y}\dot{f}_R - \ddot{f}_R = \kappa\omega\rho, \tag{7}$$

$$-\left((s+1)\frac{\ddot{Y}}{Y} + s^2\frac{\dot{Y}^2}{Y^2}\right)f_R + \frac{f}{2} + \tilde{Y}f_R - (s+1)\frac{\dot{Y}}{Y}\dot{f}_R - \ddot{f}_R = \kappa(\omega+\delta)\rho, \tag{8}$$

where $\tilde{Y} \equiv (s+2)\frac{\ddot{Y}}{Y} + (s^2+s+1)\frac{\dot{Y}^2}{Y^2}$ and the over dot is to denote time derivative.

## 3. Dynamics of Anisotropic Universe with Power Law $f(R)$ Model

Now we consider the well known $f(R)$ gravity model as

$$f(R) = \zeta R^{r+1}, \qquad \zeta,\ r \in \mathbb{R} - \{0\}. \tag{9}$$

Differentiating Eq.(9) with respect to $R$, it follows that

$$f_R(R) = \zeta(r+1)R^r, \tag{10}$$

Without loss of any generality, we may choose $\zeta = \frac{1}{r+1}$. This simplifies the work for further analysis. Since the field equations (6)-(8) are still complicated even with the choice of power law model. Thus, a power law form of metric coefficient is chosen

$$Y(t) = \xi t^{\frac{1}{s+2}}, \quad \xi \in \mathbb{R} - \{0\}. \tag{11}$$

Using these settings, Eqs.(6)-(8) provide the corresponding expressions for energy density and pressure components

$$\rho = \frac{-1}{t^2(r+1)(s+2)^2}\Bigg[\big(2rs^2+2r^2s^2-2s+4rs+8sr^2+ 8r^2+6r-1\big)\left(\frac{2(2s+1)}{t^2(s+2)^2}\right)^r\Bigg], \tag{12}$$

$$p_x = \frac{-1}{t^2(r+1)(s+2)^2}\Bigg[\big(2rs^2-2s+4r^3s^2+6r^2s^2+4rs+ 20sr^2+16r^3s+16r^2+16r^3-1\big)\left(\frac{2(2s+1)}{t^2(s+2)^2}\right)^r\Bigg], \tag{13}$$

$$p_y = \frac{-1}{t^2(r+1)(s+2)^2}\Bigg[\big(2rs-2s+4r^2s^2+4r^3s^2+16r^3s+ 18sr^2+4r+16r^3+20r^2-1\big)\left(\frac{2(2s+1)}{t^2(s+2)^2}\right)^r\Bigg] = p_z. \tag{14}$$

Manipulating Eqs.(12)-(14), EoS and skewness parameters turn out to be

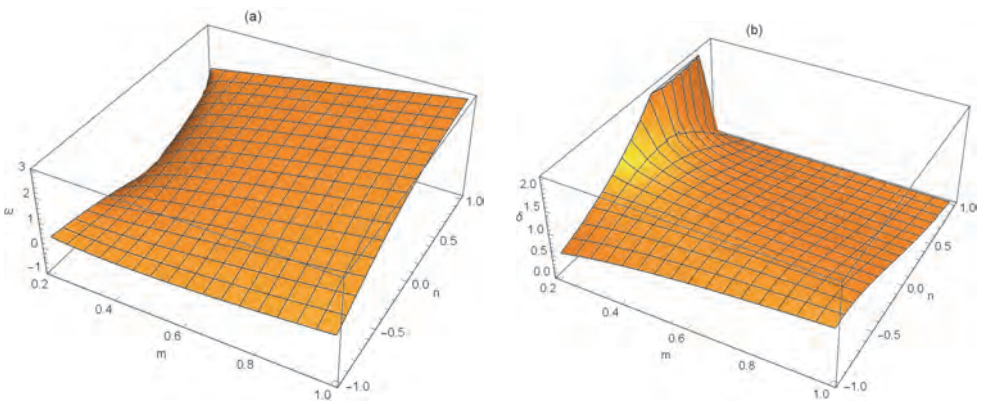

Fig. 1. Behavior of equation of state and skewness parameters

$$\omega = \frac{4r^3s^2+2s^2r+6r^2s^2-2s+20sr^2+16r^3s+4sr+16r^3+16r^2-1}{2r^2s^2+2s^2r+8sr^2+4sr-2s+8r^2+6r-1}, \tag{15}$$

$$\delta = -\frac{2r(r+1)(s+2)(s-1)}{2r^2s^2+2s^2r+8sr^2+4sr-2s+8r^2+6r-1}. \tag{16}$$

The behavior of these parameters is reflected in Fig. $(1a)$ and $(1b)$ respectively. It is worthwhile to notice that many possibilities of equation of state parameter exist. For example, an interesting case arise when $\omega = -1$ describing cosmic expansion[2,7,8].

In this case, explicit solutions of Eq.(15) turn out to be

$$r = \frac{-1 - s \pm \sqrt{3 + 6s + s^2}}{2(s+2)}, \tag{17}$$

and

$$s = \frac{-4r^2 - 3r + 1 \pm \sqrt{-5r^2 - 4r + 1}}{2r(r+1)}. \tag{18}$$

So in the light of above constraints, one can choose suitable power law $f(R)$ gravity model and the corresponding solution metric. In this case, a generic solution metric turns out to be

$$ds^2 = dt^2 - \xi^{2s} t^{\frac{2s}{s+2}} dx^2 - \xi^2 t^{\frac{2}{s+2}} (dy^2 + dz^2). \tag{19}$$

It is important to notice here that the anisotropy parameter involved in the above spacetime may also be used to reconstruct some well known solutions for physical relevance. For example, $s = -1/2$ gives the well known Kasner's universe and obviously this value corresponds to vacuum case (see Eqs.(12)-(14)).

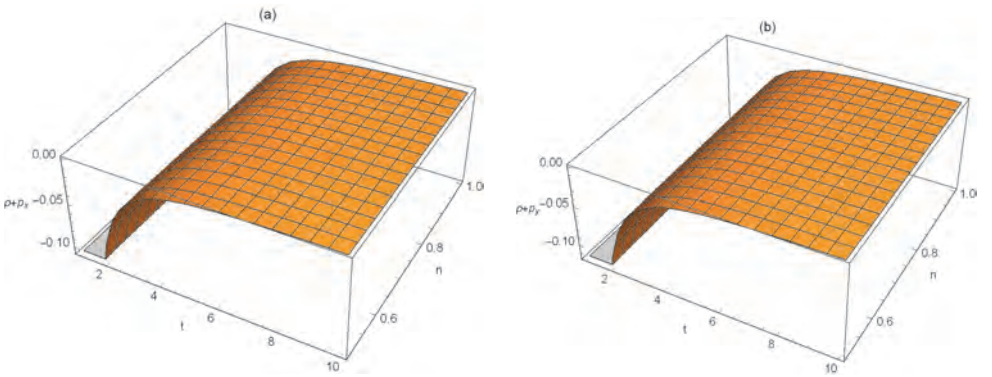

Fig. 2. Plots of NEC and WEC

### 3.1. *Power Law model and Energy Bounds*

The energy bounds have gained popularity in the modern day cosmology. It is important to mentation here that viability of cosmological models and some important theorems about black holes are associated with the energy bounds. The usual energy conditions namely null energy conditions (NEC), weak energy conditions (WEC), strong energy conditions (SEC) and dominant energy conditions (DEC)

are defined as

$$\begin{aligned}
&\text{NEC:} \quad \rho + p_x \geq 0, \quad \rho + p_y \geq 0 \\
&\text{WEC:} \quad \rho \geq 0, \quad \rho + p_x \geq 0, \quad \rho + p_y \geq 0, \\
&\text{SEC:} \quad \rho + 3p_x \geq 0, \quad \rho + 3p_y \geq 0, \quad \rho + p_x \geq 0, \quad \rho + p_y \geq 0, \\
&\text{DEC:} \quad \rho \geq 0, \quad \rho \pm p_x \geq 0, \quad \rho \pm p_y \geq 0.
\end{aligned} \tag{20}$$

The graphical behavior of these conditions is reflected in Figs. (2)-(4). It is mentioned here that we have fixed $\kappa = 1$ and the model parameter $r = 1/3$. Moreover, we choose the same range of anisotropy parameter $s$ as in the case of EoS parameter plot (see Fig. (1)). Since these values corresponds to negative $\omega$, so it is already anticipated that most of the energy bounds will not be satisfied. In particular, Fig. (3) depicts that SEC is violated. It is interesting as this violation seems to support an accelerating universe.

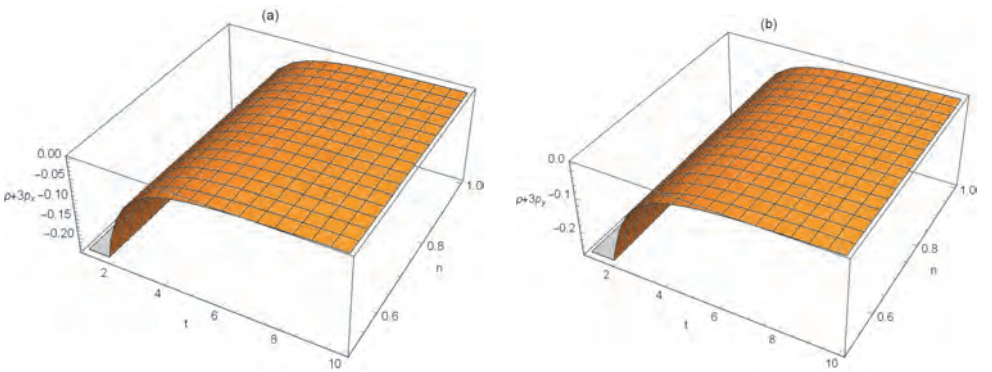

Fig. 3. Plots of SEC

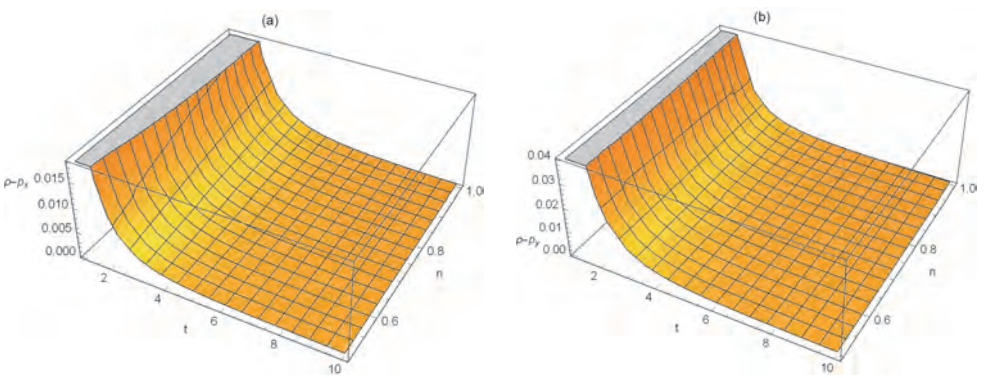

Fig. 4. Plots of DEC

## 4. Outlook

In the present work, we study the dynamics of anisotropic universe in modified gravity. LRS Bianchi type $I$ spacetime is investigated in the metric theory of $f(R)$ gravity to meet this aim. Moreover, an anisotropic fluid is considered with deviation parameter to discuss the dynamics of modified field equations. A general solution metric is reported using the well-known power law $f(R)$ gravity model. In particular, explicit equation for EoS parameter is reported in terms of anisotropy and $f(R)$ model parameters. The graphical analysis of equation of state parameter is also given which includes $\omega = -1$ predicted for cosmic expansion. The energy conditions are also discussed for a range of specific model parameter. We have only discussed some limited choices and many other possibilities can also be explored. It is shown that anisotropic universe in modified gravity anticipate some interesting solutions and viable power law $f(R)$ gravity models can be reconstructed using suitable values of model parameter.

# Stability of Einstein universe in matter-curvature coupling gravity

Sharif M.* and Waseem A.

*Department of Mathematics, University of the Punjab,*
*Lahore, 54590, Pakistan*
**E-mail: msharif.math@pu.edu.pk*
*www.pu.edu.pk*

We investigate the existence and stability of the Einstein universe in the context of $f(R,T,Q)$ gravity, where $Q = R_{\mu\nu}T^{\mu\nu}$. Considering linear homogeneous perturbations around scale factor and energy density, we formulate static as well as perturbed field equations. We parameterize the stability regions corresponding to conserved as well as non-conserved energy-momentum tensor using linear equation of state parameter for particular models of this gravity. The graphical analysis concludes that for a suitable choice of parameters, the stable regions of the Einstein universe are obtained which indicate that the big-bang singularity can be avoided successfully by the emergent mechanism in non-minimal matter-curvature coupled gravity.

*Keywords*: Stability analysis; Einstein universe; Modified gravity.

## 1. Introduction

The strong non-minimal coupling between gravity and matter fields present in $f(R,T,Q)$ gravity has gained much attention to study the issue of current accelerated cosmic expansion[1]. Odintsov and Sáez-Gómes[2] explored matter instability, $\Lambda$CDM model and de Sitter solutions in this modified theory. Sharif and Zubair investigated the validity of thermodynamical laws[3] and derived the energy conditions[4] for two different models of this gravity. The physical behavior of compact objects is also discussed in this gravity[5]. We have analyzed the dust spherical solution in the same gravity[6].

The emergent universe scenario to resolve the issue of big-bang singularity is based on the stability of Einstein universe (EU) against all kinds of perturbations. In general relativity, the idea of this emergent universe is not proved successful due to unstable EU against homogenous perturbations[7]. Seahra and Böhmer[8] showed that stable EU solutions exist in $f(R)$ models for perfect fluid with linear equation of state (EoS) and remain unstable against inhomogeneous perturbations. Shabani and Ziaie[9] discussed the stable solutions of EU in $f(R,T)$ gravity which were unstable in $f(R)$ gravity. Sharif and Ikram[10] investigated the stability of EU against linear homogeneous perturbations in $f(\mathcal{G},T)$ gravity and found stable solutions.

This paper explores the effects of strong non-minimal coupling on the stability of EU using homogeneous linear perturbations in $f(R,T,Q)$ gravity. In the next section, we formulate the field equations of this theory and investigate the stability of EU for both conserved and non-conserved energy-momentum tensor (EMT). In the last section, we concluding our results.

## 2. Stability Analysis of Einstein Universe in $f(R,T,Q)$ Gravity

The line element for closed FRW universe model is given by

$$ds^2 = dt^2 - a^2(t)\left(\frac{1}{1-r^2}dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2)\right), \tag{1}$$

where $a(t)$ represents the scale factor. The EMT for perfect fluid is

$$T_{\mu\nu} = (\rho + p)u_\mu u_\nu - pg_{\mu\nu}, \tag{2}$$

where $\rho,\ p$ and $u_\mu$ indicate energy density, pressure and four velocity, respectively. In closed FRW universe background, the field equations of $f(R,T,Q)$ gravity corresponding to $\mathcal{L}_m = -p$ are obtained as

$$\begin{aligned}\frac{3}{a^2}(1+\dot{a}^2) = \frac{1}{f_R + pf_Q}\Bigg[&\kappa^2\rho + (\rho+p)f_T + 3\left(\frac{a\ddot{a}+\dot{a}^2+1}{a^2}\right)f_R + \frac{1}{2}\\ &\times\ f(R,T,Q) - 3\frac{\dot{a}}{a}\partial_t f_R - \frac{3}{2}\left(\frac{4\dot{a}^2 - a\ddot{a}+2}{a^2}\right)\rho f_Q - \frac{3}{2}\\ &\times\ \left(\frac{a\ddot{a}+2\dot{a}^2}{a^2}\right)pf_Q + \frac{3\dot{a}}{2a}\partial_t[(p-\rho)f_Q]\Bigg],\end{aligned} \tag{3}$$

$$\begin{aligned}-2a\ddot{a} - (1+\dot{a}^2) = \frac{1}{f_R + pf_Q}\Bigg[&\kappa^2a^2p - \frac{a^2}{2}f(R,T,Q) - 3(a\ddot{a}+\dot{a}^2+1)f_R\\ &+\ 2a\dot{a}\partial_t f_R + a^2\partial_{tt}f_R + \frac{1}{2}\left(4\dot{a}^2 - a\ddot{a}+2\right)pf_Q + \frac{1}{2}(a\ddot{a}\\ &+\ 2\dot{a}^2)\rho f_Q + 2a\dot{a}\partial_t[(p+\rho)f_Q] + \frac{a^2}{2}\partial_{tt}[(\rho-p)f_Q]\Bigg],\end{aligned} \tag{4}$$

where dot shows derivative with respect to time. The conservation equation is

$$\begin{aligned}\dot{\rho} + 3\frac{\dot{a}}{a}(\rho+p) = \frac{1}{2\kappa^2 + 3(f_T - \frac{2\dot{a}^2+a\ddot{a}}{a^2}f_Q)}\Bigg[&\Bigg\{3\frac{\dot{a}}{a^3}\left(a\ddot{a} - 4\dot{a}^2\right)(\rho+p)\\ &-\ 3(\frac{a\ddot{a}-\dot{a}^2}{a^2})\partial_t p\Bigg\}f_Q - 2(\rho+p)\partial_t f_T + 6(\frac{\dot{a}}{a})^2(\rho+p)\\ &\times\ \partial_t f_Q + \partial_t p f_T\Bigg].\end{aligned} \tag{5}$$

We consider linear homogeneous perturbations to investigate the stability of EU in $f(R,T,Q)$ gravity. For this purpose, we take $a(t) = a_0 = constant$ for EU and the corresponding field equations (3) and (4) reduce to

$$\frac{3}{a_0^2} = \frac{1}{f_R + p_0 f_Q}\left[\kappa^2\rho_0 + (\rho_0+p_0)f_T + \frac{f(R_0,T_0,Q_0)}{2} + \frac{3}{a_0^2}f_R - \frac{3}{a_0^2}\rho_0 f_Q\right], \tag{6}$$

$$-\frac{1}{a_0^2} = \frac{1}{f_R + p_0 f_Q}\left[\kappa^2 p_0 - \frac{1}{2}f(R_0,T_0,Q_0) - \frac{3}{a_0^2}f_R + \partial_{tt}f_R + \frac{p_0}{a_0^2}f_Q\right], \tag{7}$$

where $R_0 = R(a_0) = -\frac{6}{a_0^2}$, $T_0 = \rho_0 - 3p_0$ and $Q_0 = 6\frac{p_0}{a_0^2}$. Here $\rho_0$ and $p_0$ denote the unperturbed energy density and pressure, respectively. In order to examine the stability regions, we consider linear EoS defined as $p(t) = \omega\rho(t)$ ($\omega$ is the EoS

parameter) and introduce the expressions for linear perturbations in scale factor and energy density depending only on time as follows

$$a(t) = a_0 + a_0\delta a(t), \quad \rho(t) = \rho_0 + \rho_0\delta\rho(t), \tag{8}$$

where $\delta a(t)$ and $\delta\rho(t)$ express the perturbed scale factor and energy density, respectively. We assume that $f(R,T,Q)$ is analytic and by applying Taylor series expansion for three variables upto first order, this turns out to be

$$f(R,T,Q) = f(R_0,T_0,Q_0) + f_R\delta R + f_T\delta T + f_Q\delta Q. \tag{9}$$

Using linear EoS, $\delta R$, $\delta T$ and $\delta Q$ become

$$\delta R = -6(\delta\ddot{a} - 2\frac{\delta a}{a_0^2}), \quad \delta T = T_0\delta\rho_0, \quad \delta Q = 3\rho_0[(\omega-1)\delta\ddot{a} - 4\frac{\omega}{a_0^2}\delta a + 2\frac{\omega}{a_0^2}\delta\rho]. \tag{10}$$

Substituting Eqs.(6)-(10) into the field equations (3) and (4), we obtain the linearized perturbed equations as

$$6(f_R+\rho_0 f_Q)\delta a + a_0^2\rho_0[\kappa^2 + (1+\omega)f_T + \frac{1}{2}(1-3\omega)f_T - \frac{3}{a_0^2}f_Q]\delta\rho = 0, \tag{11}$$

$$2(f_R+\rho_0 f_Q)\delta\ddot{a} + \frac{2}{a_0^2}(\rho_0\omega f_Q - f_R)\delta a + \rho_0[\kappa^2\omega - \frac{1}{2}(1-3\omega)f_T - \frac{\omega}{a_0^2}f_Q]\delta\rho$$
$$+\frac{1}{2}\rho_0(1-\omega)f_Q\delta\ddot{\rho} = 0. \tag{12}$$

These express a direct relation between perturbed scale factor and energy density.

### 2.1. *Stability for conserved case*

The conservation law does not hold in $f(R,T,Q)$ gravity but we assume that this law holds in this gravity for which the right hand side of Eq.(5) becomes zero and we obtain

$$\dot{p}f_T - 2(\rho+p)\partial_t f_T + \frac{3}{a^2}\left[\frac{\dot{a}}{a}(a\ddot{a} - 4\dot{a}^2)(\rho+p) - (a\ddot{a}-\dot{a}^2)\dot{p}\right]f_Q$$
$$+6(\frac{\dot{a}}{a})^2(\rho+p)\partial_t f_Q = 0. \tag{13}$$

From the standard conservation equation, we obtain the relation defined by $\delta\dot{\rho}(t) = -3(1+\omega)\delta\dot{a}(t)$. To construct the perturbed field equation in the form of perturbed scale factor, we eliminate $\delta\rho$ from Eqs.(11) and (12), obtain $a_0^2$ from Eqs.(6) and (7) and then substitute the expression of $\delta\dot{\rho}(t)$ in the resulting equation which yields

$$\left[2(f_R-\omega\rho_0 f_Q)\left[\rho_0\left\{\kappa^2 + (1+\omega)f_T - \left(\frac{3\rho_0(1+\omega)(\kappa^2+f_T)}{2f_R+\rho_0(3+\omega)f_Q}\right)f_Q + \frac{1}{2}(1-3\omega)\right.\right.\right.$$
$$\left.\left.\times\ f_T\}\right] + 6\rho_0(f_R+\rho_0 f_Q)\left\{\kappa^2\omega - \left(\frac{\omega\rho_0(1+\omega)(\kappa^2+f_T)}{2f_R+\rho_0(3+\omega)f_Q}\right)f_Q - \frac{1}{2}(1-3\omega)f_T\right\}\right]\delta a$$
$$+\left[\rho_0\left(\frac{2f_R+\rho_0(3+\omega)f_Q}{\rho_0(1+\omega)(\kappa^2+f_T)}\right)\left\{\kappa^2 + (1+\omega)f_T - \left(\frac{3\rho_0(1+\omega)(\kappa^2+f_T)}{2f_R+\rho_0(3+\omega)f_Q}\right)f_Q + \frac{1}{2}\right.\right.$$
$$\left.\left.\times\ (1-3\omega)f_T\right\}\left\{\frac{3}{2}\rho_0(1-\omega^2)f_Q - 2(f_R+\rho_0 f_Q)\right\}\right]\delta\ddot{a} = 0. \tag{14}$$

We consider a specific form of $f(R,T,Q)$ gravity given by $f(R,T,Q) = R + f(T)+g(Q)$, where $f(T)$ and $g(Q)$ are the generic functions of $T$ and $Q$, respectively. We assume that the conservation law holds for this model. Using this assumption along with $a(t) = a_0 = constant$, Eq.(13) leads to $\dot{p}f'(T) - 2(\rho + p)f''(T)\dot{T} = 0$, where prime shows derivative with respect to $T$. Consequently, using linear EoS ($p = \omega\rho$) and perturbation in energy density given in Eq.(8), the resulting second-order differential equation is obtained as $\omega f'(T) - 2(1 + \omega)Tf''(T) = 0$, whose solution is

$$f(T) = \frac{c_1 T(1+\omega)(2T(1+\omega))^{\frac{\omega}{2(1+\omega)}}}{2+3\omega} + c_2, \tag{15}$$

where $c_1$ and $c_2$ are integration constants.

It is mentioned here that the conservation law holds only for this unique expression of $f(T)$ in the proposed model. For the considered model, substitution of Eq.(15) into Eq.(14) leads to the following resulting differential equation

$$\left[6\{\Delta_1 + \Delta_2\Delta_3 + 2\Delta_3^2\Delta_4\} - 3g'(Q)\{2\Delta_5 + \Delta_3\Delta_6 - \Delta_3^2\Delta_7\}\right]\delta a - [(\Delta_8 + \Delta_9) \times g'(Q) + 2\Delta_3\Delta_{10}]\delta\ddot{a} = 0, \tag{16}$$

where $\Delta_i$'s $(i = 1, 2, 3, ..., 10)$ are

$$\Delta_1 = \frac{\rho_0\kappa^4}{3}(1 + 4\omega + 3\omega^2), \quad \Delta_2 = \rho_0\kappa^2\left(1 + \omega(10 + 7\omega) + 2\rho_0\omega(1 + 3\omega + \omega^2)\right),$$
$$\Delta_3 = \frac{c_1}{2}\left(2\rho_0(1+\omega)(1-3\omega)\right)^{\frac{\omega}{2(1+\omega)}}, \quad \Delta_4 = \rho_0\omega(2 + \omega + \rho_0(1 + \omega + \omega^2)),$$
$$\Delta_5 = \rho_0^2\omega\kappa^4(1 + 4\omega + 3\omega^2), \quad \Delta_7 = \rho_0^2(\kappa^2\omega^2(1 + 3\omega) - 3(1 + 2\omega) + 3\omega^3(2 + \omega)),$$
$$\Delta_6 = \rho_0^2\kappa^2(8\omega(1 + \omega) + 3(1 - \omega^4)), \quad \Delta_8 = \kappa^2\left(2(3 + \omega) + \rho_0(1 - 4\omega + 3\omega^2)\right)$$
$$\Delta_9 = 9 - \omega^2 + \frac{\rho_0}{2}(9 - 13\omega + 7\omega^2 - 3\omega^3), \quad \Delta_{10} = \frac{2\kappa^2}{\Delta_3} + (3 - \omega).$$

The solution of Eq.(16) is $\delta a(t) = b_1 e^{\Omega t} + b_2 e^{-\Omega t}$, where $b_1$ and $b_2$ are integration constants and $\Omega$ represents the frequency of small perturbation which is of the form

$$\Omega^2 = \frac{6(\Delta_1 + \Delta_2\Delta_3 + 2\Delta_3^2\Delta_4) - 3g'(Q)(2\Delta_5 + \Delta_3\Delta_6 - \Delta_3^2\Delta_7)}{(\Delta_8 + \Delta_9)g'(Q) + 2\Delta_3\Delta_{10}}. \tag{17}$$

### 2.2. *Stability for non-conserved case*

Here, we discuss the stability when EMT is not conserved. We consider another specific model $f(R,T,Q) = \alpha R + f(Q)$, where $\alpha$ is an arbitrary constant. For this model, the perturbed field equations (11) and (12) lead to

$$6\left[\alpha + \rho_0 f'(Q)\right]\delta a + a_0^2\rho_0\left[\kappa^2 - \frac{3}{a_0^2}f'(Q)\right]\delta\rho = 0, \tag{18}$$

$$\left[2\alpha + \rho_0(\frac{1+3\omega^2}{2})f'(Q)\right]\delta\ddot{a} + \frac{2}{a_0^2}\left[\rho_0\omega f'(Q) - \alpha\right]\delta a + \rho_0\omega[\kappa^2 - \frac{1}{a_0^2}f'(Q)]\delta\rho = 0. \tag{19}$$

The differential equation in perturbed scale factor is obtained by eliminating $\delta\rho$ and by substituting the value of $a_0^2$ of the form

$$2\kappa^2\rho_0(1+\omega)\left[\alpha(1+3\omega)+4\omega\rho_0 f'(Q)\right]\delta a-\left[4\alpha^2+\alpha\rho_0(3\omega^2-2\omega+7)f'(Q)\right]\delta\ddot{a}=0,$$

whose solution is $\delta a(t) = a_1 e^{\bar{\Omega}t} + a_2 e^{-\bar{\Omega}t}$, where $a_j$'s $(j = 1, 2)$ are integration constants and frequency of small perturbation $(\bar{\Omega})$ with $\xi_2 = \rho_0 f'(Q)$ is given by

$$\bar{\Omega}^2 = \frac{2\kappa^2\rho_0(1+\omega)\left(\alpha(1+3\omega)+4\omega\xi_2\right)}{4\alpha^2+\alpha(3\omega^2-2\omega+7)\xi_2}. \tag{20}$$

For graphical analysis, we take $\kappa^2 = 1$, $\rho_0 = 0.3$ and $g'(Q) = \xi_1$ as a new parameter. Fig. **1** shows the existence of stable EU for $\Omega^2$ corresponding to different values of $c_1$. It is observed that the stable EU exists for all values of $\omega \geq -1$ and these regions are becoming more smooth with increasing value of $c_1$. For negative values of $c_1$, the stable modes exist in the range $-1 < \omega < \frac{1}{3}$ and with decreasing value of $c_1$, the graphs show more stable regions towards positive values of EoS parameter. Figure **2** indicates the stable EU for $\bar{\Omega}^2$ and it is found that for $\alpha = 1$, the stable regions appear only for negative values of $\omega$ but for greater values of $\alpha$, we obtain stable region also for positive values of $\omega$. The stable EU for negative values of $\alpha$ also exists and this stability increases with decreasing value of $\alpha$.

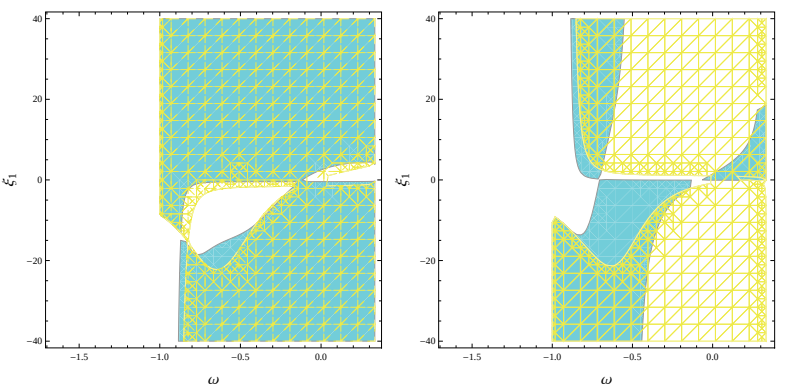

Fig. 1. Plots of stable regions in $(\omega, \xi_1)$ space for $\Omega^2$ with $c_1 = 1$ (cyan), $c_1 = 7$ (yellow) for left plot, $c_1 = -1$ (cyan) and $c_1 = -7$ (yellow) for right plot.

## 3. Concluding Remarks

This paper studies the stability of EU with closed FRW universe model and perfect fluid in $f(R, T, Q)$ gravity. We have formulated static and perturbed field equations using scalar homogeneous perturbations about energy density and scale factor. These equations are parameterized by linear EoS parameter. The second order perturbed differential equations are constructed whose solutions provide the

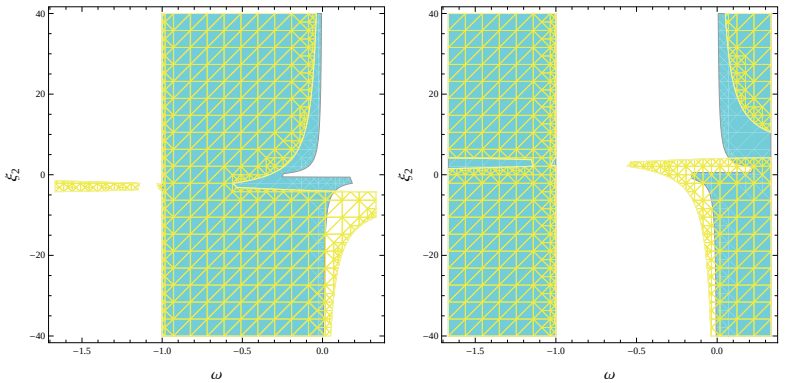

Fig. 2. Plots of stable regions in $(\omega, \xi_2)$ space for $\bar{\Omega}^2$ with $\alpha = 1$ (cyan), $\alpha = 7$ (yellow) for right plot, $\alpha = -1$ (cyan) and $\alpha = -7$ (yellow) for left plot.

existence and stability regions of EU for particular $f(R, T, Q)$ models. We have analyzed both conserved as well as non-conserved EMT cases against perturbations scheme. We conclude that stable modes of EU exist against homogeneous scalar perturbations for all values of EoS parameter if the model constraints are chosen appropriately in this gravity. The stable EU against vector perturbations also exist because any initial vector perturbations remain frozen. It is worthwhile to mention here that the range of EoS parameter is greatly enhanced as compared to that of $f(R)$ gravity and more stable regions are found as compared to $f(R, T)$ theory due to the presence of generic function of $Q$. Like all other modified theories, our results also reduce to GR in the absence of dark source terms.

# Collapsing and expanding solutions in $f(R,T)$ gravity

Sharif M. * and Siddiqa A.

*Department of Mathematics, University of the Punjab,*
*Lahore, 54590, Pakistan*
**E-mail: msharif.math@pu.edu.pk*

We discuss anisotropic source describing the phenomena of collapse and expansion in the context of $f(R,T)$ theory. For this purpose, we take an auxiliary solution of the Einstein field equations and evaluate expansion scalar whose negative values lead to collapse and positive values give expansion. For both cases, the behavior of density, pressures as well as anisotropic parameter is explored and the effects of model parameter on these quantities are examined. We also check the energy conditions for physical viability of these generating solutions.

## 1. Introduction

The force of gravity is responsible for maintaining the structure of celestial bodies, restricting them in their respective tracks as well as controlling different astrophysical phenomena. Stars are one of these heavenly objects that are in equilibrium state due to balance of inward gravity and outward thermal pressure. When this balance is disturbed, star first experiences expansion and becomes red giant or massive stars lead to red super giants. After this expansion phase, a supernova explosion occurs and star collapses resulting into compact objects like white dwarfs, neutron stars and black holes. Oppenheimer and Snyder[1] are the pioneers to explore the gravitational collapse of dust matter. Glass[2] investigated the collapsing and expanding solutions for a spherical system within the framework of general relativity (GR). Abbas explored these solutions for plane symmetric stellar structure[3], spherical symmetric charged system[4] as well as cylindrical charged fluid configurations[5] in GR. These collapsing and expanding solutions are also generated in the background of $f(R,T)$ gravity for a sphere in the absence[6] and presence of electromagnetic field.

To discuss the mysteries of dark energy and dark matter, researchers proposed different extensions or alternatives to GR. Here, we consider the $f(R,T)$ theory which couples curvature scalar and trace of energy momentum tensor. This manuscript generates the collapsing and expanding solutions for a plane symmetric anisotropic source in $f(R,T)$ context. In next section, we define the basic equations for a plane symmetric stellar structure in $f(R,T)$ theory and its subsections contain the generating solution for collapse as well as expansion. Finally, we summarize our results.

## 2. Basic Equations in $f(R,T)$ Theory

We consider the following metric and energy-momentum tensor to describe the geometry and matter distribution inside the anisotropic plane symmetric source,

respectively

$$ds^2 = -A^2(t,z)dt^2 + B^2(t,z)(dx^2+dy^2) + C^2(t,z)dz^2, \tag{1}$$

$$T_{\mu\nu} = (\rho + p_\perp)V_\mu V_\nu + p_\perp g_{\mu\nu} + (p_z - p_\perp)\chi_\mu\chi_\nu, \tag{2}$$

where $V_\mu$, $\chi_\mu$, $\rho$, $p_z$ and $p_\perp$ denote the four velocity, unit four-vector, density as well as pressures in $z$ and its perpendicular direction, respectively. Here, the four-vectors $V_\mu$ and $\chi_\mu$ have the following expressions

$$V^\mu = (A^{-1},0,0,0), \quad K^\mu = (0,0,0,C^{-1}),$$
$$\text{and} \quad V^\mu V_\nu = -1,\ \chi^\mu\chi_\nu = 1,\ V^\mu\chi_\nu = 0.$$

The $f(R,T)$ gravity action

$$S = \int d^4x\sqrt{-g}\left[\frac{1}{16\pi}f(R,T) + \mathcal{L}_m\right], \tag{3}$$

produces the following field equations

$$f_R R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}f + (g_{\mu\nu}\Box - \nabla_\mu\nabla_\nu)f_R = 8\pi T_{\mu\nu} - f_T(T_{\mu\nu}+\Theta_{\mu\nu}) + 8\pi E_{\mu\nu}, \tag{4}$$

where $f_R$ and $f_T$ denote the derivatives of $f(R,T)$ with respect to $R$ and $T$, respectively, while $\Theta_{\mu\nu}$ is defined as

$$\Theta_{\mu\nu} = g^{\gamma\alpha}\frac{\delta T_{\gamma\alpha}}{\delta g^{\mu\nu}}, \quad T_{\mu\nu} = g_{\mu\nu}\mathcal{L}_m - \frac{\partial\mathcal{L}_m}{\partial g^{\mu\nu}}, \tag{5}$$

We consider $f(R,T) = R + 2\lambda T$ suggested by Harko *et al.*[7] to investigate how curvature-matter coupling effects the generating solutions for collapse and expansion. This $f(R,T)$ model and $\mathcal{L}_m = -\rho$ yield the following field equations

$$G_{\mu\nu} = (8\pi + 2\lambda)T_{\mu\nu} + 2\lambda\rho g_{\mu\nu} + \lambda T g_{\mu\nu}, \tag{6}$$

which produces the following set of equations

$$\frac{\dot{B}^2}{B^2A^2} - \frac{B'^2}{C^2B^2} - 2\frac{B''}{BC^2} + 2\frac{\dot{C}}{C}\frac{B}{BA^2} + 2\frac{B'}{B}\frac{C'}{C^3} = (8\pi+\lambda)\rho - 2\lambda p_\perp - \lambda p_z, \tag{7}$$

$$\frac{-\ddot{B}}{BA^2} + \frac{\dot{A}\dot{B}}{A^3B^2} + \frac{A'B'}{C^2AB^2} + \frac{B''}{B^2C^2} - \frac{\dot{C}\dot{B}}{CB^2A^2} - \frac{B'C'}{B^2C^3} + \frac{A''}{ABC^2} - \frac{\ddot{C}}{CA^2B}$$
$$+\frac{\dot{A}\dot{C}}{A^2CB} - \frac{A'C'}{ABC^2} = (8\pi+4\lambda)p_\perp + \lambda\rho + \lambda p_z, \tag{8}$$

$$\frac{-2\ddot{B}}{BA^2} + \frac{2\dot{A}\dot{B}}{A^3B} + 2\frac{A'B'}{ABC^2} - \frac{\dot{B}^2}{A^2B^2} + \frac{B'^2}{B^2C^2} = (8\pi+3\lambda)p_z + \lambda\rho + 2\lambda p_\perp, \tag{9}$$

where an over dot and prime correspond to the derivative with respect to $t$ and $z$, respectively. Simultaneous solution of field equations gives the following values of

density and pressures

$$\rho = \frac{A^{-3}B^{-2}C^{-3}}{8(2\pi+\lambda)(4\pi+\lambda)}\Big[-AC\Big\{(8\pi+5\lambda)(A^2C^2\dot{B}^2+A^4B'^2)+\lambda C^4(\dot{B}^2+B'^2)\Big\}$$
$$+\ 2\lambda B^4\Big\{C^2(\dot{A}\dot{C}-A\ddot{C})-A^2A'C'+A^2CA''\Big\}+2B\Big\{(8\pi+\lambda)A^3C^2\dot{B}\dot{C}+\lambda C^5$$
$$+\ \Big(\dot{A}\dot{B}-A\ddot{B}-A'B')+(8\pi+5\lambda)(A^5B'C'A^5CB'')\Big\}+2\lambda B^3\Big\{-AC^2\dot{B}\dot{C}$$
$$+\ +C^3(\dot{A}\dot{B}-A\ddot{B})-A^3B'C'+A^2C(A'B'+AB'')\Big\}\Big], \tag{10}$$

$$p_z = \frac{A^{-3}B^{-2}C^{-3}}{8(2\pi+\lambda)(4\pi+\lambda)}[AC\{-\lambda A^2C^2\dot{B}^2+\lambda A^4B'^2-(8\pi+3\lambda)C^4(\dot{B}^2+B'^2)\}$$
$$-\ 2\lambda B^4\{C^2(\dot{A}\dot{C}-A\ddot{C})-A^2A'C'+A^2CA''\}+2B\{-\lambda A^3C^2\dot{B}\dot{C}+(8\pi+3\lambda)$$
$$\times\ C^5(\dot{A}\dot{B}-A\ddot{B}-A'B')-\lambda A^5B'C'+\lambda A^5CB''-2\lambda B^3\{-AC^2\dot{B}\dot{C}+C^3$$
$$\times\ (\dot{A}\dot{B}-A\ddot{B})-A^3B'C'+A^2C(A'B'+AB'')\}\}], \tag{11}$$

$$p_\perp = \frac{A^{-3}B^{-2}C^{-3}}{8(2\pi+\lambda)(4\pi+\lambda)}[AC\{-\lambda A^2C^2\dot{B}^2+A^4B'^2+C^4(\dot{B}^2+B'^2)\}+(4\pi+\lambda)$$
$$\times\ B^4\{C^2(\dot{A}\dot{C}-A\ddot{C})-A^2A'C'+A^2CA''\}-2\lambda B\{A^3C^2\dot{B}\dot{C}+C^5(\dot{A}\dot{B}$$
$$-\ A\ddot{B}-A'B')+A^5B'C'-A^5C\ddot{B}\}+2(4\pi+\lambda)B^3\{-AC^2\dot{B}\dot{C}+C^3(\dot{A}\dot{B}$$
$$-\ A\ddot{B})-A^3\dot{B}\dot{C}+A^2C(A'B'+AB'')\}]. \tag{12}$$

The pressure anisotropy is defined by the relation

$$\triangle = p_z - p_\perp. \tag{13}$$

The expansion scalar is obtained as

$$\Theta = \frac{1}{A}\left(\frac{2\dot{B}}{B}+\frac{\dot{C}}{C}\right), \tag{14}$$

and we consider an auxiliary solution of Eq.(8) as

$$A = \frac{\alpha\dot{B}}{B^\gamma}, \quad C = B^\gamma, \tag{15}$$

where $\gamma$ and $\alpha > 0$ are arbitrary constants. The above solution leads to

$$\Theta = (2+\gamma)B^{1-\gamma}. \tag{16}$$

The positive values of $\Theta$ provide expansion and its negative values correspond to collapse. We discuss these cases in the following subsections.

### 2.1. *Generating solution for collapse*

For collapsing solution, we find the metric coefficient $B$ using the Taub's mass[8] for plane symmetric configuration and then using the concept of trapped surfaces (that

whether the collapse lead to the formation of trapped surfaces or not). The mass function is evaluated as

$$m(t,z)=\frac{(g_{11})^{\frac{3}{2}}}{2}R_{12}^{12}=\frac{B}{2}\left(B^{2\gamma}-\frac{B'^2}{B^{2\gamma}}\right). \tag{17}$$

For $B'=B^{2\gamma}$, it has been discussed that no trapping surfaces are found for a plane symmetric object experiencing collapse[3]. Hence we have

$$B_{col}=[(1-2\gamma)z+g(t)]^{\frac{1}{1-2\gamma}}, \tag{18}$$

with $g(t)$ an integration function. This expression of $B_{col}$ in turn yields the following values of $A$ and $C$ (we take $\alpha=1$)

$$A_{col}=\frac{\dot{g(t)}}{1-2\gamma}[(1-2\gamma)z+g(t)]^{\frac{\gamma}{1-2\gamma}}, \tag{19}$$

$$C_{col}=[(1-2\gamma)z+g(t)]^{\frac{\gamma}{1-2\gamma}}. \tag{20}$$

The corresponding values of density and pressures are obtained by substituting this solution in Eqs.(10)-(12). For graphical analysis, we chose $g(t)=t$ and the analysis is summarized in Table **1**. The graphs of $\rho$ and $p_z$, for different values of $\lambda$ are shown in Figure **1**. For collapse solution, there is no change in different parameters with respect to time.

Table **1**: Change in parameters with respect to $r$, $t$ and $\lambda$ for the collapsing solution.

| **Parameter** | **As $z$ increases** | **As $\lambda$ increases** |
|---|---|---|
| $\rho$ | positively decreases | positively decreases |
| $p_z$ | positively decreases | positively increases |
| $p_\perp$ | negatively increases | negatively increases |
| $\triangle$ | positively decreases | positively decreases |

### 2.2. *Generating solution for expansion*

In order to generate a solution for an expanding plane symmetric configuration, we need the value of $B$ that leads to expansion. We assume that it is a sum of temporal and radial components and choose the values of free parameters such that $\Theta$ remains positive for these values. Thus we have the following expanding solution

$$A_{exp}=\frac{\alpha}{(r+t)^\gamma},\quad B_{exp}=\alpha(r+t),\quad C_{exp}=\alpha(r+t)^\gamma. \tag{21}$$

After replacing these values in Eqs.(10)-(12), we find the expressions of density and pressures. The plots of $\rho$ and $p_z$ are given in Figure **2** as well as the graphical analysis is summarized in Table **2**. For the expanding solution, the physical parameters also vary with varying time.

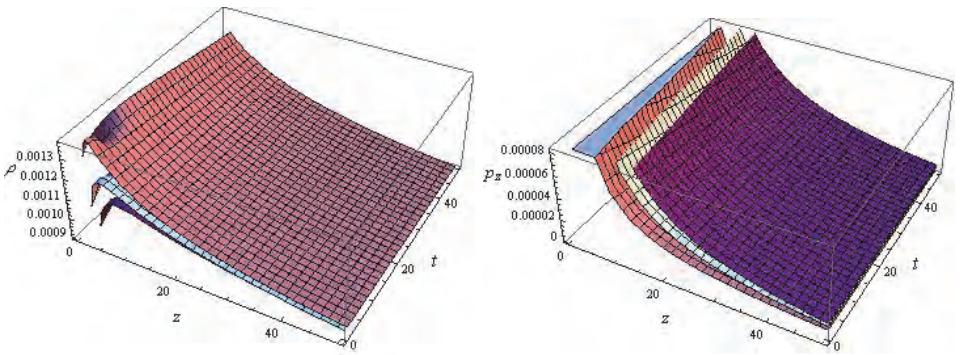

Fig. 1. Plots of $\rho$ and $p_z$ versus $r$ and $t$ for $\gamma = -5$, $\alpha = 1$, $\lambda = 0.3$ (pink), $\lambda = 0.6$ (blue), $\lambda = 0.9$ (purple).

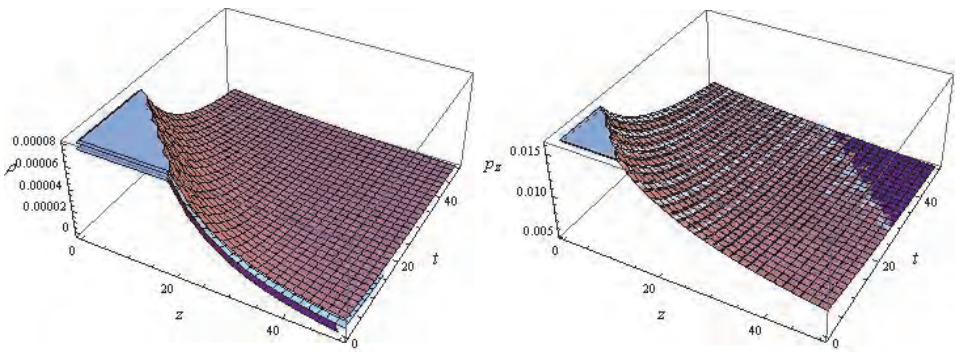

Fig. 2. Plots of $\rho$ and $p_z$ versus $r$ and $t$ for $\gamma = 0.08$, $\alpha = 1$, $\lambda = 0.01$ (pink), $\lambda = 0.02$ (blue), $\lambda = 0.03$ (purple).

Table **2**: Change in parameters with respect to $r$, $t$ and $\lambda$ for the expanding solution.

| **Parameter** | **As $z$ increases** | **As $t$ increases** | **As $\lambda$ increases** |
|---|---|---|---|
| $\rho$ | positively decreases | positively decreases | positively decreases |
| $p_z$ | positively decreases | positively decreases | positively decreases |
| $p_\perp$ | negatively decreases | negatively increases | negatively increases |
| $\triangle$ | positively decreases | positively decreases | positively decreases |

## 3. Summary

The expanding universe can affect different phenomena happening in the universe one of which is the life of a star. In this paper, we investigate the generating solutions for collapsing and expanding phases during stellar evolution and consider

an anisotropic plane symmetric source in the context of $f(R,T)$ theory. Firstly, we assume a solution in the form of metric coefficient $B$ and then find it to generate a solution for collapse and expansion. We also investigate the role of model parameter $\lambda$ on different quantities. It is found that the energy conditions are satisfied in both solutions for chosen values of parameters implying the validity of solutions.

# A classical and quantum tomographic analysis of the de Sitter universe

C. Stornaiolo*

*INFN-Sezione di Napoli, Complesso Universitario di Monte S. Angelo, Ed. 6, via Cinzia 80126 Napoli, Italy*
*E-mail: * cosmo@na.infn.it*

In this work we reformulate classical and quantum cosmology in terms of a tomographic description. This approach enables us to describe the quantum and classical states of the universe in the same way and allows us to examine some aspects of the transition from the initial quantum stage to the next classical one, which are not evident in the other formulations of quantum cosmology. For reasons of simplicity and because they allow us to very effectively illustrate some aspects of the quantum-classical transition, we have considered the Hartle-Hawking model for a de Sitter universe and the corresponding classical model. The analysis obtained can also be extended to the tunneling from nothing of Vilenkin-LInde, provided that some restrictions are made in the models. We demonstrate that the Hartle-Hawking model does not have a classic limit.

*Keywords*: Quantum cosmology; Quantum tomography.

*1. Introduction.* Tomography was originally introduced for clinical purposes as an imaging technique to create three-dimensional images of the interior of the human body from two-dimensional sections obtained by X-rays. Its application was subsequently extended to many other fields of scientific research. In particular the same principles were applied to quantum tomography in order to reconstruct the state of a quantum system. In fact the tomographic analysis of a system either in quantum optics as in quantum mechanics was used to reconstruct the Wigner function, which is a distribution function on the phase space. Similarly, a classical probability function in the phase space can be obtained through a tomographic analysis.[1, 2] This shows that classical and quantum states can both be described by a tomographic approach. This motivates the extension of the tomographic approach to quantum cosmology.

Introduction of quantum cosmology (see e.g.[3][4]) is motivated by the necessity to address the conceptual problems introduced by the prediction in classical general relativity of an initial singularity which is unacceptable from a physical point of view because the knowledge of an initial state enables us to predict the future evolution of a classical system, otherwise we can establish the probabilities of the evolution of a quantum system. With quantum cosmology we substitute this indefinite classical state with a quantum state. This is a plausible working hypothesis because distance scales are extremely small and the energy densities are extremely high at times close to the initial singularity. But the theoretical approach to quantum cosmology is quite different from that of ordinary quantum systems, because for the latter the initial conditions are imposed with respect to an external environment that does not exist in cosmology and they can be varied at will, while in cosmology the initial conditions become a physical law to all effects, because in this context we are considering just one and only one "experiment". Quantum cosmology is formulated as

the restriction of quantum gravity to homogeneous space-times; with this restriction a theory very close to quantum mechanics emerges, where the Wheeler-de Witt equation takes the place of the Schrödinger equation.

The importance of applying quantum tomography to quantum cosmology is that through the tomographic representation both classical and quantum states can be represented in the same way allowing us to compare them and eventually to study the quantum-classical transition for a system like the universe. In this paper we determine the tomogram[5] of the Hartle-Hawking initial state and compare its classical limit with the classical tomogram.

*2. Tomograms* In quantum mechanics where, due to the uncertainty principle, the state of a system is specified in terms of probability distributions by introducing a wave function or the density matrix. A quantum state can be also represented in the phase space, in analogy with classical mechanics, by the Wigner function[6] defined by the non linear transform of the wave function $\psi(x)$,

$$W(x,p) = \frac{1}{2\pi}\int \psi\left(x+\frac{u}{2}\right)\psi^*\left(x-\frac{u}{2}\right)\mathrm{e}^{-i\frac{up}{\hbar}}du\,. \tag{1}$$

and if non pure states are considered, its definition can be extended to any matrix density by

$$W(x,p) = \frac{1}{2\pi}\int \rho\left(x+\frac{u}{2},x-\frac{u}{2}\right)\mathrm{e}^{-i\frac{up}{\hbar}}du\,. \tag{2}$$

The Wigner function has to satisfy the normalization condition,

$$\int W(q,p)dq\,dp = 1. \tag{3}$$

Similarly in quantum cosmology alongside the concepts of wave function and density matrix the Wigner function was introduced with the purpose to better understand the problem of the classical transition of a quantum universe.[7, 8] Unfortunately, these representations can hardly be related directly to the observational data.

Recently the notion of standard positive probability distribution function (tomogram) was introduced in cosmology to describe the quantum state of universe as an alternative to wave function or to density matrix.[5, 9] The tomogram can be defined as the modified Radon transform, of the Wigner function

$$\mathcal{W}(X,\mu,\nu) = \int W(q,p)\delta(X-\mu x-\nu p)\frac{dxdp}{\hbar}\,. \tag{4}$$

It depends on the random variable $X$ given by the linear combination of position and momentum:

$$X = \mu x + \nu p \tag{5}$$

where $\mu = s\cos\theta$ and $\nu = s^{-1}\sin\theta$ parameterize the rotation and squeezing of the reference frames of the phase space through a set of linear canonical transformations. So, we say that the quantum state is given if the position probability distribution $\mathcal{W}(X,\mu,\nu)$ in an ensemble of rotated and squeezed reference frames in the classical

phase space is given. From Eqs. (1) and (4) it follows that we can derive the tomogram from the wave function $\psi(x)$ which is

$$\mathcal{W}(X,\mu,\nu) = \frac{1}{2\pi|\nu|\hbar}\left|\int \psi(y)\exp\left[i\left(\frac{\mu}{2\hbar\nu}y^2 - \frac{X}{\hbar\nu}y\right)\right]dy\right|^2 . \tag{6}$$

Finally when $\mu = 0$ and $\nu = 1$ the tomographic amplitude reduces to a Fourier transform from $x$ to $X \equiv p$, and is proportional to the density $|\psi(p)|^2$ in the $p$ representation.

The symplectic tomogram $\mathcal{W}(X,\mu,\nu)$ has the following properties of a) non negativity, i.e. $\mathcal{W}(X,\mu,\nu) \geq 0$ and b) normalization $\int \mathcal{W}(X,\mu,\nu)dX = 1.$ , which characterizes it as a marginal probability function. For more details see e.g. ref. [5].

*3. Classical symplectic tomography* The definition of tomogram (4) can be extended to any distribution on the phase space. Therefore we apply this definition to a classical distribution $f(q,p)$, for instance a solution of the Boltzmann equation,

$$\mathcal{W}(X,\mu,\nu) = \int f(x,p)\delta(X - \mu x - \nu p)dxdp\,. \tag{7}$$

If the classical probability distribution $f(q,p)$ is normalized also the tomogram is normalized and satisfies the following conditions,

$$\int \mathcal{W}(X,\mu,\nu)\,dX = 1 \tag{8}$$

The (initial) state of a simple particle is described the distribution function

$$f(q,p) = \delta(x - x_0)\delta(p - p_0) \tag{9}$$

we obtain by eq. (7) the tomogram of a free particle

$$\mathcal{W}(X,\mu,\nu) = \delta(X - \mu x_0 - \nu p_0) \tag{10}$$

where for a moving particle the time dependent with distribution function

$$f(q,p,t) = \delta(x - x(t))\delta(p - p(t)) \tag{11}$$

the corresponding tomogram is

$$\mathcal{W}(X,\mu,\nu) = \delta\left(X - \mu x(t) - \nu p(t)\right)\,. \tag{12}$$

*3. The de Sitter model in General Relativity.* Let us determine the tomogram that describes the classical state of the de Sitter universe where the cosmological constant is responsible for the universe expansion even in the absence of material fields. We consider a closed homogeneous and isotropic model with a cosmological constant $\Lambda$. Using the notations of [7] [8], it is described by the metric

$$ds^2 = l_p^2\left[-N^2(t)dt^2 + a^2(t)d\Omega_3^2\right] \tag{13}$$

where $a(t)$ is the expansion factor of the universe, $d\Omega_3^2$ is the metric of the unit three-sphere $N(t)$ is the lapse function, $l_p = 2/3\ell_p$, with $\ell_p$ the Planck length. Introducing the phase space variable $q = a^2$ and Hamiltonian

$$\mathcal{H} = \frac{1}{2}\left(-4p^2 + \lambda q - 1\right) \tag{14}$$

where $\lambda$ is the cosmological constant in Planck units. The constraint $\mathcal{H} = 0$ implies that position and momentum are not independent. It corresponds to a trajectory on the phase space. At any fixed time the distribution on the phase space reduces to just one point of this trajectory. Therefore the distribution function is the Dirac delta of the constraint,

$$f(q,p) = \delta\left(-4p^2 + \lambda q - 1\right) \tag{15}$$

From Eqs. (7) and (15), the classical tomogram is

$$\mathcal{W}(X,\mu,\nu) = \frac{1}{2|\mu|}\frac{1}{\left|\sqrt{\frac{\lambda^2\nu^2}{16\mu^2} + \frac{\lambda X}{\mu}} - 1\right|}\,. \tag{16}$$

As the function in Eq. (16 )is not integrable on $-\infty$ to $+\infty$, we cannot normalize the tomogram on this interval. The tomogram is a probability function and it has to satisfy the normalization condition. Therefore we impose that function (16) is different from zero only on the interval $C = \left[\frac{\mu}{\lambda}\left(1 - \frac{\lambda^2\nu^2}{16\mu^2}\right), \lambda\mu + \frac{\mu}{\lambda}\left(1 - \frac{\lambda^2\nu^2}{16\mu^2}\right)\right]$. Finally we see that if the cosmological constant is of the order of magnitude of $10^{-122}$, which is in Planck units the value nowadays accepted, the interval $C$ becomes very narrow. in other words the very high degree of homogeneity of the classical (de Sitter) universe is a consequence of the extreme smallness of the cosmological constant.

*4. The de Sitter quantum cosmological models.* In quantum cosmology the Hamiltonian constraint becomes an equation, in the de Sitter it is[10]

$$\left(4\hbar^2\frac{d^2}{dq^2} + \lambda q - 1\right)\psi(q) = 0\,. \tag{17}$$

Equation (17) becomes the Airy equation[13, 14]

All the solutions of the Airy equation are linear combinations of $\mathrm{Ai}(x)$ and $Bi(x)$. The most interesting are those which can be evolved to a classical universe with the properties actually observed in the present time. In this work we recall the Hartle and Hawking proposal,[11] we mention that there are also the models related to the "no-boundary condition" and the Vilenkin-Linde "tunneling of the universe from nothing beginning ".[12] The wave functions corresponding to all these initial conditions in a de Sitter (quantum) universe were derived originally by Halliwell and Louko[10] . This models where analyzed in[10] and extend the discussion of these models to the Wigner functions, see[7, 8] . Here we will consider just the Hartle and Hawking wave function,

$$\psi_{HH} = A\,\mathrm{Ai}\left(\frac{1-\lambda q}{(2\hbar\lambda)^{2/3}}\right), \tag{18}$$

because only with this wave function we can express the corresponding s tomogram in an analytic form allowing us to compare it with the classical tomogram (16).

To derive the tomogram the Hartle-Hawking tomogram we insert the wave function (18) in (6) and obtain

$$\mathcal{W}(X,\mu,\nu)=\frac{A^2}{|\mu|}\left|\mathrm{Ai}\left(\frac{1}{(2\hbar\lambda)^{2/3}}\left(1-\frac{\lambda X}{\mu}-\frac{\lambda^2}{16}\frac{\nu^2}{\mu^2}\right)\right)\right|^2. \tag{19}$$

Then we calculate its classical limit by taking the limit $\hbar\to 0$; indeed we consider the limit $(2\hbar\lambda)^{2/3}\to 0$ by keeping $\lambda$ fixed, as $(2\hbar\lambda)^{2/3}$ approaches zero the argument goes to infinite and using the Airy function can be substituted by its asymptotic expressions[13, 14] , in particular we notice that the argument of the Airy function in (18) is the negative of the argument of (16), so we are interested in

$$\mathcal{W}(X,\mu,\nu)\approx\frac{A^2}{8\pi^2\hbar|\mu|}\frac{(2\hbar\lambda)^{4/3}}{\left|1-\frac{\lambda X}{\mu}-\frac{\lambda^2}{16}\frac{\nu^2}{\mu^2}\right|^{1/2}}\times\left|\cos\left(\frac{2}{3}S^{3/2}-\frac{\pi}{4}\right)\right|^2, \tag{20}$$

$$\tag{21}$$

when its argument is negative.[13, 14] When its argument is positive the asymptotic expression of (19) vanishes in this limit giving no contribution to the tomogram.

The normalization constant $A$ is fixed by imposing that the quantum and classical tomograms have the same coefficient, so $A=\frac{2^{5/6}\pi}{\hbar^{1/6}\lambda^{2/3}}$.

We notice that the one over square root factor of (20) coincides with the classical tomogram, but the square modulus of the cosine does not converge when its argument goes to infinity. We conclude that the Hartle and Hawking model does not have a classical limit. Similarly we cannot find a classical limit for the Vilenkin-Linde solutions because these functions are not integrable on the real line, so that we cannot obtain a tomogram at least we do not try to modify them in some way. Finally we notice that the classical limit of the tomogram, whose expression incidentally is similar to Vilenkin's wave function,

$$\mathcal{W}(X,\mu,\nu)=\frac{A^2}{|\mu|}\left|\frac{1}{2}\left[Ai\left(\frac{1}{(2\hbar\lambda)^{2/3}}\left(1-\frac{\lambda X}{\mu}-\frac{\lambda^2}{16}\frac{\nu^2}{\mu^2}\right)\right)\right.\right. \tag{22}$$

$$\left.\left.+i\mathrm{Bi}\left(\frac{1}{(2\hbar\lambda)^{2/3}}\left(1-\frac{\lambda X}{\mu}-\frac{\lambda^2}{16}\frac{\nu^2}{\mu^2}\right)\right)\right]\right|^2. \tag{23}$$

coincides with (16) therefore It represents a quantum universe that converges to the classical de Sitter universe.

In our contribution we present spherically symmetric solutions in four dimensions to the Einstein-Weyl (and also general quadratic) gravity admitting arbitrary value of the cosmological constant. The main attention is paid to the black hole spacetimes representing one parameter extension of the well-known Schwarzschild-(anti-)de Sitter geometry of Einstein's general relativity. This additional parameter corresponds to the non-vanishing value of the Bach tensor at the black hole horizon. Our work thus generalises recent paper by Lü et al. (Phys. Rev. Lett. 114 (2015) 171) to any value of the cosmological constant. Moreover, using more convenient metric ansatz, the field equations form an autonomous system and their solution is explicitly obtained in an exact form of power series. The physical interpretation of these geometries is also discussed, namely we investigate specific tidal effects on free test particles or their basic thermodynamic properties.

*Keywords*: Einstein-Weyl theory; Quadratic gravity; Black holes; Bach tensor.

## 1. Introduction

Black holes represent one of the most important theoretical predictions of the Einstein general relativity. Almost immediately after its formulation Karl Schwarzschild[1] found a static spherically symmetric solution to the field equations. However, its 'black-hole nature' was understood many years later. In our contribution, we are interested in the extension of such a fundamental solution in the framework of the so called quadratic gravity[2,3] (including the Einstein–Weyl theory). This paper is based on our recent letters[4,5], where the main aim was to simplify the field equations, to find their explicit solution in a closed form, and to admit any value of the cosmological constant.

The most general four-dimensional quadratic gravity in vacuum can be introduced via the Einstein-Hilbert action containing the Ricci scalar $R$, the cosmological constant $\Lambda$, and a contraction of the Weyl tensor $C_{abcd}$,

$$S = \int \mathrm{d}^4x\,\sqrt{-g}\,\Big(\gamma\,(R-2\Lambda) + \beta\,R^2 - \alpha\,C_{abcd}\,C^{abcd}\Big)\,, \tag{1}$$

where $\alpha$, $\beta$, and $\gamma = G^{-1}$ are constants. Here we employ a natural simplifying assumption of the constant scalar curvature, namely

$$R = \text{const.}\,, \qquad \Rightarrow \qquad R = 4\Lambda\,, \tag{2}$$

under which the field equations become

$$R_{ab} - \Lambda\, g_{ab} = 4k\, B_{ab}\,, \qquad \text{with} \qquad k \equiv \frac{\alpha}{\gamma + 8\beta\Lambda}\,, \tag{3}$$

where $B_{ab} \equiv \big(\nabla^c\nabla^d + \frac{1}{2}R^{cd}\big)C_{acbd}$ is the traceless, symmetric and conserved *Bach tensor* ($g^{ab}B_{ab} = 0$, $B_{ab} = B_{ba}$, $B_{ab}{}^{;b} = 0$).

## 2. The spacetime geometry

A spherically symmetric spacetime is usually presented as

$$\mathrm{d}s^2 = -h(\bar{r})\,\mathrm{d}t^2 + \frac{\mathrm{d}\bar{r}^2}{f(\bar{r})} + \bar{r}^2(\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2)\,. \tag{4}$$

In Refs. 4,5 it was shown that its *more suitable form* for analysing the quadratic gravity field equation is

$$\mathrm{d}s^2 = \Omega^2(r)\big[\,\mathrm{d}\theta^2 + \sin^2\theta\,\mathrm{d}\phi^2 - 2\,\mathrm{d}u\,\mathrm{d}r + \mathcal{H}(r)\,\mathrm{d}u^2\,\big]\,, \tag{5}$$

which is related to the classic form (4) by the transformation

$$\bar{r} = \Omega(r)\,, \qquad t = u - \int \mathcal{H}(r)^{-1}\mathrm{d}r\,, \tag{6}$$

and

$$h(\bar{r}) = -\Omega^2\,\mathcal{H}\,, \qquad f(\bar{r}) = -\left(\frac{\Omega'}{\Omega}\right)^2\mathcal{H}\,, \tag{7}$$

with prime denoting the derivative with respect to the coordinate $r$. The metric (5) is *conformal* to a direct-product Kundt 'seed' of the algebraic type D, see Refs. 6–8. The *Killing horizons* corresponding to $\partial_u = \partial_t$ are located at $r_h$ introduced via condition

$$\mathcal{H}\big|_{r=r_h} = 0\,. \tag{8}$$

The geometries (5) can be characterized using the *scalar curvature invariants*,

$$C_{abcd}\,C^{abcd} = \tfrac{1}{3}\,\Omega^{-4}\,(\mathcal{H}'' + 2)^2\,, \tag{9}$$

$$B_{ab}\,B^{ab} = \tfrac{1}{72}\,\Omega^{-8}\big[(\mathcal{B}_1)^2 + 2(\mathcal{B}_1 + \mathcal{B}_2)^2\big]\,, \tag{10}$$

where we have introduced *two independent Bach components*, namely

$$\mathcal{B}_1 \equiv \mathcal{H}\mathcal{H}''''\,, \qquad \mathcal{B}_2 \equiv \mathcal{H}'\mathcal{H}''' - \tfrac{1}{2}\mathcal{H}''^2 + 2\,. \tag{11}$$

Obviously, $\mathcal{B}_1 = 0 = \mathcal{B}_2 \;\Leftrightarrow\; B_{ab} = 0 \;\Leftrightarrow\; B_{ab}\,B^{ab} = 0$ and thus we may invariantly distinguish two geometrically different classes of solutions corresponding to $B_{ab} = 0$ and $B_{ab} \neq 0$, respectively.

## 3. The quadratic gravity field equations

Using the ansatz (5) together with the conformal behaviour of the Bach tensor ($B_{ab} = \Omega^{-2}\, B_{ab}^{\rm Kundt}$) and the contracted Bianchi identities, we obtain the field equations (3) in the form of two simple ODEs for the functions $\Omega(r)$ and $\mathcal{H}(r)$, namely

$$\Omega\Omega'' - 2\Omega'^2 = \tfrac{1}{3} k\, \mathcal{B}_1 \mathcal{H}^{-1}\,, \tag{12}$$

$$\Omega\Omega'\mathcal{H}' + 3\Omega'^2\mathcal{H} + \Omega^2 - \Lambda\Omega^4 = \tfrac{1}{3} k\, \mathcal{B}_2\,. \tag{13}$$

Moreover, the trace of (3), i.e., $R = 4\Lambda$, becomes

$$\mathcal{H}\Omega'' + \mathcal{H}'\Omega' + \tfrac{1}{6}(\mathcal{H}'' + 2)\Omega = \tfrac{2}{3}\Lambda\,\Omega^3\,. \tag{14}$$

These equations do not explicitly depend on the variable $r$ (an autonomous system) and their solutions can be found as *power series* around *any* point $r_0$,

$$\Omega(r) = \Delta^n \sum_{i=0}^{\infty} a_i\, \Delta^i\,, \qquad \mathcal{H}(r) = \Delta^p \sum_{i=0}^{\infty} c_i\, \Delta^i\,, \tag{15}$$

with $\Delta \equiv r - r_0$, and $n, p \in \mathbb{R}$.

### 3.1. *Vanishing Bach tensor*

In fact, for $B_{ab} = 0 \;\Leftrightarrow\; \mathcal{B}_1 = 0 = \mathcal{B}_2$ Einstein's theory is restored, and using the gauge freedom $r \to \lambda\, r + \nu$, $u \to \lambda^{-1} u$ of the metric (5), field equations (12) and (13) yield the classic solution

$$\Omega(r) = \bar{r} = -\frac{1}{r}\,, \qquad \mathcal{H}(r) = \frac{\Lambda}{3} - r^2 - 2m\, r^3\,. \tag{16}$$

Employing the explicit relations (7) it is straightforward to show that these functions really represent the *Schwarzschild-(anti–)de Sitter* spacetime[6,7] corresponding to $f = h = 1 - 2m\,\bar{r}^{-1} - \frac{1}{3}\Lambda\,\bar{r}^2$ in the metric (4).

### 3.2. *Non-vanishing Bach tensor*

A generic case $B_{ab} \neq 0$ leads to the non-trivially coupled system of the field equations (12), (13) which solutions can be found in the form (15). Analysing dominant powers of $\Delta$ in the equations we may immediately restrict the admitted values of parameters $[n,\, p]$ and the cosmological constant $\Lambda$, see Tab. 1. The most interesting black hole case $[n,\, p] = [0,\, 1]$ will be discussed in the following section.

Table 1. The only allowed values of $[n,\, p]$ and $\Lambda$ in (15), which are restricted by dominant powers of $\Delta$ in (12), (13), and (14).

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| $n$ | 0 | 0 | 1 | $-1$ | $-1$ | 0 | 0 | $< 0$ |
| $p$ | 1 | 0 | 0 | 2 | 0 | 2 | $\geq 2$ | $2n+2$ |
| $\Lambda$ | any | any | any | 0 | $\neq 0$ | $\neq 0$ | $\frac{3}{8k}$ | $\frac{11n^2+6n+1}{1-4n^2}\,\frac{3}{8k}$ |

## 4. Explicit black hole solution expanded around horizon

In the case [0, 1], the single root of $\mathcal{H}$ given by $r_0 \equiv r_h$ represents the non-degenerate Killing horizon, see equation (8). Subsequently, the field equations (12), (13), together with the trace (14), specifically restrict the coefficients in (15) with free parameters $a_0,\ c_0,\ c_1$.

To obtain physical meaning of these free parameters we identify the Schwarzschild-(anti-)de Sitter 'background' spacetime (16). We begin with evaluation the Bach tensor (11) on the horizon, i.e., $\mathcal{B}_1(r_h) = 0$, $\mathcal{B}_2(r_h) = -\frac{3}{k} a_0^2\, b$. Here we have introduced the dimensionless parameter $b \equiv \frac{1}{3}(c_1 - 2 + \Lambda a_0^2)$. Surprisingly, setting $b = 0$ makes the Bach tensor vanishes *everywhere* and effectively leads to the Einstein case, where using the gauge freedom we may set

$$a_0 = -\frac{1}{r_h}\,, \qquad c_0 = r_h - \frac{\Lambda}{r_h}\,, \tag{17}$$

and sum up the series to obtain exactly the *Schwarzschild-(anti-)de Sitter black hole spacetime* (16) with the identification $\frac{\Lambda}{3} - r_h^2 = 2m\, r_h^3$.

In the generic case $b \neq 0$, we separate the 'Bach contribution' proportional to the parameter $b$ in the original coefficients $a_i$, $c_i$ of (15) by introducing their parts $\alpha_i$, $\gamma_i$ (and factorizing some constants). With the 'background' gauge choice (17), we get a one-parameter *extension* of the Schwarzschild-(A)dS spacetime,

$$\Omega(r) = -\frac{1}{r} - \frac{b}{r_h} \sum_{i=1}^{\infty} \alpha_i \Big( \frac{r_h - r}{\rho\, r_h} \Big)^i\,, \tag{18}$$

$$\mathcal{H}(r) = (r - r_h) \bigg[ \frac{r^2}{r_h} - \frac{\Lambda}{3r_h^3} \big( r^2 + r r_h + r_h^2 \big) + 3b\, \rho\, r_h \sum_{i=1}^{\infty} \gamma_i \Big( \frac{r - r_h}{\rho\, r_h} \Big)^i \bigg]\,, \tag{19}$$

where

$$\rho \equiv 1 - \frac{\Lambda}{r_h^2}\,, \qquad \alpha_1 \equiv 1\,, \qquad \gamma_1 = 1\,, \qquad \gamma_2 = \frac{1}{3} \Big[ 4 - \frac{1}{r_h^2} \Big( 2\Lambda + \frac{1}{2k} \Big) + 3b \Big]\,, \tag{20}$$

and $\alpha_l$, $\gamma_{l+1}$ for $l \geq 2$ are (with $\alpha_0 \equiv 0$) given by

$$\begin{aligned} \alpha_l = \frac{1}{l^2} \Big[ & - \frac{2\Lambda}{3r_h^2} \sum_{j=0}^{l-1} \sum_{i=0}^{j} \big[ \alpha_{l-1-j}\, \rho^j + \big( \rho^{l-1-j} + b\, \alpha_{l-1-j} \big) \big( \alpha_i\, \rho^{j-i} + \alpha_{j-i} (\rho^i + b\, \alpha_i) \big) \big] \\ & - \tfrac{1}{3} \alpha_{l-2} (2 + \rho) \rho (l-1)^2 + \alpha_{l-1} \big[ \tfrac{1}{3} + (1 + \rho) \big( l(l-1) + \tfrac{1}{3} \big) \big] \\ & - 3 \sum_{i=1}^{l} (-1)^i\, \gamma_i\, (\rho^{l-i} + b\, \alpha_{l-i}) \big( l(l-i) + \tfrac{1}{6} i(i+1) \big) \Big]\,, \end{aligned} \tag{21}$$

$$\gamma_{l+1} = \frac{(-1)^l}{k r_h^2\, (l+2)(l+1) l (l-1)} \sum_{i=0}^{l-1} \big[ \alpha_i\, \rho^{l-i} + \alpha_{l-i} \big( \rho^i + b\, \alpha_i \big) \big] (l-i)(l-1-3i)\,. \tag{22}$$

This solution represents a *three-parameter family of spherically symmetric static Schwarzschild-Bach-(anti-)de Sitter black holes* in the quadratic gravity, where

- the vaule $r = r_h$ corresponds to the *Killing horizon* since $\mathcal{H}(r_h) = 0$,
- the parameter $\Lambda$ representing the *cosmological constant* can be set to zero which recovers the results of Ref. 4,
- the *parameter* $b$ determines contribution of the non-trivial Bach tensor.

These physical parameters determine the scalar invariants (9), (10) on the horizon,

$$C_{abcd}\, C^{abcd}(r_h) = 12\left((1+b)r_h^2 - \tfrac{1}{3}\Lambda\right)^2, \qquad B_{ab}\, B^{ab}(r_h) = \frac{r_h^4}{4k^2}\, b^2\,. \tag{23}$$

To examine convergence of the series in (18), (19) we use the d'Alembert ratio test. With $n$ growing, the ratio between two subsequent terms approaches a specific constant and the series *asymptotically behave as geometric series*, see Fig. 1. The metric function $\mathcal{H}(r)$ outside the black-hole horizon is plotted in Fig. 2. We may observe a qualitative difference between $\Lambda < 0$ and $\Lambda > 0$, respectively, corresponding to the presence of an outer boundary of the static region ($r > r_h$) for $\Lambda > 0$.

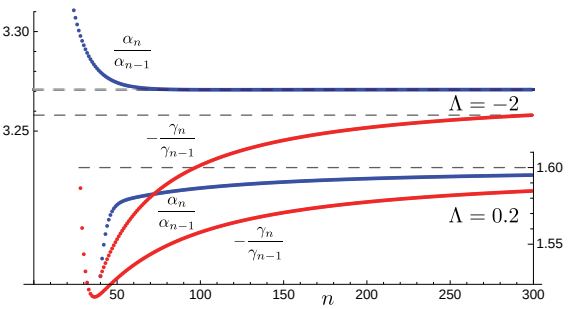

Fig. 1. The ratio convergence test for solutions (18), (19), here given by $r_h = -1$, $k = 0.5$ with $b = 0.2$, $\Lambda = -2$ (top) and $b = 0.3$, $\Lambda = 0.2$ (bottom).

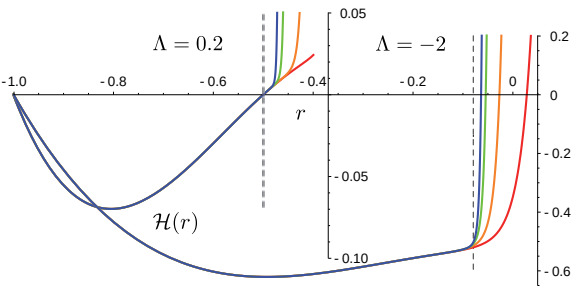

Fig. 2. Two plots of the metric function $\mathcal{H}(r)$ given by (19) with the same parameters as in Fig. 1. Vertical dashed lines indicate the radii of the convergence. For positive $\Lambda$ the function $\mathcal{H}(r)$ seems to have another root corresponding to the cosmological horizon. First 50 (red), 100 (orange), 200 (green), 300 (blue) terms in the expansions are visualized.

## 5. Physical properties

Interestingly, for the solutions introduced above the two independent parts (11) of the Bach tensor $\mathcal{B}_1, \mathcal{B}_2$ can be observed via a *specific relative motion of free test particles* described by the equation of geodesic deviation. Technical detail and explicit expressions can be found in Refs. 4,5.

Finally, let us mention the expression for the black hole *entropy* which also contain the remnant of the Bach tensor. Applying the generalized definition of entropy[9] we obtain

$$S = \tfrac{1}{4}\mathcal{A}\left(1 + \tfrac{4}{3}k\Lambda - 4k\, r_h^2\, b\right) = \tfrac{1}{4}\mathcal{A}\left(1 + \tfrac{4}{3}k\Lambda - 4k\, \bar{r}_h^{-2}\, b\right), \tag{24}$$

where $\mathcal{A} = 4\pi\, r_h^{-2} = 4\pi\, \bar{r}_h^2$ is the horizon area. More detailed discussion as well as other thermodynamic quantities are presented in our original letters.[4,5]

The $f(R,T)$ gravity theory was proposed as an extension of the $f(R)$ theories, for which besides geometrical correction terms, proportional to the Ricci scalar $R$, one has also material correction terms, proportional to the trace of the energy-momentum tensor $T$. Those material extra terms prevent the energy-momentum tensor of the theory to be conserved. On the other hand, in the context of noncommutative quantum mechanics, the presence of compact dimensions whose coordinates do not commute with time imply that time evolution is discretized, a feature which induces violations of energy conservation. In the present work we propose a connection between these two effects, so that the energy nonconservation observed in the 4-dimensional $f(R,T)$ gravity can be understood as a macroscopic effect of nonconservative quantum transitions involving the compact extra dimension. It turns out that the energy flows between the ordinary (commutative) 4-dimensional spacetime and the compact extra dimension.

*Keywords*: Modified gravity; $f(R,T)$ gravity; noncommutative quantum mechanics; discrete time; violation of energy conservation.

## 1. Introduction

The $f(R,T)$ gravity[1] is a generalization of the $f(R)$ theories. Its gravitational action depends on an arbitrary function of both the Ricci scalar $R$ and the trace of the energy-momentum tensor $T$. The dependence on $T$ was inspired initially by the consideration of existence of exotic imperfect fluids and quantum effects, the later sometimes associated with conformal anomaly[2,3].

The $f(R,T)$ action reads[1]

$$\mathcal{S}=\int d^4x\sqrt{-g}\left[\frac{f(R,T)}{16\pi}+\mathcal{L}_m\right]. \tag{1}$$

In (1), $f(R,T)$ is the general function of $R$ and $T$, $\mathcal{L}_m$ is the matter Lagrangian and $g$ is the determinant of the metric tensor $g_{\mu\nu}$.

Field equations of $f(R,T)$ gravity present extra terms, and due to those new terms the covariant derivative of the energy-momentum tensor is shown to be non-null, that is,

$$\nabla^{\mu}T_{\mu\nu} = \mathtt{F}\left[(\mathcal{L}_m g_{\mu\nu} - T_{\mu\nu})\nabla^{\mu}\ln f_T(R,T) + \nabla^{\mu}\left(\mathcal{L}_m - \frac{1}{2}T\right)g_{\mu\nu}\right], \tag{2}$$

where we introduce the notation

$$\mathtt{F} = \frac{f_T(R,T)}{8\pi + f_T(R,T)}$$

and $f_T(R,T) = \partial f(R,T)/\partial T$.

Considering the energy-momentum tensor $T_{\mu\nu}$ to describe a perfect fluid we can assume the matter Lagrangian to be $\mathcal{L}_m = \rho$.

In General Relativity the energy-momentum tensor is covariantly conserved, so that a flat space-time background leads to well-defined energy and momentum conservation laws, in particular described by the continuity and Navier-Stokes equations. Therefore, we consider the Minkowski metric as the background space-time metric, such that $\nabla_{\mu}T^{\mu\nu} = \partial_{\mu}T^{\mu\nu}$. Then, from the covariant derivative of the energy-momentum tensor (2), for $\nu = 0$, one can obtain the modified continuity equation[4]

$$\frac{\partial\rho}{\partial t} + \nabla\vec{j} = \frac{f_T}{8\pi + f_T}\left[\frac{1}{2}\frac{\partial\rho}{\partial t} - \vec{j}\cdot\vec{\nabla}(\ln f_T)\right], \tag{3}$$

where $\rho$ is the energy density of the system and $\vec{j}$ represents the energy current density.

From (3), for $f_T = 0$, the standard continuity equation is recovered. It is worth to note that equation (3) implies that in $f(R,T)$ gravity the energy conservation law is not respected, even in a flat spacetime background. This fact can be interpreted as energy flux that is ejected (injected) from (in) the system (see Ref.[4] for a detailed account). The loss or gain of energy will depend on the function $f_T(R,T)$.

## 2. Noncommutative quantum theory

### 2.1. *The algebra of noncommutative spacetime*

The canonical $D$-dimensional noncommutative spacetime is defined by replacing the coordinates $x_i$ by Hermitian operators $\hat{x}_i$ which obey the commutation relations[5,6]

$$[\hat{x}_i, \hat{x}_j] = i\theta_{ij}\mathbb{1}, \tag{4}$$

where $\theta_{ij}$ are the components of an antisymmetric $D\times D$ constant tensor and $\mathbb{1}$ is the unity element of the spacetime noncommutative algebra[5]. The components of $\theta$ determine the spacetime discretization, in the same manner as the Planck constant $\hbar$ discretizes the phase space in quantum mechanics. The geometric notion of point is

no longer meaningful, because the coordinates cannot be simultaneously measured, leading to a spacetime uncertainty relation,

$$\Delta x_i \Delta x_j \geq |\theta_{ij}|/2. \tag{5}$$

It was argued[7] that one can reach a lower bound limit on the measurements of lengths, $\Delta x_{\min} = l_{\mathrm{P}}$. In the low-energy limit, $l_{\mathrm{P}} \to 0$, one recovers the usual classical spacetime with commutative coordinates.

### 2.1.1. *The noncommutative plane*

In the special case of $D = 2$, one obtains the noncommutative plane, also called Moyal plane[8], obeying the commutation relation ($i, j \in \{0, 1\}$)

$$[\hat{x}_i, \hat{x}_j] = i\theta\epsilon_{ij}, \tag{6}$$

where $\epsilon_{ij}$ is the 2-dimensional Levi-Civita pseudo-tensor and $\theta > 0$. Equation (6) leads to the Heisenberg-like uncertainty relation

$$\Delta x_0 \Delta x_1 \geq \frac{\theta}{2}. \tag{7}$$

### 2.1.2. *Noncommutative cylinder*

Another noncommutative spacetime of interest is the noncommutative cylinder, which can be seen as resulting from the compactification of the spatial coordinate of the Moyal plane. As a consequence, the time evolution gets quantized, as shown in Ref.[9].

The classical (commutative) cylinder is topologically equivalent to $\mathbb{R} \times S^1$, where $S^1$ is a circle. In the present work we consider the compact dimension as a hidden warped space-like extra dimension, analogously to the Kaluza-Klein theory, but with the hidden dimension replaced by a noncommutative circle. Quantum Mechanics in the noncommutative cylinder was considered in Ref.[10], where it was shown that energy is no longer conserved in scattering processes.

Taking into account the extra dimension (from now on denoted by $\hat{x}_4$) together with the commutative coordinates, $x_1$, $x_2$ and $x_3$, we consider a Hamiltonian of the form $\hat{H}_{\text{ total}} = \hat{H}_{\text{commut}}(x_1, x_2, x_3) + \hat{H}_{\text{extra}}(\hat{x}_4)$, so that the physical states can be expressed as

$$\Psi_{\text{total}}(\hat{x}_0, x_1, x_2, x_3, \hat{x}_4) \equiv \psi(x_1, x_2, x_3)\, \hat{\psi}(\hat{x}_0, \hat{x}_4). \tag{8}$$

As a consequence of the topology of the extra dimension, the functions $\hat{\psi}(\hat{x}_0, \hat{x}_4)$ are periodic in $\hat{x}_4$. The spatial period is given by $2\pi r$, where $r$ is the circle radius. It follows that $\hat{\psi} = \hat{\psi}(\hat{x}_0, e^{i\frac{\hat{x}_4}{r}})$. In general the states can be expressed as linear combinations of the form

$$\hat{\psi} = \sum_{m=-\infty}^{\infty} C_m e^{im\frac{\hat{x}_4}{r}}, \tag{9}$$

and one can consider that the algebra of the noncommutative cylinder is generated by $\hat{x}_0$ and $e^{i\frac{\hat{x}_4}{r}}$. From (6) we obtain the commutation relation

$$[\hat{x}_0, e^{i\frac{\hat{x}_4}{r}}] = -\frac{\theta}{r} e^{i\frac{\hat{x}_4}{r}}, \tag{10}$$

and using the Baker-Campbell-Hausdorff formula[11] one can show that

$$e^{i\frac{\hat{x}_4}{r}} e^{i\frac{2\pi r}{\theta}\hat{x}_0} = e^{i\frac{2\pi r}{\theta}\hat{x}_0} e^{i\frac{\hat{x}_4}{r}}. \tag{11}$$

Therefore, the operator $e^{i\frac{2\pi r}{\theta}\hat{x}_0}$ commutes with all elements of the algebra of the noncommutative cylinder. According to the Schur's lemma[11], its action on the quantum states is given by $e^{i\varphi}\mathbb{1}$, where the phase $e^{i\varphi}$ classifies the possible irreducible representations of the noncommutative cylinder algebra. In what follows we choose $\varphi = 0$, so that $e^{i\frac{2\pi r}{\theta}\hat{x}_0} = \mathbb{1}$.

Now, from the eigenvalue equation $\hat{x}_0 |x_0\rangle = x_0 |x_0\rangle$ we get

$$e^{i\frac{2\pi r}{\theta}\hat{x}_0} |x_0\rangle = e^{i\frac{2\pi r}{\theta}x_0} |x_0\rangle . \tag{12}$$

Since $e^{i\frac{2\pi r}{\theta}\hat{x}_0} = \mathbb{1}$, one obtains $e^{\frac{i2\pi x_0}{\theta}} = 1$, which leads to $\frac{2\pi r x_0}{\theta} = 2\pi n$ and $x_0 = n\frac{\theta}{r}$, with $n \in \mathbb{Z}$. Hence, the spectrum of $\hat{x}_0$ is

$$\text{spec } \hat{x}_0 \equiv \left\{ n\frac{\theta}{r}, \quad \text{with} \quad n \in \mathbb{N} \right\}. \tag{13}$$

The values of the time variable correspond to the spectrum of $\hat{x}_0$, i.e., time is discretized, with a minimum interval $\frac{\theta}{r} \neq 0$ and generic time interval $\Delta t = n\frac{\theta}{r}$, with $n \in \mathbb{N}$.

According to[9,10], time discretization implies that time evolution is given by integral powers of the minimum time evolution operator $U\left(\frac{\theta}{r}\right)$, that is,

$$U\left(n\frac{\theta}{r}\right) = e^{-in\frac{\theta}{r}\hat{H}}. \tag{14}$$

Equation (14) indicates that the time evolution allows quantum transitions from eigenstates of initial energy $E_i$ to any final energy of the form $E_f = E_i + \frac{2\pi r m}{\theta}$, thus leading to the possibility of energy nonconservation.

In Ref.[8] it was shown that the energy nonconservation should occur in scattering and decay processes. Here we argue that this phenomenon can be verified in $f(R,T)$ gravity, considered as an effective theory defined on a 4-dimensional sub-space of a 5-dimensional space-time, where the time coordinate does not commute with the compactified extra coordinate. The main effect of the nonconservative quantum transitions is an energy flow between the extra dimension $S^1$ and the usual 4-dimensional spacetime. This macroscopic effect is captured by (3), where the extra terms in the continuity equation leads to energy nonconservation. In Ref.[4] this link between noncommutative quantum mechanics and the nonconservation of energy of $f(R,T)$ gravity is explained in detail.

## 3. Conclusions

Energy and momentum conservation laws are well-stablished in flat spacetime backgrounds, in the context of General Relativity. By its turn, $f(R,T)$ gravity does not present this characteristic. Since the energy-momentum tensor is not covariantly conserved, it follows that the field equations lead to extra terms in the continuity equation, even in a flat spacetime background, thus showing that the energy is not conserved.

Within the context of noncommutative theory we can also have energy nonconservation due to the time discretization induced by the presence of a noncommutative compact extra dimension.

We argue that the energy nonconservation in a 4-dimensional $f(R,T)$ theory can be understood as an effect of quantum transitions in a larger spacetime containing a fifth compact dimension which does not commute with the time operator. As a consequence, there is a flow of energy between the usual spacetime and this extra dimension. Even though the conservation laws are preserved in this larger scenario, in the 4-dimensional effective theory energy is no longer conserved.

We present the effect of the quantum corrections on the Szekeres spacetime, a system important for the study of the inhomogeneities of the pre-inflationary era of the universe. The study is performed in the context of canonical quantisation in the presence of symmetries. We construct an effective classical Lagrangian and impose the quantum version of its classical integrals of motion on the wave function. The interpretational scheme of the quantum solution is that of Bohmian mechanics, in which one can avoid the unitarity problem of quantum cosmology. We discuss our results in this context.

*Keywords*: Szekeres system; Silent universe; Quantisation; Semiclassical approach

## 1. Introduction

We focus on the quantisation of the Szekeres spacetime metric with the aim to study the effect of possible quantum corrections in the dynamics. This metric has the form [1]

$$ds^2 = -dt^2 + e^{2\alpha}dr^2 + e^{2\beta}\left(dy^2 + dz^2\right) \tag{1}$$

where $\alpha \equiv \alpha(t, r, y, z)$ and $\beta \equiv \beta(t, r, y, z)$ and represents an irrotational perfect fluid with vanishing pressure and magnetic Weyl tensor, $p = \omega_{ab} = H_{ab} = 0$. The interest in the silent universe lies on the fact that it can be seen as inhomogeneous solutions of Einstein equations with no symmetries which generalise Kantowski-Sachs, FRW and Tolman-Bondi spacetimes. Thus it is proper for the description of perturbations on these spacetimes [2–5].

We start by writing the field equations on the covariant variables $(\rho, \theta, \sigma, E)$, where $\rho = T^{\mu\nu}u_\mu u_\nu$, with $T^{\mu\nu}$ being the energy-momentum tensor of the matter,

*azampeli@phys.uoa.gr

$\theta = (\nabla_\nu u_\mu)\, h^{\mu\nu}$ is the expansion rate of the observer, while $\sigma$ and $E$ are the shear and electric component of the Weyl tensor, $E^\mu_\nu = Ee^\mu_\nu,\ \sigma^\mu_\nu = \sigma e^\mu_\nu$, in which the set of $\{u^\mu, e^\mu_\nu\}$ defines an orthogonal tetrad. The field equations then become

$$\dot{\rho} + \theta\rho = 0, \tag{2a}$$

$$\dot{\theta} + \frac{\theta^2}{3} + 6\sigma^2 + \frac{1}{2}\rho = 0, \tag{2b}$$

$$\dot{\sigma} - \sigma^2 + \frac{2}{3}\theta\sigma + E = 0, \tag{2c}$$

$$\dot{E} + 3E\sigma + \theta E + \frac{1}{2}\rho\sigma = 0, \tag{2d}$$

together with the algebraic equation which is the Hamiltonian constraint

$$\frac{\theta^2}{3} - 3\sigma^2 + \frac{{}^{(3)}R}{2} = \rho \tag{2e}$$

where $\dot{}$ denotes the directional derivative along $u^\mu$, the energy density is $\rho = T^{\mu\nu}u_\mu u_\nu$, with $T^{\mu\nu}$ being the energy-momentum tensor of the matter, the parameter $\theta = (\nabla_\nu u_\mu)\, h^{\mu\nu}$ is the expansion rate of the observer, while $\sigma$ and $E$ are the shear and electric component of the Weyl tensor, $E^\mu_\nu = Ee^\mu_\nu,\ \sigma^\mu_\nu = \sigma e^\mu_\nu$, in which the set of $\{u^\mu, e^\mu_\nu\}$ defines an orthogonal tetrad. We note that in addition to these equations, the spatial constraints ensure the integrability of the system.

In the following sections we present the quantization of this system in terms of canonical quantization in the presence of symmetries[6]. The starting point is the effective Lagrangian obtained in[7] and we adopt the Bohmian approach for our analysis[8,9] following e.g.[10], since its causal character suits the context of quantum cosmology, where the notion of an external observer cannot be justified.

## 2. Classical and Quantum Dynamics

In[7] the Szekeres system (2) was written in an equivalent form of a two second-order differential equations system which are equations of motion of a Lagrangian of the form

$$L = \frac{1}{2}G_{\alpha\beta}(q(t))\dot{q}^\alpha(t)\dot{q}^\beta(t) - V(q(t)), \quad \alpha, \beta = 0, \ldots n-1 \tag{3}$$

where $q(t)$ denote the degrees of freedom of the system and $G_{\alpha\beta}$ the metric on the configuration space of variables. Adopting proper coordinates for our case, $\rho = \frac{6}{(1-v)u^2},\ E = \frac{v}{u^3(v-1)}$, the system of the two second order equations becomes

$$\ddot{v} - \frac{2v}{u^3} = 0, \tag{4a}$$

$$\ddot{u} + \frac{1}{u^2} = 0 \tag{4b}$$

derivable from $L = \dot{u}\dot{v} - \frac{\dot{v}}{u^2}$. The system (4) admits two integrals of motion, quadratic in the velocities; the first is the Hamiltonian function since the system

is autonomous, while the second one is the quadratic function $I_0$ which can be constructed by the application of Noether's theorem for contact symmetries[7], which in the phase space become

$$p_u p_v + \frac{v}{u^2} = h, \tag{5a}$$

$$p_v^2 - 2u^{-1} = I_0 \tag{5b}$$

When turned to quantum operators and imposed on the wave function, according to the rules $\hat{p}_\alpha = -i\frac{\partial}{\partial q^\alpha}$, $\{.,.\} \to -\frac{i}{\hbar}[.,.]$, with operator-ordering respecting the general covariance and hermiticity ensured under the inner product $\int d^n q \mu \psi_1^* \psi_2$, they lead to two eigenvalue equations

$$\left(-\partial_{uv} + \frac{v}{u^2}\right)\Psi = h\Psi, \tag{6a}$$

$$\left(\partial_{vv} + \frac{2}{u}\right)\Psi = -I_0\Psi, \tag{6b}$$

In the first one we can recognise the time-independent Schroödinger equation and their solution is

$$\Psi\left(I_0, u, v\right) = \frac{\sqrt{u}}{\sqrt{2 + I_0 u}}\left(\Psi_1 \cos f\left(u, v\right) + \Psi_2 \sin f\left(u, v\right)\right) \tag{7}$$

where

$$f\left(u, v\right) = \frac{\left(hu + I_0 v\right)\sqrt{2I_0 + I_0^2 u} - 2h\sqrt{u}\,\mathrm{arcsinh}\,\sqrt{\frac{I_0 u}{2}}}{I_0^{3/2}\sqrt{u}}, \quad \text{for } I_0 \neq 0, \tag{8}$$

$$f\left(u, v\right) = \frac{\sqrt{2}\left(hu^2 + 3v\right)}{3\sqrt{u}}, \quad \text{for } I_0 = 0. \tag{9}$$

and $\Psi_1$, $\Psi_2$ denote constants of integration. Due to the linearity of (6a), the general solution is $\Psi_{Sol}\left(u, v\right) = \sum_{I_0} \Psi\left(I_0, u, v\right)$.

## 3. Semiclassical analysis and probability

In the context of the Bohmian approach, the departure from the classical theory is determined by an additional term in the classical Hamilton-Jacobi equation, known as quantum potential $Q_V = -\frac{\Box\Omega}{2\Omega}$, where $\Omega$ denotes the amplitude of the wave function in polar form, $\Psi(u, v) = \Omega(u, v)e^{iS(u,v)}$. When the quantum potential is zero, the identification

$$\frac{\partial S}{\partial q_i} = p_i = \frac{\partial}{\partial \dot{q}_i} \tag{10}$$

is possible. If this classical definition for the momenta is retained even when $Q \neq 0$, the semiclassical solutions will differ from the classical ones.

Under the assumption that the quantum corrections in the general solution (7) follow from the "frequency $I_0$" with the highest peak in the wave function, which is

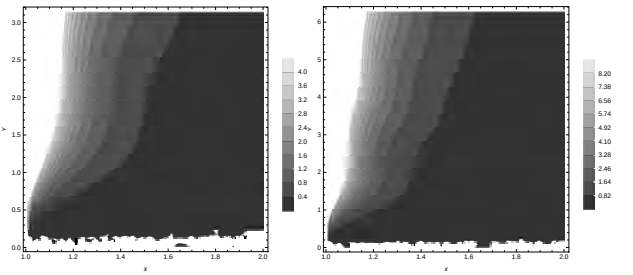

Fig. 1. Contour plot for the probability function in the space of variables $x, v$. We observe that as $x \to 0$ and $v$ is small, that is, $I_0 \to 0$, the function $P(x, v)$ reaches to a minimum extreme.

in agreement with the so-called Hartle criterion[11], the quantum potential vanishes. This provides no quantum corrections and the semiclassical equations (10) give the classical solution, i.e. the Szekeres universe remains "silent", even at the quantum level. In the particular case $h = 0$ and $\Psi_1 \to 0$, the wave function is well behaved at $u \to 0$ and $u \to \infty$. We can thus define a probability which, after a change of coordinates to $u \to \frac{2}{x^2 - I_0}$ becomes

$$P = \int_{\sqrt{I_0}+\epsilon}^{\lambda} dx \int_0^{2k\pi} dv \; \frac{4c_3^2 \sin(xv)}{x(x^2 - I_0)^2} \; , \; k \in \mathbb{N}. \tag{11}$$

where the cut-off constant $\lambda$ is introduced to exclude the case $E = 0, \rho = 0$. The qualitative behaviour of the probability function is given in the contour plot in Fig. 1. The plots show that for $I_0 \to 0$ the probability function reaches its minimum.

## 4. Conclusions

Our quantum analysis of the Szekeres system was based on the canonical quantization in the presence of symmetries and the results were interpreted by adopting the Bohmian mechanics approach. The starting point was an effective classical point-like Lagrangian which can reproduce the two dimensional system of second-order differential equations resulted from the initial field equations. This Lagrangian is autonomous, thus there exists a conservation law of "energy" corresponding to the Hamiltonian function. As for the extra contact symmetry, it leads to a quadratic in the momenta conserved quantity attributed to a Killing tensor of the second-rank. The two conserved quantities give two eigenequations at the quantum level, the Hamiltonian function being the Schrödinger equation.

The assumption that the wave function is peaked around its classical value leads to the lack of quantum corrections and the recovery of the classical solutions, thus leading to the conclusion that the Szekeres universe remains silent at the quantum level. Finally, for the particular case $h = 0$ it was shown that the probability function and relate one (unstable) exact solution with the existence of a minimum of this probability.

The classical exact solution which corresponds at the values $h = I_0 = 0$ of the integration constants is $u_A(t) = \frac{6^{\frac{2}{3}}}{2} t^{\frac{2}{3}}, v_A(t) = v_0 t^{-\frac{1}{3}}$ [7] and corresponds to an unstable critical point for the dynamical system (2). It is interesting the fact that these conditions also correspond to the extremum of the probability function, something which might be related to the existence and stability of the exact solution. This result is also in accordance with the analysis of the probability extrema in [12] where it was shown that the extrema of the probability lie on the classical values.

We investigate the problem of the orbital stability of the motion of a test body in the restricted three-body problem, where all bodies have their own rotation. The stability of the orbits is investigated by using vector elements of orbits such as orbital moment and its time derivative. We show that it is possible to get some insight into the stability properties of the motion of test bodies.

*Keywords*: Restricted three-body problem; orbital stability; vector elements

## 1. Introduction

The problem of the motion of bodies in general relativity (GR) can be split into two correlated problems, namely, the problem of motion of point like masses and the problem of motion of extended bodies. There are several methods for obtaining the equations of motion from the equations of the gravitational field, such as the method of Einstein-Infeld-Hoffmann (EIH)[1], the first approximate method of Fock[2], the second approximate method of Fock, etc. the EIH and Infeld methods allow us to find the equations of motion of point masses. There are several works devoted to investigate the restricted three body problem in GR. In[3] for three finite masses, it was showed that a triangular configuration satisfies the post-Newtonian equation of motion in general relativity, if and only if it has the relativistic corrections to each side length. Also the relativistic effect of restricted three body problem was investigated in[4] and it was shown that the relativistic effects become important when the parameter $M/R$ is increased. The motion of an extended body in GR mechanics eas first formulated by the V. Fok and after that developed by Petrova, Brumberg and Abdilldin[2 5 6 7]. Fock's methods make it possible to derive the equations of motion of extended bodies, allow us to take into account the internal structure and shape of bodies. In[8 9], we investigated the problem of the orbital stability of a circular motion of a test body in the restricted three body problem, when perturbations from the second body are of the order of relativistic corrections to the motion of a test body from the central body. It was shown than in this case the orbit of the test body is stable.

This work is organized as follows. In Sec. 2, we present the relativistic Lagrangian and derive the equation of motion. In Sec. 3, we present the evolution equation of motion of a test body. Finally, Sec. 4 contains discussions of our results.

## 2. The Lagrangian and equation of motion

The problem of the orbital stability of circular motion of a test body in the restricted three-body problem has been investigated in[8]. The resting position of the central body coincides with the reference point of coordinates, the second body moves along the circle around the central body and is not subject to the disturbance. The test body moves in a perturbed circular orbit and the relativistic corrections are:

$$U_2 \ll U_1; U_1/U_2 \approx v^2/c^2, \tag{1}$$

The relativistic Lagrange function can be represented as:

$$L = L^{(0)} + L^{(rot)}. \tag{2}$$

where $L^{(0)}$ is the relativistic Lagrange function for three point masses[10], and the second term $L^{(rot)}$ is responsible for corrections containing rotational terms. Regarding the $L^{(0)}$ term, in[8] it is shown that the motion of the test body in the plane of the orbit of the two body is stable when all bodies have no proper rotation. In this work, we consider the case when all bodies have their own rotation. Our aim to find the evolution equation of motion for the test (third) body, which describes the average change of its orbital momentum. To do that, we will study the evolution equations of motion by using the asymptotic methods of adiabatic theory, through the process of averaging of the corresponding equations using the vector elements **M** (the orbital moment) and **A** (the Laplace vector). M.M.Abdildin[6] and Burmberg[5] devoted an entire book to the motion of extended body with the internal structure and rotation in GR, where the Lagrange derived for N body using the Fok's approach. We derived the second term of Eq.(2) for the three masses without consideration of internal structure. The details of this derivation will be presented elsewhere. According to the adiabatic theory, the evolutionary motion of the test(third)body describes the average change of its orbital momentum. Therefore, we write down the orbital angular momentum of the test body:

$$\vec{M} = [\vec{r}, \vec{p}] \tag{3}$$

where the square bracket means the vector cross product. The evolutionary motion of the test(third)body is:

$$\dot{\vec{M}} = \left[\dot{\vec{r}}, \vec{p}\right] + \left[\vec{r}, \dot{\vec{p}}\right] \tag{4}$$

where the dot represents time derivative.

According to the Eqs.(2) the time derivative of orbital angular momentum reduce to $\dot{\vec{M}}^{(rot)}$

$$\dot{\vec{M}} = \dot{\vec{M}}^{(0)} + \dot{\vec{M}}^{(rot)} \tag{5}$$

The quantities $\dot{\vec{r}}$ and $\dot{\vec{p}}$ are found by means of the Hamilton equations from the Hamilton function of the system and which satisfies

$$H = \vec{\vartheta}_i \frac{\partial L}{\partial \vec{\vartheta}_i} - L \tag{6}$$

After lengthy computations, it is possible to isolate the derivatives of the canonical variables of the test body:

$$\dot{\vec{r}}_3^{(rot)} = \frac{1}{c^2} I_3 \left(\vec{\omega}_3 \cdot \vec{p}_3\right) \vec{\omega}_3 - \frac{\gamma}{2c^2} \cdot \frac{m_2 I_2 + m_3 I_3}{\left|\vec{r}_2 - \vec{r}_3\right|^3} \times \left[ -\vec{p}_2 + 3 \frac{\left(\left(\vec{r}_2 - \vec{r}_3\right) \cdot \vec{p}_2\right) \cdot \left(\vec{r}_2 - \vec{r}_3\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^3} \right], \tag{7}$$

$$\begin{aligned}
\dot{\vec{p}}_3^{(*)} = & \left\{ -\frac{3\gamma}{2c^2} \left(m_2 I_2 + m_3 I_3\right) \frac{\vec{p}_2 \vec{p}_3}{\left|\vec{r}_2 - \vec{r}_3\right|^5} + \frac{15\gamma}{2c^2} \frac{\left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{p}_2\right) \cdot \left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{p}_3\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^7} \right. \\
& - \frac{3\gamma}{c^2} \frac{1}{\left|\vec{r}_2 - \vec{r}_3\right|^3} \left(m_2 \omega_3^2 I_3 + m_3 \omega_2^2 I_2\right) + \frac{3\gamma^2}{2c^2} \frac{1}{\left|\vec{r}_2 - \vec{r}_3\right|^5} \left(m_2 I_3 + m_3 I_2\right) \\
& + \frac{\gamma^2}{2c^2} m_1 m_2 I_3 \frac{1}{\left|\vec{r}_3\right|^3 \left|\vec{r}_2 - \vec{r}_3\right|^3} - \frac{3\gamma^2}{2c^2} m_1 m_2 I_3 \frac{\left(\vec{r}_3 \left(\vec{r}_2 - \vec{r}_3\right)\right)}{\left|\vec{r}_3\right|^3 \left|\vec{r}_2 - \vec{r}_3\right|^3} \\
& \left. - \frac{\gamma^2}{2c^2} m_2 m_3 I_1 \frac{1}{\left|\vec{r}_2\right|^3 \left|\vec{r}_3\right|^3} + - \frac{9 \left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{\omega}_2\right) \left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{\omega}_3\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^5} \right\} \vec{r}_2 \\
& + \left[ \vec{r}_3, \left\{ -\frac{9\gamma}{2c^2} \left( m_2 I_2 + m_3 I_3 \frac{\vec{p}_2 \vec{p}_3}{\left|\vec{r}_2 - \vec{r}_3\right|^5} \right) \right. \right. \\
& - \frac{15\gamma}{2c^2} \frac{\left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{p}_2\right) \left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{p}_3\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^7} + \frac{3\gamma}{c^2} \frac{1}{\left|\vec{r}_3\right|^3} \left(m_1 \omega_3^2 I_3 + m_3 \omega_1^2 I_1\right) \\
& + \frac{3\gamma}{c^2} \frac{1}{\left|\vec{r}_2 - \vec{r}_3\right|^3} \left(m_2 \omega_3^2 I_3 + m_3 \omega_2^2 I_2\right) - \frac{3\gamma^2}{2c^2} \frac{\left(m_1 I_3 + m_3 I_1\right)}{\left|\vec{r}_3\right|^5} \\
& - \frac{3\gamma^2}{2c^2} \frac{\left(m_2 I_3 + m_3 I_2\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^5} - \frac{\gamma^2}{c^2} m_1 m_2 I_3 \frac{1}{\left|\vec{r}_3\right|^3 \left|\vec{r}_2 - \vec{r}_3\right|^3} \\
& - \frac{3\gamma^2}{2c^2} m_1 m_2 I_3 \frac{\left(\vec{r}_3 \left(\vec{r}_2 - \vec{r}_3\right)\right)}{\left|\vec{r}_3\right|^5 \left|\vec{r}_2 - \vec{r}_3\right|^3} - \frac{3\gamma^2}{2c^2} m_1 m_2 I_3 \frac{\left(\vec{r}_3 \left(\vec{r}_2 - \vec{r}_3\right)\right)}{\left|\vec{r}_3\right|^3 \left|\vec{r}_2 - \vec{r}_3\right|^3} \\
& + \frac{3\gamma^2}{2c^2} m_2 m_3 I_1 \frac{\left(\vec{r}_2 \vec{r}_3\right)}{\left|\vec{r}_2\right|^3 \left|\vec{r}_3\right|^5} + \frac{3\gamma^2}{2c^2} m_1 m_3 I_2 \frac{\left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{r}_2\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^5 \left|\vec{r}_2\right|^3} \\
& \left. \left. + \frac{12\gamma}{c^2} \frac{I_1 I_3}{\left|\vec{r}_3\right|^5} + \frac{12\gamma}{c^2} \frac{I_2 I_3}{\left|\vec{r}_2 - \vec{r}_3\right|^5} + \frac{9\gamma^2}{2c^2} \frac{\left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{\omega}_2\right) \left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{\omega}_3\right) \vec{r}_3}{\left|\vec{r}_2 - \vec{r}_3\right|^5} \right\} \vec{r}_3 \right] \\
& + \left[ \vec{r}_3, \frac{\gamma}{c^2} \left\{ \frac{9 \left(\vec{r}_3 \vec{\omega}_2\right) \left(\vec{r}_3 \vec{\omega}_3\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^3} \vec{r}_3 - \frac{3 \left(\vec{r}_3 \vec{\omega}_3\right)}{\left|\vec{r}_3\right|^3} \vec{\omega}_1 + \frac{3 \left(\vec{r}_3 \vec{\omega}_1\right)}{\left|\vec{r}_3\right|^3} \vec{\omega}_3 + \right. \right. \\
& \left. \left. \frac{3 \left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{\omega}_3\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^3} \vec{\omega}_2 + \frac{3 \left(\left(\vec{r}_2 - \vec{r}_3\right) \vec{\omega}_2\right)}{\left|\vec{r}_2 - \vec{r}_3\right|^3} \vec{\omega}_3 \right\} \right]
\end{aligned} \tag{8}$$

where $\vartheta_i$, $r_i$, $p_i$, $\omega_i$ and $I_i$ are the velocity, radius, momentum, angular velocity and inertia momentum of $i$-th mass, respectively [9].

## 3. Equations of motion

Our approach consists in finding the evolutionary equation of motion the test body (third), which describes the average change of its orbital momentum.

$$\dot{\vec{M}}^{(rot)} = -\frac{\gamma}{2c^2}\cdot\frac{m_2I_2+m_3I_3}{\left|\vec{r}_2-\vec{r}_3\right|^3}\left[[-\vec{p}_2,\vec{p}_3]+3\frac{\left(\left(\vec{r}_2-\vec{r}_3\right)\vec{p}_2\right)}{\left|\vec{r}_2-\vec{r}_3\right|^2}\left[\left(\vec{r}_2-\vec{r}_3\right),\vec{p}_3\right]\right]$$
$$+\left\{-\frac{3\gamma}{2c^2}(m_2I_2+m_3I_3)\frac{\vec{p}_2\vec{p}_3}{\left|\vec{r}_2-\vec{r}_3\right|^5}+\frac{15\gamma}{2c^2}\frac{\left(\left(\vec{r}_2-\vec{r}_3\right)\vec{p}_2\right)\cdot\left(\left(\vec{r}_2-\vec{r}_3\right)\vec{p}_3\right)}{\left|\vec{r}_2-\vec{r}_3\right|^7}\right.$$
$$-\frac{3\gamma}{c^2}\frac{1}{\left|\vec{r}_2-\vec{r}_3\right|^3}\left(m_2\omega_3^2I_3+m_3\omega_2^2I_2\right)+\frac{3\gamma^2}{2c^2}\frac{1}{\left|\vec{r}_2-\vec{r}_3\right|^5}\left(m_2I_3+m_3I_2\right)$$
$$+\frac{\gamma^2}{2c^2}m_1m_2I_3\frac{1}{\left|\vec{r}_3\right|^3\left|\vec{r}_2-\vec{r}_3\right|^3}-\frac{3\gamma^2}{2c^2}m_1m_2I_3\frac{\left(\vec{r}_3\left(\vec{r}_2-\vec{r}_3\right)\right)}{\left|\vec{r}_3\right|^3\left|\vec{r}_2-\vec{r}_3\right|^3}-\frac{\gamma^2}{2c^2}m_2m_3I_1\frac{1}{\left|\vec{r}_2\right|^3\left|\vec{r}_3\right|^3}$$
$$\left.+\frac{\gamma}{c^2}\frac{9\left(\left(\vec{r}_2-\vec{r}_3\right)\vec{\omega}_2\right)\left(\left(\vec{r}_2-\vec{r}_3\right)\vec{\omega}_3\right)}{\left|\vec{r}_2-\vec{r}_3\right|^5}\right\}[\vec{r}_3,\vec{r}_2] \tag{9}$$

According to the Eq.(5), the second term of the time derivative of the orbital momentum is:

$$\overline{\dot{\vec{M}}^{(rot)}} = \frac{1}{T}\int_0^T \dot{\vec{M}}^{(rot)}dt. \tag{10}$$

In order to obtain the equations of motion one needs to integrate the Eq.(10) for the repetition period of the system configurations T (synodic period of the test body).

In general, it is a complicated task to integrate the above differential equation. Suppose that the test body is moving along a circular orbit

$$\vec{r}_3 = r_{kep}\left(\vec{i}\cos\omega_3 t+\vec{j}\sin\omega_3 t\right) \tag{11}$$

and the second body

$$\vec{r}_2 = r_2\left(\vec{i}\cos\omega_2 t+\vec{j}\sin\omega_2 t\right) \tag{12}$$

Substituting the radius-vector of the test body in Eq.(10) and integrating the relativistic rotational component we can find that

$$\overline{\dot{\vec{M}}^{(rot)}} = 0 \tag{13}$$

The orbital stability of the test body by definition means the equality to zero of the average change of the angular momentum. As we can see from this expression, in GR, in the first approximation, the circular motion of a test body in the plane of the orbit of the second body in the restricted circular three-body problem is stable

## 4. Conclusions

In this work, we considered the orbital stability problem for the circular motion of a test body in the restricted three-body problem within the framework of GR, when all bodies have their own rotation. We derived the equation of motion from the Lagrange function with the rotational terms and the stability problem of the orbit is investigated by using the adiabatic theory of motion in the GR. Moreover, we derived the explicit form of the corresponding motion equation and the time derivative of momentum. The resulting equation was integrated (averaged) by the sinodic period of the test body, which eliminates perturbations,leaving only evolutionary effects.

The result of the integral is confirmed that the circular motion will be stable if the spins of all bodies are collinear within a plane. The orbital stability of quasicircular orbits of the test body is a task of further investigations.

We address the question of point particle motion coupled to classical fields, in the context of scalar fields derived from higher-order Lagrangians and BLTP electrodynamics.

*Keywords*: Point particles, fields, higher-order Lagrangian

## 1. Introduction

Finding a consistent and well-posed dynamical equations of motion for a system of point particles interacting with classical fields is an important problem of relativistic physics. The field could be scalar, gravitational or electromagnetic. For the gravitational field (Einstein-Infeld-Hoffmann problem), the subject's history is reviewed in [7], so we will restrict ourselves to brief remarks concerning electromagnetic interaction. The problem of point particle motion famously started with attempts to model the electron as point particles in classical electrodynamics. The field has been plagued ever since by the appearance of *infinities* for which renormalization procedures are required (see e.g. [6,16]). An approach free of infinities started in 1933 with a paper by Born [4], which was continued by Born and Infeld in [5]. This time, the field equations of electrodynamics were altered to the nonlinear Maxwell–Born–Infeld field equations. The MBI field equations are nonlinear and hence difficult to handle.

Bopp [2,3], Landé–Thomas [10,11], and Podolsky [13,14] went into a different direction by proposing linear, but *higher-order derivative* field equations to remove the infinite field energy problems. Recently the self-force problem in BLTP electrodynamics was studied in quite some generality by J. Gratus, W. Tucker and V. Perlick [9], after more limited earlier studies in [11] and [18]. Recently M. Kiessling and A.S. Tahvildar-Zadeh considered a system of $N$ charged point particles together with their associated BLTP self-fields. Their paper [8] contains the first well-posedness result for the combined Cauchy problem of particles and electrodynamic fields.

In this paper, we report on recent results [1,12] to provide a rigorous framework for point particles interacting via *retarded fields*. As we explain in section 2, the

usual Lagrangian framework does not lead to viable particle equations of motion. An additional principle is needed, which we take to be the conservation of energy and momentum (see also[8]). It turns out that for the higher-order field equations we describe here, a rigorous derivation of the particle equations of motion can be given, which is free of ad-hoc renormalization procedures.

## 2. Scalar Fields

The fundamental issues can be most readily illustrated in the context of scalar fields. We therefore first consider a scalar field $\phi(x^\alpha)$ defined on Minkowski space-time (with Minkowski metric $g_{\alpha\beta}$), interacting with a particle described by its world-line $\tau \mapsto q^\alpha(\tau)$. The particle world-line is associated with a scalar charge density

$$\rho(x^\alpha) = \kappa \int \frac{\delta^{(4)}(x - q(\tau))}{\sqrt{-g}} d\tau \tag{1}$$

where $\kappa$ is coupling constant between particle and field. Note that the scalar current $\rho\dot{q}^\alpha$ is conserved, i.e. $\partial_\alpha(\rho\dot{q}^\alpha) = 0$. The action $S$ of the system is *formally* given by

$$S[\phi, q] = S_{\text{field}} + S_{\text{int}} + S_{\text{particle}}$$

where

$$S_{\text{field}} = -\frac{1}{2}\int d^4x\sqrt{-g}\; g^{\alpha\beta}\partial_\alpha\phi\partial_\beta\phi, \qquad S_{\text{int}} = -\int d^4x\sqrt{-g}\;\phi\rho$$

$$S_{\text{particle}} = \int m(\tau)d\tau$$

Here, $m(\tau)$ is the bare mass of the particle, which for scalar particles has to be taken as time-dependent (see[16]). Formal variation of the action leads to the equations

$$\frac{d}{d\tau}\left(m\dot{q}^\alpha\right) = -\kappa\partial^\alpha\phi\big|_{x^\beta = q^\beta(\tau)} \tag{2}$$

$$\Box\,\phi = -\rho. \tag{3}$$

Now the retarded solution of the wave equation (3), for all $x^\alpha$ not on the world-line, is given by

$$\phi(x^\beta) = \left.\frac{\kappa}{4\pi\dot{q}_\gamma(x^\gamma - q^\gamma)}\right|_{\text{ret}} \tag{4}$$

where "ret" indicates evaluation at the retarded time on the particle world-line, i.e. $\dot{q}_\gamma(x^\gamma - q^\gamma)$ is a light-like Minkowski vector. But combining the equations (2), (3) and (4) makes no apparent sense, since (2) requires evaluation of $\phi, \partial^\alpha\phi$ at the particle's position and (4) is not well-defined there. To remedy this situation, authors have proposed renormalization procedures, avereraging axioms and the use of a combination of retarded and advanced solutions of the field equation (3) (see e.g.[16]). Clearly the Lagrangian formulation does not determine the particle equations of motion uniquely and an additional principle is needed. Preferably, the additional principle should be as fundamental as possible. Here, we consider the

possibility of using *conservation of energy and momentum* to derive the equations of motion. The most convenient, relativistic covariant way to implement this is to define the energy-momentum tensor of the particle by

$$T^{\mu\nu}_{\text{particle}}(x^\alpha) = m_0 \int \frac{u^\mu u^\nu \delta^{(4)}(x - q(\tau))}{\sqrt{-g}}\, d\tau \tag{5}$$

The conservation of energy and momentum is then simply

$$\partial_\mu \left( T^{\mu\nu}_{\text{particle}} + T^{\mu\nu}_{\text{field}} \right) = 0 \tag{6}$$

where $T^{\mu\nu}_{\text{field}}$ is the canonical energy-momentum tensor of the field. In view of (5), we need to be precise on how to mathematically interpret (6). The most straightforward way is to interpret (6) in a distributional sense. So as the definition of the action of $T^{\mu\nu}_{\text{field}}$ on any smooth tensor field $\varphi_{\mu\nu}$ we might take

$$T^{\mu\nu}_{\text{field}}(\varphi_{\mu\nu}) = \int \left[ -\frac{1}{2} g^{\mu\nu} \partial_\alpha \phi \partial^\alpha \phi + \partial^\mu \phi \partial^\nu \phi \right] \varphi_{\mu\nu}\, d^4x \tag{7}$$

where $\phi \in C_0^\infty(\mathbb{R}^4)$ is a smooth test function. The problem, of course, is that the integrand is *not locally integrable* if we plug in the retarded field (4). This is most easily seen for a charge at rest, for which $T^{00} \sim r^{-4}$ with $r$ being the spatial distance between the charge and the point $(x^\alpha)$.

## 3. Higher-Order Scalar Fields

A possible way out without resorting to renormalization is to modify the field equations. It should be kept in mind that other choices of the action are conceivable and a modification of the Lagrangian is a direction worth pursuing. As an example, we would like to mention that there is a large body of literature on modifications of Einstein's general relativity (see e.g.[17]). For now, we consider the modified action

$$S_{\text{field}} = \int d^4x \sqrt{-g}\ \left[ -g^{\alpha\beta} \partial_\alpha \phi \partial_\beta \phi + a(\Box\, \phi)^2 \right], \tag{8}$$

by the higher-order term $(\Box\, \phi)^2 = \left[ \frac{1}{\sqrt{-g}} \partial_\alpha \left( \sqrt{-g} g^{\alpha\beta} \partial_\beta \phi \right) \right]^2$. This modification keeps the field equations linear, but changes the *short-distance physics* in a way explained below. Observe also that (7) is the unique action functional involving second derivatives of $\phi$ that leads to linear field equations. The only other covariant quadratic contribution involving second order derivatives would be

$$g^{\alpha\gamma} g^{\beta\rho} (\partial_\alpha \partial_\beta \phi)(\partial_\gamma \partial_\rho \phi)$$

but this would reduce to $(\Box\, \phi)^2$ after an integration by parts. The resulting field equation for $\phi$ is

$$\Box\, (\phi + a \Box\, \phi) = -\rho. \tag{9}$$

where $\rho$ is given by (1). It turns out that the higher-order equation (9) has a regularizing effect on fields with point sources. The retarded solution $\phi$ of (9) can

be determined by Green's functions techniques and has the property that both $\phi$ and $\partial_\beta\phi$ are now bounded in the vicinity of the particle, although the value of $\partial_\beta\phi$ on the particle world-line is still ill-defined.

Recall that the canonical energy-momentum tensor is given by the variation of $S_{\text{field}}$ with respect to $g^{\mu\nu}$:

$$\delta S_{\text{field}} = -\int d^4x\sqrt{-g}\ (T_{\text{field}})_{\mu\nu}g^{\mu\nu} \tag{10}$$

A lengthy calculation gives (for $g_{\alpha\beta}$ being the Minkowski metric):

$$\begin{aligned} T^{\alpha\beta}_{\text{field}} = &-\frac{1}{2}g^{\alpha\beta}\partial_\mu\phi\partial^\mu\phi + \partial^\alpha\phi\partial^\beta\phi \\ &+ 2a\partial^\alpha\Box\,\phi\partial^\beta\phi - \frac{a}{2}(\Box\,\phi)^2 - a\partial_\mu(\Box\,\phi)(\partial^\mu\phi)g^{\alpha\beta} \end{aligned} \tag{11}$$

The energy-momentum tensor of the field can now be defined as a distribution, since it contains singularities of order at most $r^{-2}$. A thorough analysis of (6) now yields a well-defined equation of motion (see[1]), from which the "self-force" contribution can be read off. The form of the self-force can depend on the type of problem considered (e.g. a scattering problem or initial-value problem for particles and fields).

## 4. BLTP Electrodynamics

Higher-order field linear equations for electrodynamics were proposed by Bopp[2,3], Landé–Thomas[10,11], and Podolsky[13,14]. Starting point is the usual Maxwell action with an additional term containing second-order derivatives of the field tensor $F_{\mu\nu}$:

$$S_{\text{BLTP}} = \int d^4x\sqrt{-g}\ \left[-\frac{1}{16\pi}F_{\alpha\beta}F^{\alpha\beta} - \frac{1}{8\pi\kappa^2}\partial_\gamma F^{\gamma\alpha}\partial^\lambda F_{\lambda\alpha}\right] \tag{12}$$

This is the unique action giving linear field equations of order less or equal to four. $\kappa > 0$ is a fixed parameter throughout. Variation of the action with respect to the vector potential $A_\alpha$ gives

$$\begin{aligned} (I - \kappa^{-2}\Box\,)\partial^\alpha F_{\alpha\beta} &= -4\pi j_\beta \\ \partial_\alpha F_{\beta\gamma} + \partial_\beta F_{\gamma\alpha} + \partial_\gamma F_{\alpha\beta} &= 0 \end{aligned} \tag{13}$$

where $j_\alpha$ is usual particle 4-current vector. We will refer to a theory based on (13) as BLTP electrodynamics. As before, the Lagrangian formulation does not determine the particle equations of motion and we additionally impose (6) in a distributional sense. The canonical energy-momentum tensor of the field is given by

$$\begin{aligned} -4\pi T^{\alpha\gamma}_{\text{BLTP}} := &g^{\alpha\rho}F_{\rho\mu}F^{\mu\gamma} + \frac{1}{4}g^{\alpha\gamma}F_{\rho\theta}F^{\rho\theta} - \kappa^{-2}(g^{\alpha\rho}F_{\rho\mu}\Box\,F^{\mu\gamma} + g^{\alpha\rho}F^{\gamma\mu}\Box\,F_{\mu\rho} \\ &+ g^{\alpha\rho}\partial_\mu F^{\mu\gamma}\partial^\beta F_{\rho\beta}) - \frac{1}{2}\kappa^{-2}(F_{\rho\theta}\Box\,F^{\rho\theta} + \partial_\rho F^{\rho\theta}\partial^\beta F_{\beta\theta})g^{\alpha\gamma} \end{aligned} \tag{14}$$

and it can be shown that

$$\varphi_{\mu\nu} \mapsto \int T^{\mu\nu}_{\text{BLTP}} \varphi_{\mu\nu} \; d^4x$$

defines a well-defined distribution. In [12], we prove the following Theorem:

**Theorem 4.1.** *Suppose* $\{q_n^\alpha(\tau_n)\}_{n=1}^N$ *are a collection of non-intersecting world-lines satisfying certain conditions and let the field associated to the n-th particle be defined by*

$$(F_n)_{\alpha\beta}(x^\alpha) = e_n\kappa^2 \left.\frac{R_{[\alpha}u_{\beta]}}{2u^\gamma R_\gamma}\right|_{ret} + e_n\kappa^2 \int_{-\infty}^{\tau_{ret}(x^\alpha)} \frac{J_2(\kappa D) R_{[\alpha}u_{\beta]}}{D^2} d\tau \tag{15}$$

*where* $e_n$ *is the charge of the n-th particle and the integral extends over the world-line* $q_n(\tau)$*. R is defined by* $R^\alpha(x^\beta, \tau) = x^\alpha - q^\alpha(\tau)$ *and* $D = (q_n^\gamma(\tau) - q_n^\gamma(\tau'))((q_n)_\gamma(\tau) - (q_n)_\gamma(\tau'))$*. Suppose that* (6) *holds. Then*

$$m_n \frac{du_n^\alpha}{d\tau_n} = e_n \left( \mathcal{F}_n^{\alpha\beta} + \sum_{m\neq n} F_m^{\alpha\beta} \right) u_\beta \tag{16}$$

*holds. Note in particular that the force on the n-th particle splits into a self-force* $\mathcal{F}^{\alpha\beta}u_\beta$ *and the Lorentz-force exerted by all other particles. The self-field* $\mathcal{F}^{\alpha\beta}$ *is given by the formula*

$$(\mathcal{F}_n)_{\alpha\beta}(\tau) = e_n\kappa^2 \int_{-\infty}^{\tau} \frac{J_2(\kappa D) R_{[\alpha}u_{\beta]}}{D^2} d\tau'. \tag{17}$$

More details can be found in [12]. The class of world-lines covered by the Theorem is extremely broad, comprising essentially arbitrary subluminal world-lines that are twice differentiable. Hence in the context of BLTP electrodynamics, the equations of motion rigorously follow from (6).

## Acknowledgments

The authors wish to thank M. Kiessling and A. S. Tahvildar-Zadeh for a great number of stimulating discussions and for inviting VH to participate in the session "The Einstein-Infeld-Hoffmann Legacy in Mathematical Relativity" at MG'15. VH acknowledges National Science Foundation support under grants DMS-1614797 and NSF DMS-1810687.

Einstein, Infeld, and Hoffmann (EIH) claimed that the field equations of general relativity theory alone imply the equations of motion of neutral matter particles, viewed as point singularities in space-like slices of spacetime; they also claimed that they had generalized their results to charged point singularities. While their analysis falls apart upon closer scrutiny, the key idea merits our attention. This rapport identifies necessary conditions for a well-defined general-relativistic joint initial value problem of $N$ classical point charges and their electromagnetic and gravitational fields. Among them, in particular, is the requirement that the electromagnetic vacuum law guarantees a finite field energy-momentum of a point charge. This disqualifies the Maxwell(–Lorentz) law used by EIH. On the positive side, if the electromagnetic vacuum law of Bopp, Landé–Thomas, and Podolsky (BLTP) is used, and the singularities equipped with a non-zero bare rest mass, then a joint initial value problem can be formulated in the spirit of the EIH proposal, and shown to be locally well-posed — *in the special-relativistic zero-G limit*. With gravitational coupling (i.e. $G > 0$), though, changing Maxwell's into the BLTP law and assigning a bare rest mass to the singularities is by itself not sufficient to obtain even a merely well-defined joint initial value problem: the gravitational coupling also needs to be changed, conceivably in the manner of Jordan and Brans–Dicke.

## 1. Brief History and State of Affairs

> "I am plaguing myself with the derivation of the equations of motion of material points, conceived of as singularities [in the gravitational field], from the equations of general relativity." **Albert Einstein**, in a letter to **Max Born** on Dec. 4, 1926.

We don't know when **Einstein** first conceived of the notion of point particles as singularities in relativistic fields,[a] but his letter to Max Born makes it plain that by the end of 1926 his ideas had matured to the point where he pursued a dynamical theory for such point singularities, expecting that their law of motion could be extracted from his gravitational field equations. Already a month later **Einstein** & **Grommer** announced that "the law of motion is completely determined by the field equations, though shown in this work only for the case of equilibrium." In that paper[7] the case of a static, spherically symmetric spacetime with a single time-like singularity was studied. The truly dynamical many-body problem was treated a decade later by **Einstein, Infeld**, and **Hoffmann** in their famous paper Ref. 8, with follow-ups in Refs. 9, 10. They argued explicitly that the field equations of general relativity theory alone determine the equations of motion of neutral matter

[a] In 1909 he remarked that "light quanta" might be point singularities in "a field," their motion being guided by the electromagnetic field. See part II of our rapport.

particles, viewed as point singularities in space-like slices of spacetime. They also claimed that they had generalized their results to charged point-singularities, with the details written up in a set of notes deposited with the secretary of the IAS. In 1941 the motion of charged point-singularities was revisited by Infeld's student **P. R. Wallace**, who presented the details of the calculations in Ref. 28.

Here is the gist of the **Einstein-Infeld-Hoffmann** argument (modern terminology):

- Suppose you have a four-dimensional, time-oriented, asymptotically flat electromagnetic **Lorentz** spacetime $\mathcal{M}^{1,3}$ with $N$ charged, time-like singularities of infinite extent, presentable as a graph over $\mathbb{R}^{1,3} \setminus \{N \text{ time-like world-lines}\}$.
- Away from the singularities the spacetime structure obeys **Einstein**'s equations

$$\mathbf{R} - \tfrac{1}{2}R\mathbf{g} = \tfrac{8\pi G}{c^4}\mathbf{T}[\mathbf{F}, \mathbf{g}], \tag{1}$$

  where $\mathbf{T}[\mathbf{F}, \mathbf{g}]$ is the energy-momentum-stress tensor of the electromagnetic vacuum field $\mathbf{F}$, satisfying **Maxwell**'s field equations in vacuum,

$$\boldsymbol{d}\mathbf{F} = \mathbf{0} \qquad \& \qquad \boldsymbol{d}{*}\mathbf{F} = \mathbf{0}. \tag{2}$$

- The twice contracted second **Bianchi** identity implies energy-momentum conservation:

$$\boldsymbol{\nabla}\cdot\left(\mathbf{R} - \tfrac{1}{2}R\mathbf{g}\right) = \mathbf{0} \implies \boldsymbol{\nabla}\cdot\mathbf{T}[\mathbf{F}, \mathbf{g}] = \mathbf{0}. \tag{3}$$

- "Massive, charged" singularities are associated with field "fluxes," and thus

$$\boxed{\boldsymbol{\nabla}\cdot\mathbf{T}[\mathbf{F}, \mathbf{g}] = \mathbf{0} \quad \& \quad \text{flux conditions}} \implies \text{law of the time-like singularities.} \tag{4}$$

The main bullet point is of course the last one. Here are **EIH** in their own words (p.66): "It is shown that for two-dimensional [closed] spatial surfaces containing singularities , certain surface integral conditions are valid which determine the motion ." [Emphasis ours.]

Unfortunately, despite its publication in the Annals of Mathematics, the 1938 **EIH** paper is not only not rigorous, it contains questionable technical assumptions and serious blunders. Some were addressed in Ref. 10, yet *their main conclusions turn out to be false*. All the same, the core idea merits a deeper inquiry.

The issue is how to correctly handle singularities. **EIH** state (p.66): "By means of a new method of approximation, specially suited to the treatment of quasi-stationary fields, the gravitational field due to moving particles is determined." This approximation method assumes that the particles are moving *slowly* and the field strengths (as seen in a **Lorentz** frame of **Minkowski** space, in which the particles move slowly) are *weak*. As a consequence, one has to choose the radii of the closed surfaces sufficiently large to satisfy the weak-field assumption needed for the

convergence of the expansion (which was not shown). Yet, on p. 92 one reads: "It is most convenient to take definite, infinitesimally small spheres whose centers are at the singularities, ..." which clearly violates their weak-field condition. Indeed, **EIH** realize that: "... in this case infinities of the types

$$\lim const./r^n, \qquad n \text{ a positive integer}, \qquad r \to 0 \tag{5}$$

can occur in the values of the partial integrals," but then commit a major blunder by stating (**EIH**, p. 92): "Since these must cancel, however, in the final result, we may merely ignore them throughout the calculation of the surface integrals."

*Alas, the infinities do not cancel!*

In the same year **P. A. M. Dirac** invented *negative infinite bare mass renormalization* to handle those infinities, in the simpler special-relativistic purely electrodynamical setting.[6] For an electron with positive "observable mass" $m_{\rm obs}$ and charge $-e$ he obtained the equation of motion (in **Misner**–**Thorne**–**Wheeler** notation)

$$m_{\rm obs}\tfrac{\mathrm{d}^2}{\mathrm{d}\tau^2}\mathbf{q} = \mathbf{f}^{\rm ext} + \mathbf{f}^{\rm LAUE}, \tag{6}$$

where

$$\mathbf{f}^{\rm ext} = -\tfrac{e}{c}\mathbf{F}^{\rm ext}(\mathbf{q}) \cdot \tfrac{\mathrm{d}}{\mathrm{d}\tau}\mathbf{q} \tag{7}$$

is a **Lorentz Minkowski**-force due to "external sources,"

$$\mathbf{f}^{\rm LAUE} = \tfrac{2e^2}{3c^3}\left(\mathbf{g} + \tfrac{1}{c^2}\tfrac{\mathrm{d}}{\mathrm{d}\tau}\mathbf{q} \otimes \tfrac{\mathrm{d}}{\mathrm{d}\tau}\mathbf{q}\right) \cdot \tfrac{\mathrm{d}^3}{\mathrm{d}\tau^3}\mathbf{q} \tag{8}$$

is **von Laue**'s radiation-reaction **Minkowski**-force of the electron, and

$$m_{\rm obs} = \lim_{r\downarrow 0}\left(m_{\rm b}(r) + \tfrac{e^2}{2c^2}\tfrac{1}{r}\right) \tag{9}$$

defines $m_{\rm b}(r)$. [N.B.: $m_{\rm b}(r) \downarrow -\infty$ as $r \downarrow 0$]. Here, $r$ is the radius of a sphere in the instantaneous rest-frame of the electron, centered at the electron, which plays the role of the surfaces containing singularities invoked by **EIH**.

As is well-known, such mass-renormalization computations have become the template for the much more elaborate — and quite successful — renormalization group computations in quantum electrodynamics (and more generally, quantum field theory). Be that as it may, **Dirac** himself later in life became very dissatisfied with this approach, and so are we.

First of all, supposing a point electron has a bare mass, then how could it possibly depend on the radius $r$ of a sphere over which a theoretical physicist averages the fields?

Second, the third proper time derivative featuring in the **von Laue Minkowski**-force means that (6) is a third-order ODE for the position of the particle as a function of proper time, requiring vector initial data for position, velocity, and acceleration. Yet a classical theory of point particle motion should only involve initial data for position and velocity.

In 1951 **Lev Landau** & **Eugenii Lifshitz** addressed the $\dddot{\mathbf{q}}$ problem as follows:

- Test particle theory works well for many practical purposes.
- In such situations **von Laue**'s $\ddot{\mathbf{q}}$ force term must be a small perturbation of $\mathbf{f}^{\text{ext}}$.
- Compute $\dddot{\mathbf{q}}$ perturbatively: take the proper time derivative of the test-particle law,

$$\tfrac{\mathrm{d}^3}{\mathrm{d}\tau^3}\mathbf{q} \approx -\tfrac{e}{m_{\text{obs}}c}\tfrac{\mathrm{d}}{\mathrm{d}\tau}\left(\mathbf{F}^{\text{ext}}(\mathbf{q})\cdot\tfrac{\mathrm{d}}{\mathrm{d}\tau}\mathbf{q}\right). \tag{10}$$

- The right-hand side depends only on $\mathbf{q}$, $\dot{\mathbf{q}}$, $\ddot{\mathbf{q}}$. Substitute it for $\frac{\mathrm{d}^3}{\mathrm{d}\tau^3}\mathbf{q}$ in (8).

R.h.s.(8) with r.h.s.(10) substituted for $\frac{\mathrm{d}^3}{\mathrm{d}\tau^3}\mathbf{q}$ will be called the **Landau–Lifshitz Minkowski**-force of radiation-reaction, denoted $\mathbf{f}^{\text{LL}}$. Equation (6) with $\mathbf{f}^{\text{Laue}}$ replaced by $\mathbf{f}^{\text{LL}}$ is known as the **Landau–Lifshitz** equation of motion for the electron. It seems to work quite well for practical purposes in which $\mathbf{F}^{\text{ext}}$ can be approximated by some smooth field tensor, on time scales beyond the one where test particle theory works well, but not arbitrarily far beyond.[25] However[4], as soon as $\mathbf{F}^{\text{ext}}$ is taken to be the field generated by all other particles the **Landau–Lifschitz** equation of motion is typically well-posed only until the moment that a point charge meets the forward initial light cone of another point charge, a ludicrously short time span!

**Dirac**'s idea of infinite negative bare mass renormalization and **Landau–Lifshitz**'s perturbative treatment of the **von Laue** radiation-reaction **Minkowski**-force have become standard ingredients also in general-relativistic treatments of charged point particle motion. Thus, for a point electron moving in a given curved background, **Eric Poisson, Adam Pound**, & **Ian Vega** in their review Ref. 23 present the following equations of motion:

$$m_{\text{obs}}\tfrac{\mathrm{D}}{\mathrm{d}\tau}\mathbf{u} = \mathbf{f}^{\text{ext}} + \mathbf{f}^{\text{Laue}} + \mathbf{f}^{\text{tail}}, \tag{11}$$

where $\mathbf{u} := \frac{\mathrm{d}}{\mathrm{d}\tau}\mathbf{q}$ and $\frac{\mathrm{D}}{\mathrm{d}\tau}\mathbf{u} := \frac{\mathrm{d}}{\mathrm{d}\tau}\mathbf{u} + \mathbf{\Gamma}^{\text{ext}}(\mathbf{u},\mathbf{u})$, and $\mathbf{f}^{\text{ext}} = -\frac{e}{c}\mathbf{F}^{\text{ext}}(\mathbf{q})\cdot\mathbf{u}$ as before, but now

$$\mathbf{f}^{\text{Laue}} = \tfrac{2}{3}e^2\left(\mathbf{g} + \tfrac{1}{c^2}\mathbf{u}\otimes\mathbf{u}\right)\cdot\left(\tfrac{1}{6}\mathbf{R}^{\text{ext}}\cdot\tfrac{1}{c}\mathbf{u} + \tfrac{1}{c^3}\tfrac{\mathrm{D}^2}{\mathrm{d}\tau^2}\mathbf{u}\right) \tag{12}$$

with

$$\tfrac{\mathrm{D}^2}{\mathrm{d}\tau^2}\mathbf{u} \approx -\tfrac{e}{m_{\text{obs}}c}\tfrac{\mathrm{D}}{\mathrm{d}\tau}\left(\mathbf{F}^{\text{ext}}(\mathbf{q})\cdot\mathbf{u}\right), \tag{13}$$

and

$$\mathbf{f}^{\text{tail}} = 2e^2\int_{-\infty}^{\tau}\boldsymbol{H}^{\text{ret}}(\mathbf{q}(\tau),\mathbf{q}(\tau'))\cdot\mathbf{u}(\tau')\mathrm{d}\tau'\cdot\mathbf{u}(\tau), \tag{14}$$

where $\boldsymbol{H}^{\text{ret}}(\mathbf{q}(\tau),\mathbf{q}(\tau'))$ is a retarded type of Green function for the electromagnetic field tensor in curved spacetime. Equation (11) does not yet include gravitational radiation-reaction, which **Poisson, Pound**, & **Vega** discuss also, in particular the approaches of **Quinn** & **Wald** and **Detweiler** & **Whiting** (see Ref. 23), but we don't need to go there because (11) already displays a major problem due to the so-called tail force term:

*Equation (11), even with r.h.s.(13) substituted for* $\frac{\mathrm{D}^2}{\mathrm{d}\tau^2}\mathbf{u}$ *at r.h.s.(12), does not pose a second-order initial value problem for the position of the point electron but instead requires the input of the entire past history of the motion!*

One can try to extricate oneself from this dilemma by once again having recourse to a **Landau**–**Lifshitz**-type perturbation argument: the tail force, also a radiation-reaction term, must be small in situations where test particle theory works well. In this case, backward from the initial instant (say at $\tau = 0$) one can approximately replace $\mathbf{q}(\tau')$ and $\mathbf{u}(\tau')$ in the integrand by the pertinent expressions computed from test particle theory, with particle data for position and velocity given, and then treat this so-modified equation as a second-order integro-differential equation from the initial instant on forward, with $\mathbf{q}(\tau')$ and $\mathbf{u}(\tau')$ in the integrand for $\tau' > 0$ no longer test-particle expressions. This set of "effective equations of motion" may work well in many practical situations.

Yet from a mathematical relativity point of view this state of affairs is very unsatisfactory, both technically (being non-rigorous) and conceptually (involving heuristic but arbitrary arguments).

## 2. Rigorous Approach

In the following we report on recent rigorous advances in formulating a joint initial value problem for classical charged point particles and the electromagnetic and gravitational fields they generate, with the key idea of the 1938 **EIH** paper, as outlined on p.1 of this rapport, serving as our point of departure. To avoid the mistakes made by **EIH**, we inquire into necessary conditions on the energy-momentum-stress tensor which allow one to extract a law of motion associated with the time-like singularities from an equation like (4) without invoking infinite mass renormalization, nor arbitrary averaging over some neighborhood of an a-priori ill-defined force field, as done in Ref. 23. For the simpler special-relativistic zero-gravity limit (cf. Ref. 16, 17) we even state a well-posedness theorem, so this case is treated first.

### 2.1. *The zero-G Limit*

#### 2.1.1. *Time-like particle world-lines in Minkowski spacetime*

In the limit $G \downarrow 0$, (1) is solved by $\mathcal{M}^{1,3} = \mathbb{R}^{1,3} \setminus \{N \text{ time-like world-lines}\}$, with metric $\mathbf{g} = \boldsymbol{\eta}$ away from the world-lines. The question is which conditions on $\mathsf{T}$ lead, in a mathematically clean way, to the **EIH**-type conclusion

$$\boxed{\boldsymbol{\nabla}\cdot\mathsf{T}[\mathsf{F},\boldsymbol{\eta}] = \mathbf{0} \quad \& \quad \text{flux conditions}} \implies \text{law of the time-like world-lines.} \qquad (1)$$

To answer this question, we extend $\mathcal{M}^{1,3}$ continuously to $\mathbb{R}^{1,3}$ (by adding the time-like world-lines), and switch to a distributional formulation. We can formulate everything for $N$ charged, massive, time-like world-lines, but for simplicity we set $N = 1$ in the following.

Since the issue is the formulation of a well-posed initial value problem, we also choose an arbitrary Lorentz frame, with space vector $\boldsymbol{s} \in \mathbb{R}^3$ and time $t \in \mathbb{R}$. Then the space part of l.h.s.(1) becomes the *local conservation law for the total momentum*,

$$\tfrac{\partial}{\partial t}\boldsymbol{\Pi}(t,\boldsymbol{s}) + \nabla \cdot T(t,\boldsymbol{s}) = \boldsymbol{0}, \tag{2}$$

where it is *postulated* (equivalent to "minimal coupling") that

$$\boldsymbol{\Pi}(t,\boldsymbol{s}) := \boldsymbol{\Pi}^{\text{field}}(t,\boldsymbol{s}) + \boldsymbol{\Pi}^{\text{charge}}(t,\boldsymbol{s}) \tag{3}$$

is the total momentum vector-density, with $\boldsymbol{\Pi}^{\text{field}}(t,\boldsymbol{s})$ the contribution from the field and $\boldsymbol{\Pi}^{\text{charge}}(t,\boldsymbol{s})$ (a distribution) the usual contribution from the point charge, which must be assigned a non-vanishing bare rest mass $m_{\text{b}}$. Similarly, it is *postulated* that

$$T(t,\boldsymbol{s}) := T^{\text{field}}(t,\boldsymbol{s}) + T^{\text{charge}}(t,\boldsymbol{s}) \tag{4}$$

is the symmetric total stress tensor, with $T^{\text{charge}}(t,\boldsymbol{s})$ the usual stress tensor of the point particle, and $T^{\text{field}}(t,\boldsymbol{s})$ that of the field (except for our unconventional choice of sign!)

Incidentally, energy conservation follows as a corollary from momentum conservation.

Next, we integrate (2) over all $\boldsymbol{s} \in \mathbb{R}^3$, at $t \in \mathbb{R}$. This yields total momentum conservation

$$\tfrac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{p}(t) = -\tfrac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^3} \boldsymbol{\Pi}^{\text{field}}(t,\boldsymbol{s})d^3s. \tag{5}$$

Clearly, for (5) to make sense, the field momentum vector-density $\boldsymbol{\Pi}^{\text{field}}(t,\boldsymbol{s})$ has to be integrable over $\mathbb{R}^3$, and this integral differentiable in time. This rules out the **Maxwell**–**Lorentz** field equations, but leaves other options, notably the **M**$_{\text{axwell}}$–**B**$_{\text{orn}}$–**I**$_{\text{nfeld}}$ (**MBI**) and **M**$_{\text{axwell}}$–**B**$_{\text{opp}}$–**L**$_{\text{andé}}$–**T**$_{\text{homas}}$–**P**$_{\text{odolsky}}$ (**MBLTP**) field equations (see below).

Comparing equation (5) with **Newton**'s law for the rate of change of momentum,

$$\tfrac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{p}(t) = \boldsymbol{f}(t), \tag{6}$$

where $\boldsymbol{f}(t)$ is the force acting on the particle at time $t$, it is clear that the force $\boldsymbol{f}(t)$ needs to be extracted from r.h.s.(5). Since the particle's bare momentum $\boldsymbol{p}(t)$ is given in terms of its bare mass $m_{\text{b}}$ and velocity $\boldsymbol{v}(t) = \frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{q}(t)$ by the **Einstein-Lorentz-Poincaré** law

$$\boldsymbol{p}(t) := m_{\text{b}}\frac{\boldsymbol{v}(t)}{\sqrt{1-\frac{1}{c^2}|\boldsymbol{v}(t)|^2}}, \tag{7}$$

the expression for the force also has to be compatible with the requirements of a second-order initial value problem for the position of the point particle! Thus, beside the existence of the time-derivative of the space integral over the field momentum vector-density, it is important that the result involves, initially, only the initial

electromagnetic fields and the initial data for position and velocity of the point particle and, at later times $t > 0$, at most the history of position, velocity, and acceleration of the particle, and of the fields, from the initial instant on, yet not beyond $t$. Whenever this is possible we obtain a well-defined joint initial value problem for field and particle, which may or may not be well-posed.

We were able to explicitly extract a well-defined force on the point charge from the **MBLTP** field equations, and to prove that the resulting joint initial value problem for charge and field is well-posed. We expect this to be feasible also for the **MBI** field equations, but their formidable nonlinearity makes rigorous progress a slow process.

Common to all these classical systems of electromagnetic field equations are the *pre-metric* ***Maxwell–Lorentz*** *field equations*, viz. the evolution equations

$$\partial_t \mathbf{B}(t,\boldsymbol{s}) = -c\boldsymbol{\nabla} \times \mathbf{E}(t,\boldsymbol{s}) \tag{8}$$

$$\partial_t \mathbf{D}(t,\boldsymbol{s}) = +c\boldsymbol{\nabla} \times \mathbf{H}(t,\boldsymbol{s}) + 4\pi e\dot{\boldsymbol{q}}(t)\delta_{\boldsymbol{q}(t)}(s) \tag{9}$$

and the constraint equations

$$\boldsymbol{\nabla} \cdot \mathbf{B}(t,\boldsymbol{s}) = 0 \tag{10}$$

$$\boldsymbol{\nabla} \cdot \mathbf{D}(t,\boldsymbol{s}) = -4\pi e\delta_{\boldsymbol{q}(t)}(s) \tag{11}$$

for the **B**, **D** fields. They differ in the *Electromagnetic Vacuum Law*: $(\mathbf{B},\mathbf{D}) \leftrightarrow (\mathbf{H},\mathbf{E})$. The **Born-Infeld** law[2] reads

$$\mathbf{H} = \frac{\mathbf{B} - \frac{1}{b^2}\mathbf{D}\times(\mathbf{D}\times\mathbf{B})}{\sqrt{1+\frac{1}{b^2}(|\mathbf{B}|^2+|\mathbf{D}|^2)+\frac{1}{b^4}|\mathbf{B}\times\mathbf{D}|^2}} \tag{12}$$

$$\mathbf{E} = \frac{\mathbf{D} - \frac{1}{b^2}\mathbf{B}\times(\mathbf{B}\times\mathbf{D})}{\sqrt{1+\frac{1}{b^2}(|\mathbf{B}|^2+|\mathbf{D}|^2)+\frac{1}{b^4}|\mathbf{B}\times\mathbf{D}|^2}} \tag{13}$$

The **Bopp–Landé–Thomas–Podolsky** law[1,19,20,22] reads

$$\mathbf{H}(t,\boldsymbol{s}) = \left(1+\varkappa^{-2}\Box\right)\mathbf{B}(t,\boldsymbol{s}) \tag{14}$$

$$\mathbf{D}(t,\boldsymbol{s}) = \left(1+\varkappa^{-2}\Box\right)\mathbf{E}(t,\boldsymbol{s})\,. \tag{15}$$

(N.B.: $\Box := c^{-2}\partial_t^2 - \Delta$.) When $b \to \infty$, respectively when $\varkappa \to \infty$, both these vacuum laws reduce to the **Maxwell-Lorentz** law $\mathbf{H} = \mathbf{B} \quad \& \quad \mathbf{E} = \mathbf{D}$.

For given particle motions with subluminal velocity $|\dot{\boldsymbol{q}}(t)| < c$, the field **Cauchy** problems are globally well-posed in the sense of distributions for both the **ML** and **MBLTP** field equations. The **MBI** field Cauchy problem, unfortunately, has not yet been conquered to the extent needed. Global well-posedness of the classical initial value problem has only been shown with small data (no charges!) in Ref. 24; **F. Pasqualotto** presented an extension of **Speck**'s result to **MBI** field evolutions on the **Schwarzschild** background.[21] A local well-posedness result for **MBI** field evolutions with subluminal point sources (and inevitably large data) should be possible, but so far only the special case of electrostatic solutions with $N$ point

charge sources has been conquered in Ref. 15. There it was shown that a unique finite-energy electrostatic weak solution of the **MBI** field equations with $N$ point charges placed anywhere in $\mathbb{R}^3$ exists, and that the solution is real analytic away from the point charges for any choices of their signs and magnitudes.

For the field momentum densities $\mathbf{\Pi}$ (dropping the superscript "field") one has the following expressions. For the **ML** and for **MBI** field equations,

$$4\pi c\mathbf{\Pi} = \mathbf{D} \times \mathbf{B}, \tag{16}$$

whereas for the **MBLTP** field equations,

$$4\pi c\mathbf{\Pi} = \mathbf{D} \times \mathbf{B} + \mathbf{E} \times \mathbf{H} - \mathbf{E} \times \mathbf{B} - \varkappa^{-2}\big(\nabla \cdot \mathbf{E}\big)\big(\nabla \times \mathbf{B} - \varkappa \dot{\mathbf{E}}\big). \tag{17}$$

For **MBLTP** field evolutions with point sources we showed that $\mathbf{\Pi}(t, \boldsymbol{s})$ is in $L^1_{loc}(\mathbb{R}^3)$ about each $\boldsymbol{q}(t)$, see Ref. 17. We expect such a result also for **MBI** fields. It is surely false for **ML** fields!

With appropriate decay rates at spatial infinity imposed on the field initial data, the **MBLTP** field momentum $\int_{\mathbb{R}^3} \mathbf{\Pi}(t, \boldsymbol{s})\mathrm{d}^3 s$ exists for all $t$. Moreover, given **Lipschitz** maps $t \mapsto \boldsymbol{q}(t)$, $t \mapsto \boldsymbol{v}(t)$ and bounded $t \mapsto \boldsymbol{a}(t)$, we showed that $\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^3} \mathbf{\Pi}(t, \boldsymbol{s})\mathrm{d}^3 s$ exists for all $t$.

The crucial step in showing that (5), with (7), yields an equation of motion is now the following. The fields $\mathbf{B}, \mathbf{D}, \mathbf{E}, \dot{\mathbf{E}}$ (and $\mathbf{H}$) at $(t, \boldsymbol{s})$ are given by explicit functionals of the vector functions $\boldsymbol{q}(\cdot)$ and $\boldsymbol{v}(\cdot)$, and $\mathbf{D}$ & $\mathbf{H}$ also involve $\mathbf{a}(\cdot)$; their dependence on $\mathbf{a}(\cdot)$ is linear. For $t < 0$ we set $\boldsymbol{q}(t) = \boldsymbol{q}(0) + \boldsymbol{v}(0)t$ and $\boldsymbol{v}(t) = \boldsymbol{v}(0)$, and $\boldsymbol{a}(t) = \mathbf{0}$. Treating $\boldsymbol{q}(\cdot)$ and $\boldsymbol{v}(\cdot)$ as given, and $\mathbf{a}(\cdot)$ as independent vector function variable for $t > 0$, (5) together with (7) is equivalent to a **Volterra** integral equation for $\mathbf{a} = \mathbf{a}[\boldsymbol{q}, \boldsymbol{p}]$, viz.

$$\mathbf{a} = W[\boldsymbol{p}] \cdot \Big(\boldsymbol{f}^{\mathrm{vac}}[\boldsymbol{q}, \boldsymbol{v}] + \boldsymbol{f}^{\mathrm{source}}[\boldsymbol{q}, \boldsymbol{v}; \mathbf{a}]\Big) \tag{18}$$

where

$$\boldsymbol{v} = \frac{1}{m_{\mathrm{b}}} \frac{\boldsymbol{p}}{\sqrt{1 + \frac{|\boldsymbol{p}|^2}{m_{\mathrm{b}}^2 c^2}}}; \quad m_{\mathrm{b}} \neq 0 \tag{19}$$

and

$$W[\boldsymbol{p}] := \mathrm{sgn}(m_{\mathrm{b}}) \frac{c}{\sqrt{m_{\mathrm{b}}^2 c^2 + |\boldsymbol{p}|^2}} \left[\boldsymbol{I}_{3\times 3} - \frac{\boldsymbol{p} \otimes \boldsymbol{p}}{m_{\mathrm{b}}^2 c^2 + |\boldsymbol{p}|^2}\right], \tag{20}$$

and where we have written the field as a sum of a source-free (vacuum) field and a field having the point charge as source, resulting in a **Lorentz** force due to that vacuum field,

$$\boldsymbol{f}^{\mathrm{vac}}[\boldsymbol{q}, \boldsymbol{v}](t) \equiv -e\left[\mathbf{E}^{\mathrm{vac}}(t, \boldsymbol{q}(t)) + \tfrac{1}{c}\boldsymbol{v}(t) \times \mathbf{B}^{\mathrm{vac}}(t, \boldsymbol{q}(t))\right], \tag{21}$$

and a "self"-type force $\boldsymbol{f}^{\text{source}}[\boldsymbol{q},\boldsymbol{v};\mathbf{a}]$, in ***BLTP*** *electrodynamics*[b] given by

$$\boldsymbol{f}^{\text{source}}[\boldsymbol{q},\boldsymbol{v};\mathbf{a}](t) = -\frac{\mathrm{d}}{\mathrm{d}t}\int_{\mathbb{R}^3}\boldsymbol{\Pi}^{\text{source}}(t,\boldsymbol{s})d^3s \tag{22}$$

$$= -\frac{\mathrm{d}}{\mathrm{d}t}\int_{B_{ct}(\boldsymbol{q}_0)}\left(\boldsymbol{\Pi}^{\text{source}}(t,\boldsymbol{s}) - \boldsymbol{\Pi}^{\text{source}}(0,\boldsymbol{s}-\boldsymbol{q}_0-\boldsymbol{v}_0t)\right)d^3s \tag{23}$$

$$= \tfrac{e^2}{4\pi}\Big[ - \mathbf{Z}^{[2]}_{\boldsymbol{\xi}}(t,t) + \mathbf{Z}^{[2]}_{\boldsymbol{\xi}^\circ}(t,t) \tag{24}$$

$$- \sum_{0\leqslant k\leqslant 1} c^{2-k}(2-k)\int_0^t\Big[\mathbf{Z}^{[k]}_{\boldsymbol{\xi}}\big(t,t^{\mathrm{r}}\big) - \mathbf{Z}^{[k]}_{\boldsymbol{\xi}^\circ}\big(t,t^{\mathrm{r}}\big)\Big](t-t^{\mathrm{r}})^{1-k}\mathrm{d}t^{\mathrm{r}} \tag{25}$$

$$- \sum_{0\leqslant k\leqslant 2} c^{2-k}\int_0^t\Big[\tfrac{\partial}{\partial t}\mathbf{Z}^{[k]}_{\boldsymbol{\xi}}\big(t,t^{\mathrm{r}}\big) - \tfrac{\partial}{\partial t}\mathbf{Z}^{[k]}_{\boldsymbol{\xi}^\circ}\big(t,t^{\mathrm{r}}\big)\Big](t-t^{\mathrm{r}})^{2-k}\mathrm{d}t^{\mathrm{r}}\Big] \tag{26}$$

where $\boldsymbol{\xi}(t) \equiv (\boldsymbol{q},\boldsymbol{v},\mathbf{a})(t)$, and $\boldsymbol{\xi}^\circ(t) \equiv (\boldsymbol{q}_0+\boldsymbol{v}_0t, \boldsymbol{v}_0, \mathbf{0})$, and where

$$\mathbf{Z}^{[k]}_{\boldsymbol{\xi}}\big(t,t^{\mathrm{r}}\big) = \int_0^{2\pi}\int_0^{\pi}\big(1-\tfrac{1}{c}\big|\boldsymbol{v}(t^{\mathrm{r}})\big|\cos\vartheta\big)\,\boldsymbol{\pi}^{[k]}_{\boldsymbol{\xi}}\big(t,\boldsymbol{q}(t^{\mathrm{r}})+c(t-t^{\mathrm{r}})\boldsymbol{n}\big)\sin\vartheta\mathrm{d}\vartheta\mathrm{d}\varphi\,, \tag{27}$$

with $\boldsymbol{n} = (\sin\vartheta\cos\varphi\ ,\ \sin\vartheta\sin\varphi\ ,\ \cos\vartheta)$, and where, with the kernels

$$\mathrm{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s}) := \tfrac{J_1\left(\varkappa\sqrt{c^2(t-t')^2-|\boldsymbol{s}-\boldsymbol{q}(t')|^2}\right)}{\sqrt{c^2(t-t')^2-|\boldsymbol{s}-\boldsymbol{q}(t')|^2}}, \tag{28}$$

$$\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s}) := \tfrac{J_2\left(\varkappa\sqrt{c^2(t-t')^2-|\boldsymbol{s}-\boldsymbol{q}(t')|^2}\right)}{c^2(t-t')^2-|\boldsymbol{s}-\boldsymbol{q}(t')|^2}\left(\boldsymbol{s}-\boldsymbol{q}(t')-\boldsymbol{v}(t')(t-t')\right), \tag{29}$$

we have

$$\boldsymbol{\pi}^{[0]}_{\boldsymbol{\xi}}(t,\boldsymbol{s}) = -\varkappa^4\frac{1}{4}\left[\frac{\left(\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})-\frac{1}{c}\boldsymbol{v}\right)\times\left(\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\times\frac{1}{c}\boldsymbol{v}\right)}{\left(1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\right)^2}\right]_{\text{ret}} \tag{30}$$

$$+\varkappa^4\frac{1}{2}\left[\frac{\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})-\frac{1}{c}\boldsymbol{v}}{1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})}\right]_{\text{ret}}\times\int_{-\infty}^{t^{\text{ret}}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}\boldsymbol{v}(t')\times\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t' \tag{31}$$

$$-\varkappa^4\frac{1}{2}\left[\frac{\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\times\frac{1}{c}\boldsymbol{v}}{1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})}\right]_{\text{ret}}\times\int_{-\infty}^{t^{\text{ret}}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}c\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t' \tag{32}$$

$$-\varkappa^4\int_{-\infty}^{t^{\text{ret}}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}c\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t'\times\int_{-\infty}^{t^{\text{ret}}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}\boldsymbol{v}(t')\times\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t' \tag{33}$$

$$-\varkappa^4c\int_{-\infty}^{t^{\text{ret}}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}\mathrm{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t'\int_{-\infty}^{t^{\text{ret}}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}\mathrm{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\boldsymbol{v}(t')\mathrm{d}t', \tag{34}$$

[b]None of the four original contributors formulated a well-defined expression for the force, yet we believe that our formulation accomplishes what they had intended; hence the name of the theory.

$$\boldsymbol{\pi}^{[1]}_{\boldsymbol{\xi}}(t,\boldsymbol{s}) = -\varkappa^2\frac{1}{2}\left[\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\times\frac{\left(\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})-\frac{1}{c}\boldsymbol{v}\right)\times\boldsymbol{a}}{c^2\left(1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\right)^3}\right]_{\rm ret} \tag{35}$$

$$-\varkappa^2\left[\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\times\frac{\left(\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})-\frac{1}{c}\boldsymbol{v}\right)\times\boldsymbol{a}}{c^2\left(1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\right)^3}\right]_{\rm ret}\times\int_{-\infty}^{t^{\rm ret}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}\boldsymbol{v}(t')\times\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t' \tag{36}$$

$$+\varkappa^2\left[\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\times\left[\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\times\frac{\left(\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})-\frac{1}{c}\boldsymbol{v}\right)\times\boldsymbol{a}}{c^2\left(1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\right)^3}\right]\right]_{\rm ret}\times\int_{-\infty}^{t^{\rm ret}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}c\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t' \tag{37}$$

$$-\varkappa^3\left[\frac{1}{1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})}\right]_{\rm ret}\int_{-\infty}^{t^{\rm ret}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}\mathrm{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\left[\boldsymbol{v}(t^{\rm ret}_{\boldsymbol{\xi}}(t,\boldsymbol{s}))+\boldsymbol{v}(t')\right]\mathrm{d}t', \tag{38}$$

$$\boldsymbol{\pi}^{[2]}_{\boldsymbol{\xi}}(t,s) = -\varkappa^2\left[\frac{1}{\left(1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\right)^2}\frac{1}{c}\boldsymbol{v}\right]_{\rm ret} \tag{39}$$

$$+\varkappa^2\left[\left[1-\tfrac{1}{c^2}\left|\boldsymbol{v}\right|^2\right]\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\times\frac{\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})-\frac{1}{c}\boldsymbol{v}}{\left(1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\right)^3}\right]_{\rm ret}\times\int_{-\infty}^{t^{\rm ret}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}c\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t' \tag{40}$$

$$-\varkappa^2\left[\left[1-\tfrac{1}{c^2}\left|\boldsymbol{v}\right|^2\right]\frac{\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})-\frac{1}{c}\boldsymbol{v}}{\left(1-\frac{1}{c}\boldsymbol{v}\cdot\boldsymbol{n}(\boldsymbol{q},\boldsymbol{s})\right)^3}\right]_{\rm ret}\times\int_{-\infty}^{t^{\rm ret}_{\boldsymbol{\xi}}(t,\boldsymbol{s})}\boldsymbol{v}(t')\times\mathbf{K}_{\boldsymbol{\xi}}(t',t,\boldsymbol{s})\mathrm{d}t', \tag{41}$$

and $\big|_{\rm ret}$ means that $\boldsymbol{q}(\tilde{t})$, $\boldsymbol{v}(\tilde{t})$, $\boldsymbol{a}(\tilde{t})$ are evaluated at $\tilde{t}=t^{\rm ret}_{\boldsymbol{\xi}}(t,\boldsymbol{s})$.

**Remark 2.1.** The decomposition of the electromagnetic fields into a sum of two types of fields, one with the point charge as source, the other source-free, is to some extent arbitrary. For this reason it is futile to try to identify *the self-field force* of a point charge. At best one can speak of a "self"-field force, the scare quotes referring to the ambiguity in identifying how much of the field is "self"-generated by the charge and how much is not.

The following *key proposition* about the Volterra equation is proved in Ref. 17. Its proof takes several dozen pages of careful estimates.

**Proposition 2.2.** *Given $C^{0,1}$ maps $t\mapsto\boldsymbol{q}(t)$ and $t\mapsto\boldsymbol{p}(t)$, with Lip$(\boldsymbol{q})=v$, Lip$(\boldsymbol{v})=$ a big enough, and $|\boldsymbol{v}(t)|\leqslant v<c$, the Volterra equation (18) as a fixed point map has a unique $C^0$ solution $t\mapsto\mathbf{a}(t)=\boldsymbol{\alpha}[\boldsymbol{q}(\,\cdot\,),\boldsymbol{p}(\,\cdot\,)](t)$ for $t\geqslant 0$. Moreover, the solution depends **Lipschitz** continuously on the maps $t\mapsto\boldsymbol{q}(t)$ and $t\mapsto\boldsymbol{p}(t)$ (treated as independent).*

The well-posedness result of the joint initial value problem for **MBLTP** fields and their point charge sources is a corollary of Proposition 2.2. Namely, now setting $\boldsymbol{a}(t):=\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{v}(t)$ and $\boldsymbol{v}(t):=\frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{q}(t)$, and recalling (7), the solution to the **Volterra** integral equation for the acceleration poses a **Newton**-type second-order initial value problem for the position of the point charge with a complicated yet **Lipschitz**-continuous force. Once the motion is computed, inserting the vector functions $\boldsymbol{q}(\cdot)$,

$\boldsymbol{v}(\cdot)$, and $\mathbf{a}(\cdot)$ of the solution into the functionals of the fields yields $\mathbf{B}, \mathbf{D}, \mathbf{E}, \dot{\mathbf{E}}$ at $(t, \boldsymbol{s})$ for $t > 0$, too. This is a Theorem in Ref. 17, summarized informally as follows.

**Theorem 2.3.** *As a consequence of Proposition 2.2, the joint initial value problem for **MBLTP** fields and their point charge source is equivalent to the fixed point equations*

$$\boldsymbol{q}(t) = \boldsymbol{q}(0) + \frac{1}{m_b}\int_0^t \frac{\boldsymbol{p}}{\sqrt{1+|\boldsymbol{p}|^2/m_b^2}}(\tilde{t})d\tilde{t} =: Q_t(\boldsymbol{q}(\cdot), \boldsymbol{p}(\cdot)) \tag{42}$$

$$\boldsymbol{p}(t) = \boldsymbol{p}(0) - \int_{\mathbb{R}^3} (\boldsymbol{\Pi}(t, \boldsymbol{s}) - \boldsymbol{\Pi}(0, \boldsymbol{s}))\, d^3s =: P_t(\boldsymbol{q}(\cdot), \boldsymbol{p}(\cdot)), \tag{43}$$

*where $Q_t$ and $P_t$ are **Lipschitz** maps. Thus, **BLTP** electrodynamics is locally well-posed.*

In fact, in Ref. 17 the **Cauchy** problem for the **MBLTP** field with $N$ point charges is treated. *Local well-posedness* is proved for *admissible initial data* (see below) & $m_\mathrm{b} \neq 0$, and *global well-posedness* shown to hold if in finite time: (a) no particle reaches the speed of light; (b) no particle is infinitely accelerated; (c) no two particles reach the same location.
By "admissible" initial data we mean the following: the initial particle velocities are subluminal ($|\boldsymbol{v}(0)| < c$) and no two particles occupy the same location; the electromagnetic initial fields are the sum of a spatially sufficiently rapidly decaying vacuum field plus $N$ fields each with a single point charge source — the sourced fields are boosted electrostatic fields with boost velocity equal to the initial velocity of the source.

Although our result seems to be the first formulation of a well-posed joint initial value problem for classical electromagnetic fields and their point charge sources, and this endows **BLTP** electrodynamics with a mathematically superior status compared to the ill-defined **Lorentz** electrodynamics, we do not claim that **BLTP** electrodynamics is the correct classical limit of the illusive mathematically well-formulated quantum theory of electromagnetism. In particular, the **MBLTP** field equations feature "physical" oddities: (a) a field energy functional which is unbounded below; (b) subluminal transversal electromagnetic wave modes; (c) longitudinal electrical wave modes.
Moreover, since the **MBLTP** field equations demand initial data for $\mathbf{B}, \mathbf{D}, \mathbf{E}, \dot{\mathbf{E}}$ at $t = 0$ while physically we only can prescribe $\mathbf{B}$, $\mathbf{D}$ (N.B.: in **Lorentz** electrodynamics, $\mathbf{D} = \mathbf{E}$; not so in **BLTP** electrodynamics), one needs to find a prescription which expresses $\mathbf{E}, \dot{\mathbf{E}}$ at $t = 0$ in terms of $\mathbf{B}, \mathbf{D}$ at $t = 0$. In Ref. 17 we show that a reasonable choice is the map $(\mathbf{B}, \mathbf{D})_0 \mapsto (\mathbf{E}, \dot{\mathbf{E}})_0$ obtained by *maximizing the field energy* w.r.t. $\mathbf{E}_0$ and $\dot{\mathbf{E}}_0$ (treated independently). This can be made co-variant by stipulating that the maximization is carried out in the **Lorentz** frame in which total momentum vanishes initially.

Back to the mathematically superior status of **BLTP** electrodynamics, one can now apply rigorous analysis, and controlled numerical techniques, to study

the theory. For instance, a rigorous comparison of our expression (22) for the "self"-force with a differently defined "self"-field force which was studied in Ref. 12 was carried out recently by Hoang & Radosz and their students, see Ref. 5, 13. One of our next projects is to rigorously extract effective equations of motion with more user-friendly expressions for the "self"-force. In particular, whether or to which extent the **Landau–Lifshitz** equation approximately governs the motion is an interesting question.

### 2.1.2. *Topologically non-trivial flat spacetimes with time-like singularities*

The *zero-gravity limit* of singular spacetimes does not automatically yield **Minkowski** spacetime minus a number of world-lines. In Ref. 27 the zero-$G$ limit of **Carter**'s maximal analytical extension of the electromagnetic **Kerr–Newmann** spacetime was analyzed. The limiting spacetime is axially symmetric and static. It is locally isometric to **Minkowski** spacetime, but is topologically non-trivial, featuring **Zipoy** topology. Its constant-time slices are double-sheeted, and have the topology of $\mathbb{R}^3$ branched over the un-knot. The spacetime is singular on a 2-dimensional time-like cylinder $\mathbb{S}^1 \times \mathbb{R}$, which is the world-tube of a space-like ring-type singularity. The most intriguing aspect of this solution is that at any instant of time the ring singularity, when viewed from one of the two sheets of space, appears to be positively charged, and from the other sheet, negatively charged, as already noticed by **Carter**. The electromagnetic fields it supports where discovered in the 19th century by **P. Appell** as "multi-valued electromagnetic fields," while **A. Sommerfeld** soon realized that they represent single-valued electromagnetic fields on a topologically non-trivial multi-sheeted space.

A natural next step would be to formulate the corresponding zero-gravity two-body problem for two space-like ring-type singularities of z$G$**KN**-type, evolving in time jointly with the electromagnetic fields they generate. We know for example that the space should be four-sheeted (in general, $2^N$ sheets are needed for $N$ ring-type singularities). However, as the z$G$**KN** fields solve the **Maxwell–Lorentz** vacuum field equations away from the singularities, it is not surprising that one again encounters the infinite field energy-momentum problems which plague **Lorentz** electrodynamics. Thus one would first need to find either **MBI** or **MBLTP** analogues of the **Appell–Sommerfeld** fields. The nonlinearity of the **MBI** field equations makes this a daunting task, but we are confident that the feat can be accomplished with the **MBLTP** field equations. In that case the zero-$G$ **EIH**-type approach explained in the previous subsection should allow the formulation of a well-posed initial value problem for ring-type singularities and their electromagnetic **MBLTP** fields. Note that the law of motion would most likely be a system of partial differential equations, as the ring-type singularity has to be allowed to bend, twist, warp, stretch, and such.

### 2.2. *Turning on gravity: $G > 0$*

#### 2.2.1. *The neighborhood of Minkowski spacetime*

By rigorously establishing well-posedness of **BLTP** electrodynamics with point charges as a consequence of postulating the conservation law (2) for the total momentum vector-density (3), with the expressions for the particles given be the usual special-relativistic ones and those for the fields determined by the field equations,Ref. 17 demonstrates that a key idea of the 1938 **EIH** paper is viable in the zero-$G$ limit when applied with a suitable set of electromagnetic field equations, and with non-zero bare rest mass assigned to the point charges. We now address the question whether this result extends continuously to a $G > 0$ neighborhood of special relativity, free of black holes. By a result of **Geroch**–**Traschen**[11] a no-Black-Holes spacetime with a one-dimensional time-like singularity cannot exist if the singularity has positive bare mass, different from the special-relativistic case, where the bare mass merely had to be non-zero.

One of the main ingredients of the **EIH** argument is of course, that the conservation law of energy-momentum is implied by the twice contracted $2^{nd}$ **Bianchi** identity in concert with **Einstein**'s general-relativistic field equations. However, for the spacetimes with time-like singularities envisaged by **EIH** (and **Weyl**) this is not automatically true. An important step, therefore, is to determine the **Lorentz** spacetimes with time-like singularities on which the twice contracted $2^{nd}$ **Bianchi** identity holds in a weak form.

Together with **A. Y. Burtscher** we have begun a systematic study of the favorable conditions. In Ref. 3 we study the simplest non-trivial case: static spherically symmetric spacetimes with a single time-like singularity. We obtain some necessary and, for certain electromagnetic vacuum laws, also sufficient conditions that the twice contracted $2^{nd}$ **Bianchi** identity holds in a weak form. Interestingly, in the naked singularity regime (no Black Hole!), the answer is *negative* for the electromagnetic **Reissner**–**Weyl**–**Nordström** spacetime, but *positive* for the **Hoffmann** spacetime[c] in which electromagnetic **MBI** fields are coupled with **Einstein**'s gravity; see Ref. 26 for a rigorous discussion. Our goal is to generalize our study, one step at a time, to dynamical spacetimes without symmetry.

The crucial question, then, is whether the weak twice contracted $2^{nd}$ **Bianchi** identity implies the law of the electromagnetic spacetime's time-like singularities with bare energy-momentum assigned to them. Interestingly, it seems that merely changing **Maxwell**'s into the **BLTP** or **MBI** vacuum law is by itself not sufficient to allow the formulation of a well-defined joint initial value problem for the massive point charges and the electromagnetic and gravitational fields they generate: the gravitational coupling also needs to be changed, for instance in the manner of

[c]It is curious that although **Hoffmann**[14] had worked out his spacetime solution by 1935, the fact that his spacetime with non-positive bare mass is less singular than the **RWN** spacetime did not in 1938 compell **EIH** to use the **MBI** instead of **Maxwell**–**Lorentz** field theory.

**Jordan, Brans–Dicke**, or $f(\mathbf{R})$ gravity, to obtain a well-defined joint **Cauchy** problem. Put differently, the gravitational coupling of spacetime structure with bare matter and the electromagnetic fields needs to be "mediated" by a certain type of scalar field which moderates the strength of the spacetime singularities enough so that the strategy explained in the previous subsection can be applied. This scalar field in the classical theory would play a role vaguely reminiscent of the role played by the scalar Higgs field in the quantum field-theoretical standard model of elementary particle physics.

2.2.2. *The neighborhood of zGKN-type spacetimes*

Everything stated in the previous subsection about the neighborhood of the **Minkowski** spacetime has an analogue problem for the gravitational neighborhood of topologically non-trivial flat spacetimes of (generalized) z*G***KN** type.

# The Einstein-Infeld-Hoffmann legacy in mathematical relativity II: Quantum laws of motion for singularities of spacetime

A. Shadi Tahvildar-Zadeh† and Michael K. H. Kiessling

*Dept. of Mathematics, Rutgers–New Brunswick*
*E-mail: †shadit@math.rutgers.edu, miki@math.rutgers.edu*

We report on recent developments towards a relativistic quantum mechanical theory of motion for a fixed, finite number of electrons, photons, and their anti-particles, as well as its possible generalizations to other particles and interactions.

## 1. Introduction

As reported in Part I, the goal of the classical part of our program is to formulate and analyze a generally covariant joint initial value problem for the motion of massive charged particles, together with the electromagnetic and gravitational fields that they generate. We believe that proving local well-posedness, i.e. existence and uniqueness of a solution to this initial value problem, and continuous dependence of the solution on initial data, is a first necessary step towards the formulation of a deeper quantum theory of motion, for which the above could serve as the classical limit.

In the second part of our report, we expand on what such a relativistic quantum theory could look like, and present the results of our preliminary efforts towards achieving our ultimate goal, which is twofold: (1) to provide an accurate account of empirical electromagnetism in terms of a special-relativistic $N$-body quantum theory of electrons, photons, and their anti-particles; and (2) to extend that effort to general relativity by taking gravitational effects into account.

At the same time, inspired by Einstein's[12,13] and Bell's[3] writings, we want to find out whether it is possible to formulate such a theory as a generalization of the non-relativistic theory of de Broglie[6] and Bohm[4] in which the quantum-mechanical wave function $\psi$ guides the actual motion of all the particles involved.

Our approach to a relativistic quantum theory is based on a number of working hypotheses. Before listing them, we summarize the assumptions that formed the basis of our approach to the *classical* theory of motion of charged particles, as was outlined in Part I of this report:

1. All forms of matter are of a discrete (particulate) nature.
2. Particles, whether feature-less point-particles or structured ones such as ring-particles, have well-defined world-lines or world-tubes that form the *singular boundary* of spacetime, in the sense that the spacetime metric and/or classical fields permeating the spacetime develop a singularity as a point on this boundary is approached. Moreover, these singularities must be weak enough to give rise to locally integrable field energy-momentum

densities, but not so weak as to be confined to characteristic hypersurfaces (which are completely determined by the field equations).
3. The metric of the spacetime satisfies the weak version of the twice-contracted second Bianchi identity everywhere, including in a neighborhood of any singularity of spacetime (of the type discussed in item 2 above), thus allowing the usual conservation laws of total (i.e. field+particle) energy, momentum, and angular momentum to hold in a weak sense.

In Part I, we showed how these principles may be used to derive a classical equation of motion for world-lines of matter particles (which are identified with time-like singularities of spacetime) based entirely on momentum balance laws.

Our approach to a quantum law of motion begins by replacing the third item above with another set of hypotheses[a]:

3. The quantum-mechanical wave function of a single particle is a section of a Clifford-algebra-valued spin bundle over configuration spacetime. Different species of particles are distinguished by their wave functions at a point in spacetime belonging to different *generalized ideals* (stable subspaces) of that Clifford algebra[b].
4. The wave function of a system of $N$ relativistic particles is defined on the $N$-body configuration spacetime, and takes its values in a tensor space generated by the tensor product of bases for the constituent 1-body wave function spaces.
5. The wave function of a single particle satisfies a relativistic wave equation that is equivariant with respect to the action of the Poincaré group on the bundle of frames for the tangent space at any point in spacetime.
6. As a consequence of satisfying that wave equation, the wave function of a single particle possesses a conserved, future-directed, timelike (or causal, if the particle is massless), and normalizable current, whose component in the normal direction to a given spacelike foliation of spacetime, when evaluated at a point on a leaf of that foliation gives the probability density of the particle trajectory crossing the leaf at that point (by the Born rule.) The same holds for the $N$-particle version of the wave function and an $N$-particle tensor current that is jointly conserved.
7. The motion of a system of $N$ particles is guided by a multi-time wave function defined on the $N$-particle configuration spacetime, in accordance with a relativistic generalization of the de Brogile-Bohm guiding law, such as the Hypersurface Bohm-Dirac Law, in which a conserved $N$-particle tensor current evaluated at the actual positions of those $N$-particles determines their actual velocities.

[a] We emphasize that this is a preliminary list based on what we know so far, and is subject to modification and expansion as our investigations continue.
[b] See Furey[14,15] for details on this point of view.

8. In the classical limit, the quantum motions converge to those described in part I.

## 2. Least Invasive Quantization

In this section we demonstrate by way of a very simple example, how it may be possible to continuously deform a classical law into a quantum law of motion for the same particle.

Consider a particle of (bare) mass $m$ in an external potential $V = V(t, q)$, $q \in \mathbb{R}^d$. The relativistic Lagrangian for the particle's motion is

$$\ell(t, q, \dot{q}) = m(1 - \sqrt{1 - \dot{q}^2}) - V(t, q). \tag{1}$$

The corresponding action is

$$\mathcal{A}[q] := \int_{t_1}^{t_2} \ell(t, q, \dot{q}) dt. \tag{2}$$

We define the canonical momentum to be

$$p := \frac{\partial \ell}{\partial \dot{q}} = \frac{m\dot{q}}{\sqrt{1 - \dot{q}^2}}, \tag{3}$$

so the Hamiltonian is

$$H(t, q, p) = p\dot{q} - \ell = \sqrt{m^2 + p^2} - m + V(t, q). \tag{4}$$

The Hamilton equations are therefore

$$\dot{q} = \frac{\partial H}{\partial p} = \frac{p}{\sqrt{m^2 + p^2}}, \qquad \dot{p} = -\frac{\partial H}{\partial q} = -\partial_q V(t, q). \tag{5}$$

The *Hamilton-Jacobi equation*

$$\frac{\partial S}{\partial t} + H(q, \frac{\partial S}{\partial q}, t) = 0, \tag{6}$$

is a first-order nonlinear PDE for the *Hamilton-Jacobi phase function* $S = S(t, q)$. It arises in the context of solving Hamilton's equations by finding a *canonical transformation*, i.e. a change of variable in phase space $(q, p)$ such that the transformed Hamiltonian is constant. We note that $S$ is defined on the space of generic positions of the particle, i.e. it's a function defined on the configuration space (or configuration spacetime, in the relativistic setting.)

In the case of our particular example, it's easy to see that the Hamilton-Jacobi equation has the form of an eikonal equation:

$$|\partial_t \tilde{S} + V|^2 - |\partial_q \tilde{S}|^2 = m^2, \qquad \tilde{S} := S - mt. \tag{7}$$

Moreover, this equation is derivable from an action principle: Let $\varrho \geqslant 0$ be another function defined on the configuration spacetime, set

$$\mathcal{L} := \varrho \left( |\partial_t \tilde{S} + V|^2 - |\partial_q \tilde{S}|^2 - m^2 \right), \tag{8}$$

and let $\mathcal{S} := \iint \mathcal{L} dqdt$ be the corresponding action. It is then obvious that the stationary points of $\mathcal{S}$ with respect to compactly supported variations in $\varrho$ satisfy (7). If we now let $\varrho$ be an active variable, and set the variation of $\mathcal{S}$ with respect to $\tilde{S}$ also equal to zero, we obtain the following continuity-type equation for $\varrho$:

$$\partial^\mu(\varrho u_\mu) = 0. \tag{9}$$

Here $\mu = 0, \ldots, d$, indices are raised and lowered using the Minkowski metric $\eta = \mathrm{diag}(1, -1, \ldots, -1)$ on the configuration spacetime, and we are employing the Einstein summation convention. The covectorfield $u$ is by definition

$$u_0 := \partial_t \tilde{S} + V, \qquad u_i = \partial_{q^i} \tilde{S}, \tag{10}$$

so that by (7),

$$u_\mu u^\mu = m^2. \tag{11}$$

Let us now define a complex-valued field on the configuration spacetime

$$\psi := \sqrt{\varrho} e^{i\tilde{S}/\hbar}. \tag{12}$$

Evidently, using that $(\varrho, \tilde{S})$ satisfy the Euler-Lagrange equations for the stationary points of the action $\mathcal{S}$, one can derive the equation that $\psi$ must satisfy, which will be a nonlinear PDE.

The goal of a *least invasive quantization* procedure is to find a continuous deformation of the Lagrangian $\mathcal{L}$, now thought of as $\mathcal{L}[\psi]$, to a *nearby* Lagrangian $\tilde{\mathcal{L}}[\psi] = \mathcal{L}[\psi] + \hbar^2 \mathcal{L}'[\psi]$ in such a way that the Euler-Lagrange equation of the new action corresponding to $\tilde{\mathcal{L}}$ is a *linear* PDE in $\psi$. This is easily accomplished by adding a *Fisher-like* term to $\mathcal{L}$: Let

$$\tilde{\mathcal{L}} := \mathcal{L} + \hbar^2 \frac{\partial_\mu \varrho \partial^\mu \varrho}{4\varrho}. \tag{13}$$

A computation then shows that

$$\tilde{\mathcal{L}}[\psi] = \hbar^2 |(\partial_t + \frac{i}{\hbar} V)\psi|^2 - \hbar^2 |\partial_q \psi|^2 + m^2 |\psi|^2 \tag{14}$$

so that a stationary point $\psi$ will satisfy the linear Klein-Gordon equation

$$\left(D^\mu D_\mu + m^2\right) \psi = 0, \qquad D_\mu := -i\hbar\partial_\mu + A_\mu, \tag{15}$$

which (under appropriate assumptions relating $A_\mu$ and $V$), is a Lorentz-covariant equation for a massive spin-0 particle.

It should be noted that in the above admittedly over-simplified setting, $V$ was taken to be an "external" field, but in order to connect with our program of finding equations of motions for singularities of a dynamic field, $V$ needs to be determined by the field for which the particle in question is a singularity. For example, if we are to identify the electron with certain singularities of the electromagnetic field, then the corresponding $V$ in the wave equation for the electron would have to be determined in terms of that electromagnetic field, evaluated at generic positions of

the electron. For a detailed discussion of a proper least invasive quantization in the electromagnetic context see Ref. 21. In any case, since the electron is a spin-1/2 particle, the appropriate wave equation is not Klein-Gordon's but Dirac's, so the above process needs to be suitably modified.

Finally, we should note that even though in (9) one may formally set $\rho := \varrho u^0$ and $v^k := u^k/u^0$ to obtain what looks like a continuity equation for a probability density

$$\partial_t \rho + \partial_k(\rho v^k) = 0 \tag{16}$$

and proceed to derive a Born Rule and guiding law for the particle from it, there is a-priori no reason why $\rho$ would be non-negative. This suggests that even for spin-0 particles, the Klein-Gordon may not be the correct equation. Indeed, the lack of a future-directed timelike conserved current for solutions of the Klein-Gordon equation is a main reason for researchers doubting whether bosons can be treated as particles. We believe they can, and have already addressed this issue for photons[19]. The question of what the correct wave equation is for spin-0 bosons will be addressed in a forthcoming publication of ours.

## 3. Quantum Law of Motion for Point Test Particles

### 3.1. *Point particle in Hoffmann-like spacetimes*

We now move on to a more realistic scenario, of a single point charge, thought of as the only time-like singularity of a static, spherically symmetric 4-dimensional electrovacuum spacetime, i.e. a solution of the Einstein-Maxwell equations. As was shown in Ref. 7, the case where the electromagnetic vacuum law is the standard, linear law of Maxwell ($D = E, H = B$) yields a spacetime that is too singular for weak Bianchi identity to be satisfied at the singularity, so that our third working hypothesis is not satisfied. We showed however, that there are *nonlinear* vacuum laws, including the one proposed by Born & Infeld[5], for which the corresponding static spherically symmetric solution of the Einstein-Maxwell equations (which was fully analyzed in Ref. 23) *does* satisfy the weak Bianchi identity. The spacetime that corresponds to the Born-Infeld vacuum law was discovered by Hoffmann[16] in 1935.

As a first step towards a full-blown two-body quantum-mechanical problem, one may study the dynamics of a single electron, thought of as a *test* point charge, placed in the electrostatic and gravitational field of another, much more massive point charge such as a nucleus, the latter thought of as the central singularity of a static spherically symmetric spacetime, while the contribution of the former to the geometry of the spacetime is ignored. At the same time, the Born-Oppenheimer approximation allows one to reduce the 2-body quantum mechanical situation to a single body one. The dynamics of the electron is thus determined by its wave function that, due to the electron being a massive spin-1/2 particle, satisfies the

Dirac equation on the background spacetime of the nucleus, with the electrostatic field of the nucleus appearing in the Dirac operator as a minimal coupling term.

This program was carried out successfully in Ref. 1, where it was shown that the Dirac Hamiltonian on Hoffmann-like spacetimes is essentially self-adjoint regardless of the nuclear charge, its essential spectrum is the same as that of the free Dirac operator on Minkowski space, its point spectrum is non-empty and consists of infinitely many eigenvalues in the gap, accumulating at the right endpoint. Numerical investigations of this problem are in the works, including comparison of the eigenvalues with those of the Dirac+Coulomb potential and the Dirac+Born electrostatic potential Hamiltonians on a Minkowski background.

### 3.2. *Point particle in zero-gravity Kerr-Newmann spacetime*

As mentioned above, the main obstacle on the path to a well-defined quantum theory that could encompass both gravity and electromagnetism is that when Maxwell-Lorentz electrodynamics is coupled to Einstein's gravity, the infinities inherent in ML cause the spacetime to have curvature singularities that are too strong for even a weak notion of energy-momentum conservation to hold. In our quest to find a remedy for the strong curvature singularities of well-known solutions of Einstein-Maxwell equations such as the Kerr-Newmann solution, another avenue that we have pursued is to work with the *zero-gravity limit* of such singular spacetimes. This is a (geometrically well-defined) limit when Newton's gravitational constant $G$, which appears as a parameter in these metrics, is set to zero. The limiting spacetime and the electromagnetic field on it were analyzed in Ref. 22. It is axially symmetric, static, and locally isometric to Minkowksi space, but is topologically non-trivial. These facts were already known to Carter[8], who discovered the maximal analytical extension of the Kerr-Newmann solution. It was also known that the constant time slices of this manifold are double-sheeted, and have the topology of $\mathbb{R}^3$ branched over the un-knot (See Fig. 1.)

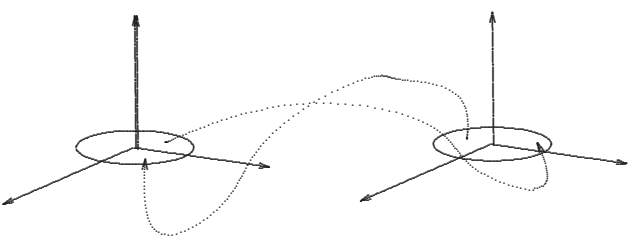

Fig. 1. Visualizing the double-sheeted spacelike slices of zero-$G$ Kerr-Newmann spacetime as a branched cover of the un-knot. Arrows indicate that the top of the disk in one copy of $\mathbb{R}^3$ is to be identified with the bottom of the disk in the other copy.

The spacetime is indeed singular on a 2-dim. timelike cylinder $\mathbb{S}^1 \times \mathbb{R}$, which is the world-tube of a ring-like singularity. The most intriguing aspect of this solution

is that at any instant of time the ring singularity, when viewed from one of the two sheets of space, appears to be positively charged, and from the other sheet, negatively charged.

As a first step in studying the quantum problem, one may identify the zero-gravity Kerr-Newmann (zGKN) solution with the spacetime outside a ring-like singularity representing a positively charged particle such as a proton. Since the metric of zGKN and the electromagnetic field corresponding to it are well known, it is easy to formulate the quantum dynamics of a test electron placed in the vicinity of the ring singularity by studying the Dirac equation on the zGKN background. This task was carried out in Ref. 17, where it was shown, using techniques developed in Refs. 2 & 26, that the pertinent Dirac Hamiltonian is essentially self-adjoint and its essential spectrum is the same as the standard Dirac operator on Minkowski space. We further showed that its discrete spectrum is nonempty, provided the radius of the ring is small enough. The ground state of the Dirac Hamiltonian for the single test electron has support in both sheets of the spacetime, but is mainly concentrated in the sheet where the ring singularity appears to be positively charged, see Fig. 2, where the horizontal axis is a radial coordinate that runs from $-\infty$ to 0 in one sheet and 0 to $\infty$ in the other sheet, while the vertical axis is $|\psi|^2$.

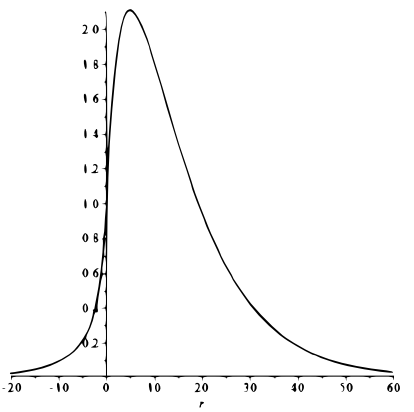

Fig. 2. Ground state of single-electron Dirac Hamiltonian on a zGKN background

Further analysis showed that the radius of the ring should be of the order of the *anomalous magnetic moment of the electron*, and that given this choice, the full spectrum will be close to the standard Dirac+Coulomb problem for Hydrogenic atoms. Furthermore, the broken symmetry due to nonzero ring radius causes the well-known degeneracy in the Dirac spectrum of Hydrogen to be broken, resulting in effects that are qualitatively similar to Lamb shift and hyperfine splitting, without the need to appeal to QED methods, see Fig. 3 (axes have the same meaning as in Fig. 2.)

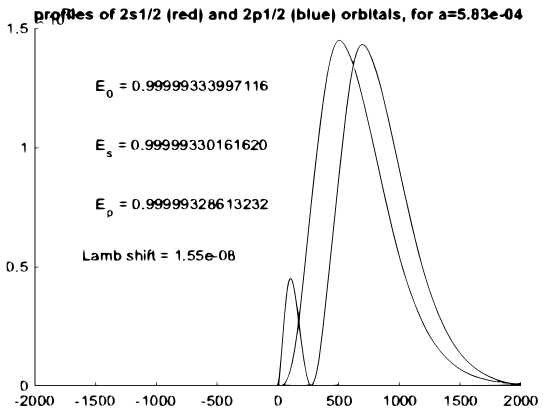

Fig. 3. Numerical evidence of a qualitative Lamb shift for Dirac's Hamiltonian on zGKN. The prameter $a$ is the ring radius, which here is set equal to electron's anomalous magnetic moment, measured in units of the Compton wavelength of electron.

## 4. Towards a Quantum Law of Motion for Ring-Like Singularities of Spacetime

Going back to the intriguing feature of the ring singularity of zGKN, i.e. that the same ring is found to have a positive charge when seen from one of the two sheets of that spacetime, and a negative charge when seen from the other sheet, one may wonder whether this ring singularity is representing both a particle and its anti-particle. In Ref. 18, extrapolating from the existence of such "bi-particle" structures in General Relativity, we proposed a novel interpretation of Dirac's "wave equation for the relativistic electron" in which the electron and the positron are merely the two different "topological spin" states of a single more fundamental particle, not distinct particles in their own right. This novel interpretation resolves the dilemma that Dirac's wave equation seems to be capable of describing both the electron and the positron in 'external' fields in many relevant situations, while the bi-spinorial wave function has only a single position variable in its argument, not two –as it should if it were a quantum-mechanical two-particle wave equation. We formulated a Dirac equation for such a ring-like bi-particle which interacts with a static point charge located elsewhere in the topologically non-trivial physical space associated with the moving ring particle. Indeed, for quasi-static motions of the ring, this equation is nothing but the one we have been discussing in the previous section, namely Dirac's equation on the zGKN background! The difference is in the interpretation, since the wave function in the present case is defined on the configuration space of the center of the ring, which is now moving with respect to a fixed point charge located on one of the two sheets. See Fig. 4 for a schematic illustration of the two interpretations. Furthermore, we showed that the motion of the ring can be governed by a de Broglie-Bohm type law extracted from the Dirac equation.

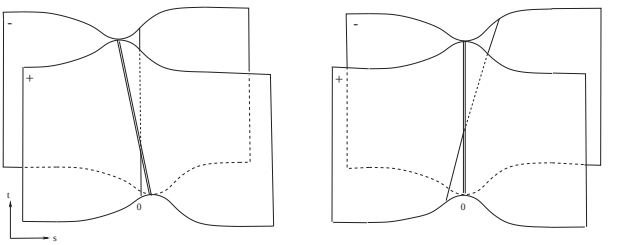

Fig. 4. Left: The physical spacetime with a single ring singularity in straight line motion relative to the rest frame of a designated origin, which in the depicted scenario gets "swept over" by the ring singularity; Right: Trajectory of a test particle in straight line motion in the static z$G$KN spacetime having the center of its ring singularity as the origin (marked 0). The test particle transits through the ring from one sheet to the other.

Our work in this direction is so far limited to quasi-static motions of the ring, which result in the ring remaining circular to the leading order, so that its motion can be specified solely in terms of the trajectory of the center of the circle, together with the evolving unit normal to the plane of the circle. Clearly, much work remains to be done in order to extend these results to the general case, which would presumably involve deformations of the ring as it moves.

The next natural step in this direction would be to study the full 2-body quantum problem, either in the context of nonlinear electrodynamics, or in the zero-gravity context by studying the two-rings analog of zGKN. Due to the strong nonlinearity of the BI vacuum law however, there is currently no explicit solution known to the *classical* 2-body problem, even in the absence of gravity, thus making any progress in that direction quite difficult. As to the two rings, that analysis is already under way. We know for example that the space should be four-sheeted (in general, $2^N$ sheets are needed for $N$ ring singularities), and that it is possible to come up with a Dirac equation for the 2-body wave function (with synchronized times), equipped with a minimal coupling term that models the electromagnetic interaction of the two rings. It is important to note however, that there is no chance of "turning gravity back on" in these models, since doing so will bring back the strong singularities of the type present in the Kerr-Newman spacetime, together with all the causal pathologies that they entail.

As described in Part I of this report, there are other electromagnetic theories, such as the Bopp-Lande-Thomas-Podolsky (BLTP) theory, which may allow us to find electromagnetic spacetimes whose singularities are mild enough so that they can represent charged particles. Once such solutions are known, a least invasive quantization procedure as outlined in Section 2 could conceivably lead to a quantum law of motion for those particles. Investigations are currently under way on various aspects of this program.

## 5. Quantum Laws of Motion for Interacting Point-Particle Systems

As mentioned at the outset, our goal is the eventual formulation of a relativistic quantum-mechanical theory of motion for a fixed number $N$ of electrons, photons, and their anti-particles in 3+1-dimensional Minkowski spacetime, and its generalization to other particles and interactions. We are certainly not the first researchers to state this as our goal, as can be attested to by the following passage in Ref. 9:

> "The Compton effect, at its discovery, was regarded as a simple collision of two bodies, and yet the detailed discussion at the present time involves the idea of the annihilation of one photon and the simultaneous creation of one among an infinity of other possible ones. We would like to be able to treat the effect as a two-body problem, with the scattered photon regarded as the same individual as the incident, in just the way we treat the collisions of electrons."

Such a goal however, of treating electrons and photons on an equal footing, within a quantum-*mechanical* framework of a fixed number of particles, has so far remained elusive. Progress has been obstructed in particular by the lack of a viable candidate for the quantum-mechanical photon wave function and its pertinent relativistic wave equation which furnishes a conserved probability current for the photon position, obeying Born's rule. Recently such a photon wave function and wave equation have been constructed in Ref. 19. In a forthcoming joint work with M. Lienert[20], we show how the photon wave equation of Ref. 19 can be coupled with Dirac's well-known relativistic wave equation for the electron in a Lorentz-covariant manner to accomplish what Darwin has asked us to do: to "treat the effect as a two-body problem, with the scattered photon regarded as the same individual as the incident, in just the way we treat the collisions of electrons."

We work with Dirac's manifestly Lorentz-covariant formalism of multi-time wave functions[10]. For our $N = 2$ body problem the wave function $\Psi(\mathbf{x}_{\rm ph}, \mathbf{x}_{\rm el})$ depends on the two generic spacetime events $\mathbf{x}_{\rm el}$ and $\mathbf{x}_{\rm ph}$ of the electron and the photon, respectively, which must be space-like separated. Both the Dirac operator of a free electron[25], and the Dirac-type operator of a free photon constructed in Ref. 19, act on $\Psi(\mathbf{x}_{\rm ph}, \mathbf{x}_{\rm el})$. Unique solvability of this system of evolution equations requires imposing a suitable *boundary condition* at the subset of co-incident events, $\{\mathbf{x}_{\rm el} = \mathbf{x}_{\rm ph}\}$. Conservation of the particle currents dictates the boundary condition, up to a choice in a phase. We prove that the resulting initial-boundary-value problem is well-posed.

It is intuitively obvious that a boundary condition at co-incident events $\{\mathbf{x}_{\rm el} = \mathbf{x}_{\rm ph}\}$ amounts to a local pair interaction between electron and photon in a Lorentz-covariant manner. Our boundary condition is compatible with the kind of interaction expected for an electron and a photon in Compton scattering. In particular, when we plot the joint 2-body probability density $\rho$ as a function of generic positions of the two particles, we observe that, as it evolves in time, the density forms four peaks, corresponding to the wave function being mostly supported near four distinct configurations: (1) both particles going to the left, (2) both particles going

to the right, (3) particles going away from each other for all time; and (4) particles initially moving towards each other and "bouncing off" of one another. Indeed the fourth peek appears to "hit" the boundary and get reflected, see Fig. 5 for snapshots of the evolving density[c].

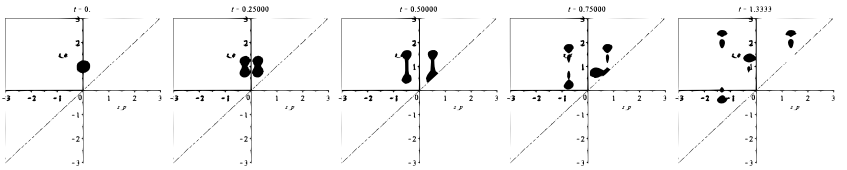

Fig. 5. Contour plot of the density $\rho$ in photon-electron configuration space at six consecutive snapshots of common time $t = t_{\mathrm{el}} = t_{\mathrm{ph}}$. The photon axis is horizontal, the electron axis vertical.

We have also carried out a limited number of numerical experiments with our system of equations, which indeed demonstrate the process of Compton scattering, but which also have revealed an unexpected novel phenomenon: photon capture and subsequent release by the electron. For all practical purposes this scenario seems indistinguishable from the scenario of an annihilation of a photon, followed by a subsequent emission of another one. In our quantum-mechanical $N = 2$-body model the photon of course never gets destroyed or created, precisely as envisioned by Darwin.

Beyond demonstrating that relativistic quantum mechanics with a fixed finite number $N$ of interacting particles is feasible, we also formulate the de Broglie–Bohm-type foundations of this Lorentz-covariant quantum model[d]. This is accomplished by adapting to our interacting 2-body model the so-called "hypersurface Bohm–Dirac"-type formulation for non-interacting particles[11]. This formulation requires one to specify a foliation of spacetime by spacelike hypersurfaces. In our model these hypersurfaces are given by a time-like Killing vector field that is determined self-consistently by the initial data of the wave function. The guiding law for the particles is furnished by the conserved current of our quantum-mechanical multi-time wave function. We extend a theorem of Teufel–Tumulka[24], which implies that unique particle motions typically exist globally in time.

The numerically computed trajectories confirm that our boundary condition causes the particles to scatter off of one another. See Fig. 6 for example of a two pairs of particles with identical initial conditions, one evolved according to the free evolution (i.e. without any boundary condition on the coincidence set) and the other using our boundary condition.

[c]You can see an animation of the density plot of $\rho$ as a function of the two positions by going to `http://sites.math.rutgers.edu/~shadi/phel1dint_slow.gif`

[d]This should put to rest the often-voiced claim that the de Broglie–Bohm theory could not be made relativistic.

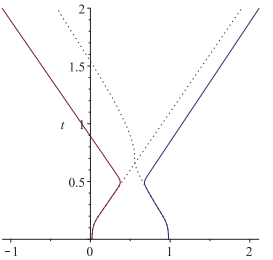

Fig. 6. Interacting (solid) versus non-interacting (dotted) electron-photon trajectories.

The intriguing phenomenon of photon "capture and release" by the electron that we alluded to in the above can also be illustrated by the numerically computed electron and photon trajectories, see Fig. 7.

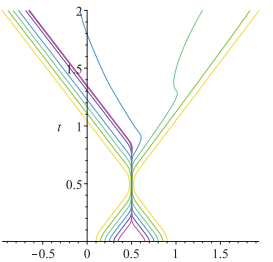

Fig. 7. World-lines corresponding to possible capture-and-release phenomena (Different colors correspond to the photon-electron pair starting at different initial positions that are successively closer to each other.)

Finally, by sampling a large ensemble of random positions distributed according to the initial wave function, we can also illustrate that the empirical statistics over the possible actual trajectories reproduces Born's rule in our model, a consequence of the equivariance of the evolution of the probability densities. See Fig. 8 and note the four clusters of trajectories that correspond to the four peaks of the joint probability density that was mentioned in the above.

More numerical investigation is currently under way, to explore various regions in the parameter space for the dynamics (e.g. mass and energy of incident electron, frequency profile of incident photon, their initial distance, etc.) and to quantify the energy and momentum transfer between the two particles.

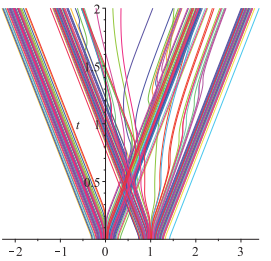

Fig. 8. Electron & photon world-lines corresponding to 100 pairs of typical initial positions.

# The problem of Boltzmann brains and how Bohmian mechanics helps solve it

Roderich Tumulka

*Mathematisches Institut, Eberhard-Karls-Universität,*
*Auf der Morgenstelle 10, 72076 Tübingen, Germany*
*E-mail: roderich.tumulka@uni-tuebingen.de*

Most versions of classical physics imply that if the 4-volume of the entire space-time is infinite or at least extremely large, then random fluctuations in the matter will by coincidence create copies of us in remote places, so called "Boltzmann brains." That is a problem because it leads to the wrong prediction that *we* should be Boltzmann brains. The question arises, how can any theory avoid making this wrong prediction? In quantum physics, it turns out that the discussion requires a formulation of quantum theory that is more precise than the orthodox interpretation. Using Bohmian mechanics for this purpose, we point out a possible solution to the problem based on the phenomenon of "freezing" of configurations.

*Keywords*: quantum fluctuation; Bunch-Davies vacuum; late universe; scalar fields in cosmology; de Sitter space-time

## 1. The problem of Boltzmann brains

A "Boltzmann brain" [1,2] is this: Let $M$ be the present macro-state of your brain. For a classical gas in thermal equilibrium, it has probability 1 that after sufficient waiting time, some atoms will "by coincidence" ("by fluctuation," "by ergodicity") come together in such a way as to form a subsystem in a micro-state belonging to $M$. That is, this brain comes into existence not by childhood and evolution of life forms, but by coincidence; this brain has memories (duplicates of your present memories), but they are false memories: the events described in the memories never happened to this brain! Boltzmann brains are, of course, very unlikely. They are fluctuations in which entropy spontaneously decreases. But they will happen if the waiting time is long enough, and they will happen more frequently if the system is larger (bigger volume, higher number of particles).

The problem with Boltzmann brains is this: If the universe continues to exist forever, and if it reaches universal thermal equilibrium at some point, then the overwhelming majority of brains in the history of the universe will be Boltzmann brains. According to the "Copernican principle," we should see what a typical observer sees. But we do not, as most Boltzmann brains find themselves surrounded by thermal equilibrium, not by other intelligent beings on a planet. In fact, if a theory predicts that the great majority of brains are Boltzmann brains, then one should conclude that we are Boltzmann brains. But we are not. We had childhoods. We know because we trust out memories more than any physics theory.

How can any of our serious theories avoid making this incorrect prediction? One possibility is that there will be a Big Crunch, and that the total 4-volume of the universe will be finite and not too large. Then the probability that an

unlikely fluctuation ever happens can be small. However, it is expected (e.g., from Λ-cold-dark-matter, often called the standard model of cosmology) that the late universe will be close to de Sitter space-time and thus has infinite lifetime and infinite 4-volume. We will describe another way out of the problem.[5,9]

## 2. Concrete version of the Boltzmann brain problem

It is further expected from Λ-cold-dark-matter that the state of matter in the late universe will be close (in terms of local observables) to the Bunch-Davies vacuum, a quantum state invariant under the isometries of de Sitter space-time (in particular, a stationary state). The $|\psi|^2$ probability distribution it defines on configuration space gives $> 99\%$ weight to thermal equilibrium configurations, but positive probability to brain configurations, in fact $> 99\%$ probability to configurations containing brains if 3-space is large enough (in particular if infinite).

Does this mean there are Boltzmann brains in the Bunch-Davies vacuum? Actually, does a stationary state mean that nothing happens? Or does the factual situation visit different configurations over time according to $|\psi|^2$? This is a point at which foundational questions of quantum theory become relevant to cosmology. We need to ask, what is the significance of this particular wave function for reality?

We will analyze a Bohm-type model of the situation and conclude that there are no Boltzmann brains in the Bunch-Davies state. For comparison, for Everett's many-worlds interpretation of quantum theory, Boddy, Carroll, and Pollack[2] have argued that in a stationary state nothing moves, whereas David Wallace, a leading advocate of the many-worlds view, disagrees (personal communication).

## 3. Bohmian mechanics

Bohmian mechanics[3,4] is a version of quantum mechanics with trajectories. For non-relativistic quantum mechanics, it can be defined as follows. The theory takes "particles" literally and proposes that electrons are material points moving in 3-space that have a definite position $\boldsymbol{Q}_k(t)$ at every time $t$. There is a wave-particle duality in the sense that there are particles and there is a wave (the usual wave function $\psi_t$ of quantum mechanics on the configuration space $\mathbb{R}^{3N}$ of $N$ particles).

The theory has two dynamical laws: for $\psi_t$ the usual Schrödinger equation

$$i\hbar \frac{\partial \psi_t}{\partial t} = H\psi\,, \tag{1}$$

and for $\boldsymbol{Q}_k(t)$ Bohm's equation of motion

$$\frac{d\boldsymbol{Q}_k(t)}{dt} = \frac{\hbar}{m_k} \nabla_k \operatorname{Im} \log \psi_t\big(\boldsymbol{Q}_1(t), \ldots, \boldsymbol{Q}_N(t)\big)\,. \tag{2}$$

Figure 1 shows a sample of Bohmian trajectories after passing through a double slit. The law of motion (2) is equivalent to

$$\frac{dQ}{dt} = \frac{j(Q)}{\rho(Q)}\,, \tag{3}$$

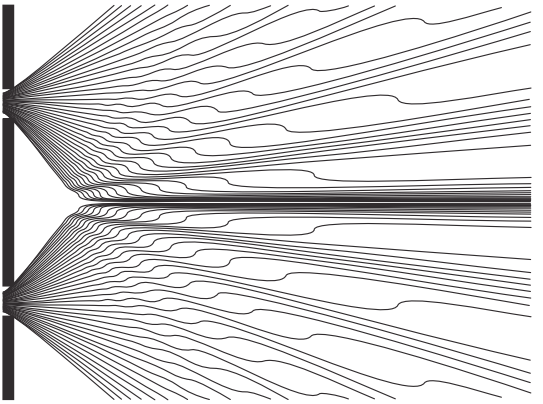

Fig. 1. Several alternative Bohmian trajectories in a double slit experiment, each coming from the left and passing through one of the slits. (Reprinted from Ref. 4)

where $Q = (\boldsymbol{Q}_1, \ldots, \boldsymbol{Q}_N)$ is the configuration, $\rho = |\psi|^2$ is the standard probability density, and $j$ is the standard probability current vector field in configuration space. As a consequence of the continuity equation for $\rho$ and $j$, one obtains the *equivariance theorem* that if $Q(t = 0)$ is random with distribution density $|\psi(t = 0)|^2$, then at any time $t$, $Q(t)$ has distribution $|\psi(t)|^2$. As a part of the theory, we assume that the initial configuration is in fact so chosen. Figure 1 illustrates that the arrival points on the screen are $|\psi|^2$ distributed. The central fact about the empirical predictions of Bohmian mechanics is that the inhabitants of a Bohmian world would observe outcomes in agreement with the predictions of quantum mechanics.

## 4. How Bohmian mechanics helps against Boltzmann brains

### 4.1. *Freezing in Bohmian mechanics*

In Bohmian mechanics, there is the phenomenon of "freezing," whose basic form is as follows.

**Theorem 4.1.** *If $\psi$ is a non-degenerate eigenstate of a Hamiltonian that is a non-relativistic Schrödinger operator, then the Bohmian configuration does not move.*

That is because the conjugate of $\psi$ must be another eigenstate with the same eigenvalue, so $\psi$ must be real up to a global phase. As a consequence, according to (2), particle velocities vanish. Freezing may be surprising because the momenum distribution, $|\hat{\psi}(k)|^2$ with $\hat{\psi}$ the Fourier transform of $\psi$, is not concentrated on the origin. In Bohmian mechanics, momentum corresponds not to the instantaneous velocity but to the asymptotic velocity that the particle would reach if the potential were turned off. [4]

It follows that, if non-relativistic Bohmian mechanics were true, and if the late universe were in a non-degenerate eigenstate, then the configuration would

be frozen. Arguably, the Boltzmann brain problem is absent then, as any such brain, even if it existed, would not be functioning. Turning now to a more realistic scenario, we will see that although freezing as such does not occur in the late universe, asymptotic freezing does.

### 4.2. *Concrete model of the late universe*

Let us take for granted that the late universe is asymptotically a de Sitter space-time with metric

$$ds^2 = dt^2 - e^{2Ht}\delta_{ij}dx^i dx^j\,, \tag{4}$$

where $H$ is the Hubble parameter (expansion speed of the universe—not the Hamiltonian!) and $i, j$ are summed over the values $1, 2, 3$. Actually, this coordinate patch covers only half of de Sitter space-time, but that is alright because we are considering only the late universe. As a model of the matter, we consider a simple quantum field theory with a single Hermitian scalar quantum field $\varphi(\mathbf{x}, t)$. The quantum state can then be written as a wave functional $\Psi(\varphi, t)$ on the space of field configurations $\varphi$, which are real-valued functions of $\mathbf{x} = (x^1, x^2, x^3)$. It will be convenient to rescale time according to $dt = e^{Ht}\,d\eta$, where the new coordinate $\eta$ is called the conformal time. As $t$ varies from $-\infty$ to $+\infty$, $\eta$ runs from $-\infty$ only up to 0; in particular, the long-time limit $t \to \infty$ that is relevant to us corresponds to $\eta \to 0$ from the left. We also rescale the field variable according to $y = e^{Ht}\varphi$. Moreover, it will be useful to express the field configuration in terms of its Fourier modes $y_{\mathbf{k}}$ (note that $y_{-\mathbf{k}} = y_{\mathbf{k}}^*$ since $y(\mathbf{x})$ is real). The Schrödinger equation for $\Psi$ in the Schrödinger picture then reads[5,7]

$$i\frac{\partial\Psi}{\partial\eta} = \int_{\mathbb{R}^{3+}} d^3\mathbf{k}\left[-\frac{\delta^2}{\delta y_{\mathbf{k}}^*\delta y_{\mathbf{k}}} + k^2\, y_{\mathbf{k}}^*\, y_{\mathbf{k}} + \frac{i}{\eta}\left(\frac{\delta}{\delta y_{\mathbf{k}}^*}y_{\mathbf{k}}^* + y_{\mathbf{k}}\frac{\delta}{\delta y_{\mathbf{k}}}\right)\right]\Psi\,, \tag{5}$$

where $k = |\mathbf{k}|$, and $\mathbb{R}^{3+}$ means an arbitrary choice of half space (containing exactly one of $\mathbf{k}$ and $-\mathbf{k}$ for almost every $\mathbf{k}$).

We consider a Bohmian model with a field ontology,[6,7] that is, we assume that there is an actual field configuration $\varphi(\mathbf{x}, t)$ (the analog of $Q(t)$), equivalently expressed as $y_{\mathbf{k}}(\eta)$, which is "guided" by $\Psi$ according to the equation

$$\frac{dy_{\mathbf{k}}}{d\eta} = \frac{\delta \mathrm{Im}\log\Psi}{\delta y_{\mathbf{k}}^*} - \frac{1}{\eta}y_{\mathbf{k}}\,, \tag{6}$$

which is the natural analog in this setting of Bohm's equation of motion (2).[7]

### 4.3. *Asymptotic freezing in the Bunch-Davies state*

In this representation, the Bunch-Davies state reads

$$\Psi = \prod_{\mathbf{k}\in\mathbb{R}^{3+}} \frac{1}{\sqrt{2\pi}f}\exp\left\{-\frac{1}{2f^2}|y_{\mathbf{k}}|^2 + i\left[\left(\frac{f'}{f} + \frac{1}{\eta}\right)|y_{\mathbf{k}}|^2 - \mathrm{phase}(k,\eta)\right]\right\} \tag{7}$$

with $f = f_k(\eta) = \sqrt{1+1/k^2\eta^2}/\sqrt{2k}$. In particular, the different field modes $\mathbf{k}$ are disentangled. The phase of $\Psi$ is not constant, so $y_\mathbf{k}$ is not frozen, but $\Psi$ is simple enough so we can explicitly solve[5] the Bohmian equation of motion (6):

$$y_\mathbf{k}(\eta) = \tilde{c}_\mathbf{k}\, f_k(\eta) \tag{8}$$

or, expressed in the original variables,

$$\varphi_\mathbf{k}(t) = c_\mathbf{k}\sqrt{1+k^2\exp(-2Ht)/H^2}\,. \tag{9}$$

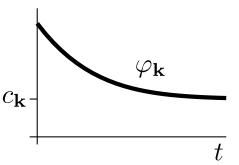

Fig. 2. Graph of $\varphi_\mathbf{k}$ as a function of $t$

Note that $\lim_{t\to\infty}\varphi_\mathbf{k}(t)$ exists and is equal to $c_\mathbf{k}$, which means the Bohmian field is asymptotically freezing. This suggests that the configuration becomes constant for large $t$, precluding a functioning brain. In fact, the situation is a little more subtle because the $x^j$ coordinates are moving apart, so that at any time only the modes with wave lengths large compared to the Hubble distance $1/H$ are frozen. But even before (9) becomes constant, its simple behavior is as good as freezing, as it is too simple to support the complex behavior of a functioning brain. Hence, in Bohmian mechanics there are no Boltzmann brains in the Bunch-Davies vacuum.

### 4.4. *Asymptotic freezing in a generic state*

However, $\Psi$ will not be close to the Bunch-Davies state in Hilbert space. It will look locally similar, but Bohmian mechanics depends nonlocally on the wave function. This issue is taken care of by the following

**Theorem 4.2 (Ryssens[8] 2012, Tumulka[9] 2015).** *For a large class of wave functions $\Psi$ and most initial field configurations, the asymptotic long-time behavior of $\varphi$ is*

$$\varphi_\mathbf{k}(t) \approx c_\mathbf{k}\sqrt{1+k^2\exp(-2Ht)/H^2} \quad \text{for } t > t_0\,, \tag{10}$$

*where $t_0$ is independent of $\mathbf{k}$ (but depends on $\Psi$). In particular, $\lim_{t\to\infty}\varphi_\mathbf{k}(t)$ exists.*

### 4.5. *Idea of proof*

Consider a single mode $\mathbf{k}$. Rescale the field variable, setting $z = \gamma(\eta)^{-1}y$, with the function $\gamma$ to be chosen later. Rescale and phase-transform wave function,

$$\Phi(z,\eta) = e^{\alpha(\eta)+i\beta(\eta)z^*z}\Psi(\gamma(\eta)\,z,\eta) \tag{11}$$

with functions $\alpha$ and $\beta$ to be chosen later. Also rescale time according to $d\tau = \gamma^{-2}\, d\eta$. For a suitable (explicitly known[9]) choice of the scaling functions $\alpha, \beta, \gamma$, the evolution of $\Phi$ reduces to a non-relativistic Schrödinger equation in a 2d harmonic oscillator potential,

$$i\frac{\partial \Phi}{\partial \tau} = -\frac{\partial^2 \Phi}{\partial z^* \partial z} + \omega^2 z^* z \Phi \tag{12}$$

and the non-relativistic Bohmian equation of motion

$$\frac{dz}{d\tau} = \frac{\partial \mathrm{Im} \log \Phi(z,\tau)}{\partial z^*}\,. \tag{13}$$

These evolutions do not become singular as $\tau \to 0-$ ($\Leftrightarrow$ $\eta \to 0-$ $\Leftrightarrow$ $t \to \infty$). Thus, $\lim_{\tau \to 0-} z(\tau)$ exists, so, for $\tau$ sufficiently close to 0, $z(\tau) \approx$ const. $\Leftrightarrow$ $y(\eta) \approx \gamma(\eta) \times$ const. $\Leftrightarrow$ $\varphi(t) \approx c_{\mathbf{k}} \sqrt{1 + k^2 \exp(-2Ht)/H^2}$.

### 4.6. *Upshot*

For almost any $\Psi$, the Bohmian motion becomes very simple as $t \to \infty$. While there is a positive probability for a brain configuration to occur, this subsystem would not function as a brain because it cannot move in a complex way. (In fact, the probability of a brain configuration in a Hubble volume is tiny.) Thus, Boltzmann brains do not occur in Bohmian mechanics according to this particular model.

Traversable Wormhole are amazing astrophysical objects predicted by General Relativity which are able to connect remote region of space-time. Even if their existence has not been proved yet they are object of continuous investigation. From the theoretically point of view, to exist, traversable wormholes need a special form of energy density termed "*exotic*". Since this exotic source must be concentrated on the throat of the wormhole, we discuss the implications of assuming Yukawa-like profiles which could be realize such a configuration.

## 1. Introduction

Traversable wormholes are solutions of the Einstein's Field Equations (EFE) which have the property of connecting remote space-time regions[1,2]. In Schwarzschild coordinates, the traversable wormhole metric can be cast into the form

$$ds^2 = -\exp\left(-2\phi\left(r\right)\right)dt^2 + \frac{dr^2}{1-\frac{b(r)}{r}} + r^2 d\Omega^2. \tag{1}$$

where $\phi\left(r\right)$ is called the redshift function, while $b\left(r\right)$ is called the shape function and where $d\Omega^2 = d\theta^2 + \sin^2\theta d\phi^2$ is the line element of the unit sphere. $\phi(r)$ and $b(r)$ are arbitrary functions of the radial coordinate $r \in [r_0, +\infty)$. A fundamental property of a wormhole is that a flaring out condition of the throat, given by $(b - b'r)/b^2 > 0$, must be satisfied as well as the request that $1 - b(r)/r > 0$. Furthermore, at the throat $b(r_0) = r_0$ and the condition $b'(r_0) < 1$ is imposed to have wormhole solutions. It is also fundamental that there are no horizons present, which are identified as the surfaces with $e^{2\phi} \to 0$, so that $\phi(r)$ must be finite everywhere. The first step to establish if a traversable wormhole exists is given by solving the EFE in an orthonormal reference frame

$$\rho\left(r\right) = \frac{1}{8\pi G}\frac{b'}{r^2}, \tag{2}$$

$$p_r\left(r\right) = \frac{1}{8\pi G}\left[\frac{2}{r}\left(1-\frac{b\left(r\right)}{r}\right)\phi' - \frac{b}{r^3}\right], \tag{3}$$

$$p_t\left(r\right) = \frac{1}{8\pi G}\left(1-\frac{b\left(r\right)}{r}\right)\left[\phi'' + \phi'\left(\phi' + \frac{1}{r}\right)\right] - \frac{b'r - b}{2r^2}\left(\phi' + \frac{1}{r}\right), \tag{4}$$

where $\rho\left(r\right)$ is the energy density, $p_r\left(r\right)$ is the radial pressure, and $p_t\left(r\right)$ is the lateral pressure and using the conservation of the stress-energy tensor, in the same

orthonormal reference frame, one gets

$$p_r' = \frac{2}{r}\left(p_t - p_r\right) - \left(\rho + p_r\right)\phi'. \tag{5}$$

One strategy to obtain solutions for the EFE is represented by imposing an Equation of State (EoS) of the following forms:

(1) $p_r(r) = \omega\rho(r)$, with $\omega$ constant,
(2) $p_r(r) = \omega\left(r\right)\rho(r)$, with $\omega$ function of the radial coordinate $r$,
(3) $p_r(r) = \omega\rho^{\gamma}(r)$, with $\gamma \in \mathbb{R}$.

Of course, this list does not exhaust the possibilities of constraining the relationship between $p_r(r)$ and $\rho(r)$. For instance, by imposing the first EoS, one finds

$$\phi' = \frac{b\left(r\right) + \omega b\left(r\right)' r}{2r^2\left(1 - \frac{b(r)}{r}\right)} \tag{6}$$

and if we also assume Zero Tidal Forces (ZTF), one gets

$$\phi\left(r\right) = C \qquad \text{and} \qquad b\left(r\right) = r_0\left(\frac{r_0}{r}\right)^{\frac{1}{\omega}}, \tag{7}$$

where the condition $b\left(r_0\right) = r_0$ has been used. The parameter $\omega$ is restricted by the following conditions

$$b'\left(r_0\right) < 1; \qquad \frac{b\left(r\right)}{r} \underset{r\to+\infty}{\to} 0 \qquad \Longrightarrow \qquad \begin{cases} \omega > 0 \\ \omega < -1 \end{cases} \tag{8}$$

and the metric (1) assumes the particular simple expression

$$ds^2 = -dt^2 + \frac{dr^2}{1 - \left(\frac{r_0}{r}\right)^{\frac{1}{\omega}+1}} + r^2 d\Omega^2. \tag{9}$$

It is interesting to note that when $\omega \to \infty$, one finds

$$ds^2 = -dt^2 + \frac{dr^2}{1 - \frac{r_0}{r}} + r^2 d\Omega^2, \tag{10}$$

namely a traversable wormhole with zero energy density and ZTF. The corresponding Stress-Energy Tensor (SET) is given by

$$T_{\mu\nu} = \left(\rho\left(r\right), p_r\left(r\right), p_t\left(r\right), p_t\left(r\right)\right) = \frac{r_0}{2\kappa r^3}\left(0, 0, 1, 1\right), \tag{11}$$

that is it is formed by pure transverse pressure. To establish how much negative energy density is necessary, it is useful the computation of the "volume integral quantifier", which provides information about the "total amount" of averaged null energy condition (ANEC) violating matter in the space-time[3]. This is defined by

$$I_V = \int \left[\rho(r) + p_r(r)\right] dV \tag{12}$$

and for the line element (1), one can write

$$I_V = \frac{1}{\kappa}\int_{r_0}^{+\infty}(r-b(r))\left[\ln\left(\frac{e^{2\phi(r)}}{1-\frac{b(r)}{r}}\right)\right]' dr. \tag{13}$$

For instance, for the metric (10), one finds

$$I_V = -\frac{1}{\kappa}\int_{r_0}^{+\infty}(r-r_0)\left[\ln\left(1-\frac{r_0}{r}\right)\right]' dr = -\frac{r_0}{\kappa}\left[\ln(r)\right]_{r_0}^{+\infty} \to -\infty \tag{14}$$

which means that an infinite amount of negative energy is necessary to build such a wormhole. This was also confirmed in Ref.[1]. For this reason, we are going to explore the possibilities offered by the second EoS. The third EoS requires a careful analysis and it will not presented here. In particular, we would like to consider Yukawa-type profiles for $b(r)$ and $\omega(r)$. The hope is that such a profile concentrates more the energy density to the wormhole throat and thus minimizes the usage of exotic matter.

## 2. The Inhomogeneous Equation of State and the Volume Integral Quantifier

When we apply the inhomogeneous EoS $p_r = \omega(r)\rho$ to find the corresponding shape function, one finds

$$b(r) = r_0 \exp\left[-\int_{r_0}^{r}\frac{d\bar{r}}{\omega(\bar{r})\bar{r}}\right]. \tag{15}$$

The shape function (15) is obtained by imposing $\phi'(r) = 0$. Since we know the form of the redshift function and of the shape function, the SET can also be easily computed

$$T_{\mu\nu} = \frac{r_0}{\kappa r^3}\left(-\frac{1}{\omega(r)}, -1, \frac{1}{2\omega(r)}+\frac{1}{2}, \frac{1}{2\omega(r)}+\frac{1}{2}\right)\exp\left[-\int_{r_0}^{r}\frac{d\bar{r}}{\omega(\bar{r})\bar{r}}\right]. \tag{16}$$

Note that the SET (16) is traceless. We will examine two specific choices for $\omega(r)$.

### 2.1. *Two examples for $\omega(r)$*

We are going to focus our attention on two examples. The first one is represented by

$$\omega(r) = \frac{1}{\mu r} \qquad \Longrightarrow \qquad \omega(r_0) = \frac{1}{\mu r_0}, \tag{17}$$

leading to

$$b(r) = r_0\exp\left[-\mu(r-r_0)\right] \qquad and \qquad b'(r) = -\mu r_0\exp\left[-\mu(r-r_0)\right] \tag{18}$$

satisfying therefore the flare-out condition since $b'(r_0) = -\mu r_0$. The form of the metric (1) therefore becomes

$$ds^2 = -dt^2 + \frac{dr^2}{1-\frac{r_0\exp[-\mu(r-r_0)]}{r}} + r^2 d\Omega^2, \tag{19}$$

which looks like a Yukawa profile, at least on the radial part. From the line element (19), the SET is easily computed and assumes the following form

$$T_{\mu\nu} = \frac{r_0}{2\kappa r^3}\left[diag\left(-2\mu r, -2, \mu r+1, \mu r+1\right)\right]\exp\left[-\mu\left(r-r_0\right)\right]. \tag{20}$$

Note that the SET is also traceless as it should be, because it is a particular case of the SET (16). On the throat the SET becomes

$$T_{\mu\nu} = \frac{1}{2\kappa r_0^2}\left[diag\left(-2\mu r_0, -2, \mu r_0+1, \mu r_0+1\right)\right] \tag{21}$$

and the following property is satisfied

$$\lim_{\mu\to 0}\lim_{r\to r_0} T_{\mu\nu} = \lim_{r\to r_0}\lim_{\mu\to 0} T_{\mu\nu}. \tag{22}$$

On the other hand, we find

$$\lim_{\mu\to\infty}\lim_{r\to r_0} T_{\mu\nu} \neq \lim_{r\to r_0}\lim_{\mu\to\infty} T_{\mu\nu}. \tag{23}$$

In particular, $\lim\limits_{\mu\to\infty}\lim\limits_{r-r_0} T_{\mu\nu}$ is not defined, while (27)

$$\lim_{r\to r_0}\lim_{\mu\to\infty} T_{\mu\nu} = \left[diag\left(0,0,0,0\right)\right] \tag{24}$$

corresponding to the Minkowski space written in spherical coordinates. This can be confirmed also by looking at the line element (19). The corresponding $I_V$ for the line element (1) becomes

$$\begin{aligned} I_V &= \frac{1}{\kappa}\int_{r_0}^{+\infty}\left(r - r_0 e^{-\mu(r-r_0)}\right)\left[\ln\left(1-\frac{r_0}{r}e^{-\mu(r-r_0)}\right)\right]' dr \\ &= \frac{r_0}{\kappa}\left(1+e^{\mu r_0}\,\mathrm{Ei}_1\left(\mu r_0\right)\right), \end{aligned} \tag{25}$$

where $\mathrm{Ei}_1\left(x\right)$ is the exponential integral. Since the integrand is finite, we can easily evaluate the behavior close to the throat, whose result is

$$\begin{aligned} I_V \simeq \frac{r_0}{\kappa}\,&\left(1-\exp\left(\mu r_0\right)\mathrm{Ei}_1\left(\mu\left(r_0+\varepsilon\right)\right) + \exp\left(\mu r_0\right)\mathrm{Ei}_1\left(\mu r_0\right) - \exp\left(-\mu\varepsilon\right)\right) \to 0 \\ &\text{when } \varepsilon \to 0, \end{aligned} \tag{26}$$

namely $I_V$ can be arbitrarily small. The second example we are going to discuss is the following

$$\omega\left(r\right) = \frac{\exp\left[-\mu\left(r-r_0\right)\right]}{\mu r}, \tag{27}$$

which has the following properties

$$\omega\left(r\right) \underset{r\to\infty}{\to} 0 \qquad and \qquad \omega\left(r_0\right) = \frac{1}{\mu r_0}. \tag{28}$$

Plugging (27) into the shape function (15), one finds

$$\begin{aligned} b(r) &= r_0\exp\left[1-\exp\left(\mu\left(r-r_0\right)\right)\right] \\ b'(r) &= -\mu r_0\,\exp\left[\mu\,\left(r-r_0\right)+1-\exp\left(\mu\,\left(r-r_0\right)\right)\right], \end{aligned} \tag{29}$$

satisfying the flare-out condition since

$$b'(r_0) = -\mu r_0\,. \tag{30}$$

Even in this case, the SET is easily computed and assumes the explicit form

$$T_{\mu\nu} = \frac{r_0}{2\kappa r^3}\left[diag\left(-\frac{2}{\omega\,(r)}, -2, \frac{1}{\omega\,(r)}+1, \frac{1}{\omega\,(r)}+1\right)\right]\exp\left[1-\exp\left(\mu\,(r-r_0)\right)\right], \tag{31}$$

where $\omega\,(r)$ is given by Eq.(27). On the throat, one gets

$$T_{\mu\nu} = \frac{1}{2\kappa r_0^2}\left[diag\left(-2\mu r_0, -2, \mu r_0+1, \mu r_0+1\right)\right] \tag{32}$$

and also in this case we obtain the same behavior of the SET (20). It is interesting to note that, on the throat, the behavior of the SET in (20) and in (31) are equal. The corresponding $I_V$ for the line element (1) becomes

$$I_V = -\frac{1}{\kappa}\int_{r_0}^{+\infty}\left(r - r_0\exp\left[1-\exp\left(\mu\,(r-r_0)\right)\right]\right) \times\left[\ln\left(1-\frac{r_0\exp\left[1-\exp\left(\mu\,(r-r_0)\right)\right]}{r}\right)\right]'dr = -\frac{1}{\kappa}\int_{r_0}^{+\infty} f\,(r)\,dr, \tag{33}$$

where

$$f\,(r) = \frac{r_0\exp\left[1-\exp\left(\mu\,(r-r_0)\right)\right]\left(\exp\left(\mu\,(r-r_0)\right)\mu\,r+1\right)}{r}. \tag{34}$$

The exact evaluation of $I_V$ is quite complicated but, an estimate when $r \gg r_0$ is possible to see if the integral is finite for large $r$. Indeed, one finds that the integrand becomes

$$f\,(r) \underset{r\to\infty}{\simeq} \frac{\mu r_0\exp\left(\mu\,(r-r_0)+1\right)}{\exp\left(\exp\left(\mu\,(r-r_0)\right)\right)}$$
$$\Longrightarrow I_V \simeq -r_0\exp\left(1-\exp\left(\mu\,(r-r_0)\right)\right) \to 0 \qquad \text{when } r\to\infty \tag{35}$$

and therefore $I_V$ will be finite close to infinity. On the other hand, close to the throat, we can write

$$I_V \simeq \frac{1}{\kappa}\int_{r_0}^{r_0+\varepsilon}\left(\mu r_0+1\right)dr \to 0 \qquad \text{when } \varepsilon\to 0. \tag{36}$$

Note that we might have chosen the following form

$$\omega\,(r) = \frac{\exp\left(-\mu r\right)}{\mu r}, \tag{37}$$

instead of (27). However, while the properties at infinity are equal to the profile (27), close to the throat one finds

$$\omega\,(r_0) = \frac{\exp\left(-\mu r_0\right)}{\mu r_0}. \tag{38}$$

As a consequence, the shape function becomes

$$b\left(r\right)=r_{0}\exp\left(\exp\left(\mu r_{0}\right)-\exp\left(\mu r\right)\right) \tag{39}$$

while the energy density is

$$\rho(r)=-\frac{\mu r_{0}}{\kappa r^{2}}\exp\left(\mu r+\exp\left(\mu r_{0}\right)-\exp\left(\mu r\right)\right). \tag{40}$$

If we compare the energy density obtained with (27) with the one computed with (37), we can see that, on the throat, the amount of negative energy density is larger for the choice (37) because

$$\rho(r)=-\frac{\mu}{\kappa r_{0}}\exp\left(\mu r_{0}\right). \tag{41}$$

This implies that the choice (27) is favored from an energetically point of view. The same conclusion can be reached comparing the energy density obtained with (37) with the one obtained with (17). On the other hand, when we compare the energy density obtained with (17) and the one obtained with (27), we find

$$\frac{\rho_{\omega_{2}}(r)}{\rho_{\omega_{1}}(r)}=\frac{\exp\left[\mu\ \left(r-r_{0}\right)+1-\exp\left(\mu\ \left(r-r_{0}\right)\right)\right]}{\exp\left[-\mu\left(r-r_{0}\right)\right]}\underset{r\rightarrow\infty}{\longrightarrow}0, \tag{42}$$

where $\rho_{\omega_{1}}(r)$ is the energy density obtained with the help of (17) and represented by the first component of the SET (20), while $\rho_{\omega_{2}}(r)$ is the energy density obtained with the help of (27) and represented by the first component of the SET (31). The behavior shown in (42) reveals that the negativity of the energy density is really concentrated in the proximity of the throat. A further investigation inspired by Yukawa profiles could be related to the Self Sustained Traversable Wormholes, i.e., traversable wormholes which are sustained by their own quantum fluctuations[4–7].

A lot can be learned about black holes and wormholes by re-scaling spacetime itself without changing the coordinates used to describe it. Such a conformal transformation is called a Weyl transformation. It takes spacetime from a given frame — called Einstein frame — to a conformal frame — called Jordan frame. Such a transformation reveals that horizons and wormholes might appear/disappear in the conformal frame even if they were absent/present in the original frame. It arises both from the simple prescription for defining black holes and wormholes, as well as from the more sophisticated definitions. In addition, some definitions might be transformed into one another under Weyl transformations.

*Keywords*: Black holes; Wormholes; Weyl transformation; Cosmology.

## 1. Introduction

A Weyl transformation consists in re-scaling spacetime without changing its coordinates. It is described by a simple transformation that takes an original spacetime metric $g_{\mu\nu}$ into a new metric $\tilde{g}_{\mu\nu}$ such that,

$$\tilde{g}_{\mu\nu} = e^{2\Omega} g_{\mu\nu}, \tag{1}$$

where $\Omega(x)$ is spacetime-dependent function, everywhere regular and non-vanishing.

On the other hand, various definitions of black holes and wormholes have been given in the literature. They range from what could be considered as a simple "prescription" to what could be called "sophisticated" definitions.

## 2. The simple "prescription"

This prescription works only for spherically symmetric metrics that depend only on the time coordinate $t$ and a radial coordinate. The latter could be chosen to be the physical areal radius $R$ that multiplies $\mathrm{d}\Theta^2 = \mathrm{d}\vartheta^2 + \sin^2\vartheta \mathrm{d}\varphi^2$. The radial coordinate could also be chosen to be any other real parameter $r$ on which all the components of the metric would depend.

Using $R$ as the radial coordinate, a spherically symmetric metric is written as,

$$\mathrm{d}s^2 = -A(t,R)\mathrm{d}t^2 + B(t,R)\mathrm{d}R^2 + R^2\mathrm{d}\Theta^2, \tag{2}$$

where, $A(t,R)$ and $B(t,R)$ are functions of the time coordinate $t$ and the areal radius $R$. The simple prescription for defining black holes and wormholes consists then

*This talk is based on the published paper 1

(see Ref. 2 and the references therein) in checking whether the following algebraic equation,

$$g^{\mu\nu}\nabla_\mu R\nabla_\mu R = 0, \tag{3}$$

has a single- or a double-root. The single-root solution is identified with the location of the closed 2-surface of a black hole horizon, whereas the double-root is identified with the location of the 2-surface of a wormhole throat. Although this procedure is incomplete and imprecise, it is useful in practice since it gives a quick way of localizing the radial coordinate of an apparent horizon and/or a wormhole throat.

### 2.1. *Weyl transformation and the simple prescription*

The Weyl conformal transformation (1) changes the prescription (3) and the metric (2) into the following ones, respectively, to be used in the conformal frame,[2]

$$\mathrm{d}\tilde{s}^2 = -e^{2\Omega}A(t,R)\mathrm{d}t^2 + e^{2\Omega}B(t,R)\mathrm{d}R^2 + \tilde{R}(t)^2\mathrm{d}\Theta^2, \tag{4}$$

$$\tilde{g}^{\mu\nu}\tilde{\nabla}_\mu\tilde{R}\tilde{\nabla}_\mu\tilde{R} = 0. \tag{5}$$

Here, $\tilde{R}(t) = e^{2\Omega}R(t)$ is the areal radius in te conformal frame. Using the metric (4), after having rewritten it entirely in terms of the pair $(\tilde{t},\tilde{R})$ — which is in itself a very tedious task 2 — and then applying the conformal prescription (5), one finds,

$$\frac{1}{B}(\Omega_{,R}R+1)^2 - \frac{1}{A}\Omega_{,t}^2R^2 = 0. \tag{6}$$

While this condition does give the locations of the various possible black hole horizons and wormhole throats in the static case, it does not describe in detail their real origin in the dynamical case. As shown in Ref. 1, if one uses instead an arbitrary parameter $r$ as the radial coordinate and writes the metric (2) as,

$$\mathrm{d}s^2 = -A(t,r)\mathrm{d}t^2 + B(t,r)\mathrm{d}r^2 + R(t,r)^2\mathrm{d}\Theta^2, \tag{7}$$

Weyl's conformal transformation (1) turns the latter into the following form,

$$\mathrm{d}\tilde{s}^2 = -e^{2\Omega}A(t,r)\mathrm{d}t^2 + e^{2\Omega}B(t,r)\mathrm{d}r^2 + \tilde{R}(t,r)^2\mathrm{d}\Theta^2. \tag{8}$$

Applying the conformal prescription (5) on this last form of the metric gives after a pretty short and a simple calculation the following condition for detecting black holes and/or wormholes,[1]

$$\frac{1}{B}(\Omega_{,r}R+R_{,r})^2 - \frac{1}{A}(\Omega_{,t}R+R_{,t})^2 = 0. \tag{9}$$

We clearly see form this condition how and when a black hole and/or a wormhole might arise in the conformal frame. In fact, contrary to Eq. (6), the condition (9) contains all the necessary information on the time and space dependences of both the areal radius $R$ and the conformal exponent $\Omega$.

## 3. "Sophisticated" definitions for general spacetimes

Besides the simple prescription (3) for detecting black hole horizons and wormholes, various other definitions are also given in the literature. Since these other definitions are rather valid for any spacetime and involve the concept of null vectors, trapped surfaces, and geodesic expansions, we call them the sophisticated definitions. An important fundamental feature of the sophisticated definitions is that, in contrast to the simple prescription (3), these more rigorous definitions do not allow a black hole horizon to coincide with a wormhole throat. These definitions make a clear distinction between the two concepts.

### 3.1. *Black hole horizon*

A generic black hole horizon is defined as being the future outer trapping horizon.[3] Such a statement is translated into the following three conditions to be satisfied on the 2-surface $H$ of the horizon,[3]

$$\theta_+|_H = 0, \qquad \theta_-|_H < 0, \qquad \partial_-\theta_+|_H < 0. \tag{10}$$

The quantities $\theta_\pm$ represent the expansion of the outgoing (ingoing) null geodesics, the tangent vectors of which are denoted $l^\mu_\pm$, respectively. The partial derivatives, $\partial_\pm$, stand for derivative with respect to an affine parameter $u^\pm$ along the geodesic $l^\mu_\pm$.

### 3.2. *Hochberg-Visser wormhole*

A simple, covariant, and quasilocal definition of a wormhole throat, as defined in Ref. 4, and which we shall call a Hochberg-Visser wormhole, is that of a marginally anti-trapped surface. This definition does not involve any information about the faraway region outside the throat. It simply consists of the hypersurface foliated by compact spatial 2-surfaces $S$ on which the following conditions are satisfied,[4]

$$\theta_\pm|_S = 0 \qquad \text{and} \qquad \partial_\pm\theta_\pm|_S > 0. \tag{11}$$

### 3.3. *Hayward wormhole*

Another simple, covariant, and quasilocal definition for wormholes is the one given in Ref. 5, and which we shall call here a Hayward wormhole. According to this definition, a wormhole throat is a *timelike* hypersurface foliated by a non-vanishing minimal spatial 2-surface $S$ on a null hypersurface, *i.e.*, a timelike trapping horizon. This statement is formally expressed by the following three conditions,[5]

$$\theta_\pm|_S = 0, \qquad \partial_\pm\theta_\pm|_S > 0, \qquad \partial_\mp\theta_\pm|_S < 0. \tag{12}$$

In other words, Hochberg-Visser wormholes include spacelike hypersurfaces and therefore are not necessarily Hayward wormholes.

### 3.4. *Maeda-Harada-Carr wormhole*

This wormhole is a 2-surface required to be extremal on a spacelike hypersurface. Using a null coordinate foliation, a spherically symmetric metric takes the form $\mathrm{d}s^2 = -2e^{2f}\mathrm{d}u\mathrm{d}v + R^2\mathrm{d}\Theta^2$, where $u$ and $v$ are the null coordinates and $f = f(u, v)$ is a function of these. The Maeda-Harada-Carr wormhole then consists of the 2-sphere $S$, of radius $R = R(u, v)$, which is extremal and minimal in a spacelike radial direction $\zeta^\mu$. Formally, this translate into the following two conditions,[6]

$$R_{|A}\zeta^A\big|_S = 0 \qquad \text{and} \qquad R_{|AB}\zeta^A\zeta^B\big|_S > 0. \tag{13}$$

A vertical bar with the subscript, $|_A$, stands for a covariant derivative with respect to the two-metric $g_{AB}$ of the two-dimensional spacetime spanned by the null vectors $\partial_u$ and $\partial_v$.

### 3.5. *Tomikawa-Izumi-Shiromizu wormhole*

As in the case of the Maeda-Harada-Carr wormhole, the minimality of the 2-surface $S$ representing a Tomikawa-Izumi-Shiromizu wormhole is imposed on a spacelike hypersurface. In contrast to all the above definitions, however, what is required for this wormhole is the vanishing, not of the expansions themselves, but of the difference $\theta_+ - \theta_-$ between the outgoing and ingoing expansions. This translates into the following two conditions,[7]

$$\theta_+ - \theta_-|_S = 0 \qquad \text{and} \qquad (\partial_+ - \partial_-)(\theta_+ - \theta_-)|_S > 0. \tag{14}$$

## 4. Weyl transformation and the sophisticated definitions

In order to find the affect of a Weyl transformation on each of the above more rigorous definitions, one only needs to figure out how the null tangents $l^\mu_\pm$, the transverse metric $h_{\mu\nu}$, and the null expansions $\theta_\pm$ transform under (1). It is straightforward to show that $\tilde{h}_{\mu\nu} = e^{2\Omega}h_{\mu\nu}$, $\tilde{l}^\mu_\pm = e^{-\Omega}l^\mu_\pm$ and that $\tilde{\theta}_\pm = e^{-\Omega}\left(\theta_\pm + 2\partial_\pm\Omega\right)$.[1] With these simple transformations at hand, it is easy to find the behavior under Weyl's conformal transformation of all the above sophisticated black hole and wormhole definitions.

### 4.1. *Conformal black holes*

The definition (10) conformally transforms into the following three conditions,[1]

$$\begin{gathered}\theta_+ + 2\partial_+\Omega\big|_H = 0, \qquad \theta_- + 2\partial_-\Omega\big|_H < 0, \\ \partial_-\theta_+ + 2\partial_-\partial_+\Omega\big|_H < 0.\end{gathered} \tag{15}$$

From the first equality, we learn that in the absence of a black hole in the original frame, it is possible for a black hole horizon to arise in the new frame provided only that the conformal exponent $\Omega$ does vary with $u^+$. On the other hand, to have a black hole in the conformal frame if one already exists in the original frame, $\Omega$ must be independent of $u^+$.

### 4.2. *Conformal Hochberg-Visser wormhole*

The definition (11) of such a wormhole conformally transforms into the following two conditions,[1]

$$\theta_{\pm} + 2\partial_{\pm}\Omega\big|_S = 0 \quad \text{and} \quad \partial_{\pm}\theta_{\pm} + 2\partial_{\pm}\partial_{\pm}\Omega\big|_S > 0. \tag{16}$$

From the first equality we see that to have a Hochberg-Visser wormhole in the new frame if one already exists in the old frame, the conformal exponent must again be independent of the parameter $u^{\pm}$.

### 4.3. *Conformal Hayward wormhole*

The definition (12) of such a wormhole conformally transforms into the following three conditions,[1]

$$\begin{gathered} \theta_{\pm} + 2\partial_{\pm}\Omega\big|_S = 0, \qquad \partial_{\pm}\theta_{\pm} + 2\partial_{\pm}\partial_{\pm}\Omega\big|_S > 0, \\ \partial_{\mp}\theta_{\pm} + 2\partial_{\mp}\partial_{\pm}\Omega\big|_S < 0. \end{gathered} \tag{17}$$

Like for the Hochberg-Visser wormhole, if a Hayward wormhole already exists in the old frame another one might arise in the new frame if $\Omega$ is indepednet of $u^{+}$. Recall that a Hayward wormhole is necessarily a Hochberg-Visser wormhole but the converse is not true. However, if the conformal factor is chosen such tha the last inequality in (17) is not satisfied but the second inequality is, then a Hayward wormhole transforms into a pure Hochberg-Visser wormhole.

### 4.4. *Conformal Maeda-Harada-Carr wormhole*

The definition (13) of such a wormhole conformally transforms into the following three conditions,[1]

$$\begin{aligned} &\zeta^A \left(R_{|A} + R\Omega_{|A}\right)\Big|_S = 0 \\ &\zeta^A\zeta^B \left(R_{|AB} + R\Omega_{|AB} - R\Omega_{|A}\Omega_{|B}\right) \\ &\qquad + \zeta^A\zeta^B g_{AB}\left(R_{|C}\Omega^{|C} + R\Omega_{|C}\Omega^{|C}\right)\Big|_S > 0. \end{aligned} \tag{18}$$

Although these conditions are more complicated, it is clear that a Maeda-Harada-Carr wormhole can arise or disappear in the conformal frame depending on one's choice of $\Omega$. For a worked out example, though, see Ref. 1.

### 4.5. *Conformal Tomikawa-Izumi-Shiromizu wormhole*

The definition (14) of such a wormhole conformally transforms into the following two conditions,[1]

$$\begin{gathered} \theta_+ - \theta_- + 2\left(\partial_+\Omega - \partial_-\Omega\right)\Big|_S = 0, \\ \left(\partial_+ - \partial_-\right)\left[\theta_+ - \theta_- + 2\left(\partial_+\Omega - \partial_-\Omega\right)\right]\Big|_S > 0. \end{gathered} \tag{19}$$

Again, we see that a Tomikawa-Izumi-Shiromizu wormhole can arise in the conformal frame, even if in the original frame there was none, provided that the conformal factor is chosen to satisfy both conditions (19). Worked out examples are found in Ref. 1.

## 5. Conclusion

A conformal transformation can make black holes and wormholes appear or disappear just by judiciously choosing the conformal factor $\Omega$. A conformal transformation thus does have a non-trivial effect on a given physical concept just as it was already shown in Refs. 8, 9 regarding the fate of the concept of a quasilocal mass.

Ever since their revival three decades ago, in the seminal work of Morris and Thorne, Lorentzian wormholes in General Relativity have led an uncomfortable existence because they require matter which violates the well-known energy conditions. However, in scalar-tensor and other theories of gravity, realistic wormholes can indeed exist with 'normal matter'. We illustrate this with some known examples and also by explicitly constructing a zero Ricci scalar wormhole in a four dimensional scalar-tensor, on-brane gravity theory arising from the two-brane Randall-Sundrum model with one extra dimension. If such a wormhole could arise as the end-state of some astrophysical process, its ringdown may be studied using gravitational waves. With this aim, we obtain the scalar quasinormal modes in this class of wormholes and choose to identify them as for the 'breathing mode' associated with gravitational waves in scalar-tensor theories. Finally, if a breathing mode is indeed observed in LIGO-like detectors with design sensitivity, and has a maximum amplitude equal to that of the tensor mode that was observed of GW150914, then for a range of values of the wormhole parameters we will be able to discern it from a black hole. If in future observations we are able to confirm the existence of such wormholes, we would, at one go, have some indirect evidence of a modified theory of gravity as well as extra spatial dimensions.

## 1. Lorentzian wormholes: a quick introduction

The earliest example of a spacetime resembling the Lorentzian wormhole of today is the well-known Einstein-Rosen bridge[1], which, though a two-sheeted geometry, is however non-traversable and has a degenerate metric (the determinant of $g_{ij}$ vanishes at the throat). Subsequent to Einstein-Rosen, wormholes appear in the Misner-Wheeler study of *geons*[2]. Later, in the early 1970s, Ellis and Bronnikov[3] constructed a wormhole solution of the Einstein-scalar equations (the 'phantom' scalar had a wrong-sign kinetic energy). The modern-day Lorentzian wormhole was defined largely in the 1988 paper of Morris and Thorne[4] who also constructed a wormhole time machine[5]. Various other methods, such as *Schwarzschild surgery* were developed by Visser in the 1990s (see[6] for further details and an overview of early work).

Lorentzian wormholes have an existence problem in General Relativity(GR), largely due to the fact that they require matter to violate the *Weak or Null Energy Condition*. The cause behind this is the nature of the geometry which acts as a *defocusing lens* for a congruence of null or timelike geodesics[4]. Such defocusing entails a violation of the *convergence conditions, null or timelike*. Since the convergence

conditions are directly related to the energy conditions via Einstein's field equations of GR, we end up violating the energy conditions obn matter as well[4]. Various ways have been suggested in order to resolve this issue[7] within GR, but success, at best, is very limited.

A way out of this impasse is to consider modified theories of gravity. Here we will focus on one class of such theories which are born out of the effective on-brane scalar-tensor gravity resulting from the two-brane Randall-Sundrum model with one orbifolded extra dimension[8]. In such an effective theory one can avoid energy-condition violation, though violation of the convergence condition (as expected for wormholes) remains upheld. The above possibility emerges because we have a *scalar field* contribution on the R. H. S. of the field equations, apart from the energy-momentum of matter. The scalar field piece is not quite 'matter', because its origin lies in the *distance between the branes embedded in the bulk*. We can therefore have *realistic Lorentzian wormholes* in this theory, a fact we demostrate below, in brief.

Given such a possible wormhole with 'good' matter, one is therefore encouraged to see if there are chances of detecting it. If we imagine some astrophysical collision process creating such a wormhole, then, its quasinormal (QNM) ringing will indeed be a signature. It is also important to note that among the allowed gravitational wave polarisations in a scalar-tensor theory there is a *scalar breathing mode*, apart from the standard + and × polarisations which exist in GR. Hence, a study of the scalar wave equation and a determination of the scalar quasinormal modes could be a way of detecting the wormhole. After deriving the frequencies and time-constants of the QNMs as functions of the metric parameters, we use them to estimate the percentage errors in the parameters via the Fisher matrix formalism. We follow this line of investigation in our work. Our findings suggest that observations with multiple detectors can be used to put interesting limits on scalar-mode emissions and, thereby, constrain parameters of such wormholes.

## 2. A WEC satisfying realistic wormhole in a two-brane RS model

Let us first write down the wormhole spacetime which is a solution in a effective on-brane scalar-tensor theory and is threaded by matter satisfying the WEC. The Einstein field equations for such a scalar-tensor theory are given as[8]:

$$\Phi G_{\mu\nu} = \bar{\kappa} T^b_{\mu\nu} + (\nabla_\mu \nabla_\nu \Phi - g_{\mu\nu} \nabla^\alpha \nabla_\alpha \Phi) - \frac{3}{2(1+\Phi)} \left( \nabla_\mu \Phi \nabla_\nu \Phi - \frac{1}{2} g_{\mu\nu} \nabla^\alpha \Phi \nabla_\alpha \Phi \right) \tag{1}$$

The scalar field equation turns out to be:

$$\Box \Phi = \frac{\bar{\kappa}}{l} \frac{T^b}{2\omega + 3} - \frac{1}{2\omega + 3} \frac{d\omega}{d\Phi} \nabla^\alpha \Phi \nabla_\alpha \Phi \tag{2}$$

Note that the R. H. S of the Einstein equations has a 'matter stress energy' (the $T^b_{\mu\nu}$) and a contribution from the scalar field $\phi$. If one uses the $G_{\mu\nu}$ in the R. H. S. of,

say, the null Raychaudhuri equation, one notices that *the convergence condition can be violated, without violating the WEC for matter*. In other words, the negativity required for the violation of the convergence condition can be supplied via the $\phi$ dependent pieces on the R. H. S. in the Einstein equation, keeping $T^b_{\mu\nu}k^\mu k^\nu$ always positive. The $R = 0$ line element which achieves this, with an everywhere finite and non-zero scalar field is[9–11]:

$$ds^2 = -\left(\kappa + \lambda\sqrt{1 - \frac{2M}{r}}\right)^2 dt^2 + \frac{dr^2}{1 - \frac{2M}{r}} + r^2 d\Omega_2^2 \tag{3}$$

where $\kappa, \lambda > 0$, $r \geq 2M$. The wormhole throat is at $r = 2M$. It has a spatial slice identical to that for the Schwarzschild black hole.

The WEC inequalities for the required matter ($\rho \geq 0, \rho + \tau \geq 0, \rho + p \geq 0$, where $\rho$, $\tau$, $p$ are the non-zero, diagonal components of the energy momentum tensor), have been checked and are satisfied[11] as shown in Figs. 1,2,3. In these plots $x = \frac{M}{2r'}$ where $r'$ is the isotropic coordinate.

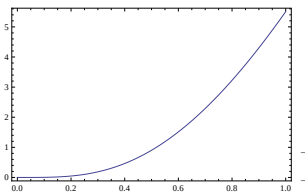

Fig. 1. $\rho$ vs. $x$

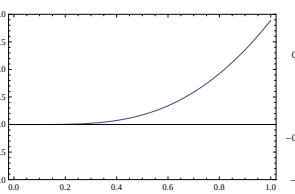

Fig. 2. $\rho + \tau$ vs. $x$

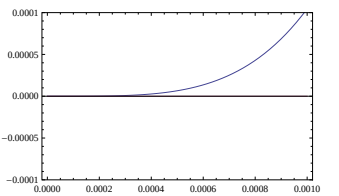

Fig. 3. $10^6(\rho + p)$ vs. $x$

## 3. How to detect: observational possibities using GWs

As mentioned earlier, we imagine the end-state of a collision of astrophysical objects (black holes, neutron stars, wormholes?) as a two-parameter ($M$ and $\frac{\kappa}{\lambda}$) wormhole of the type discussed in the previous section. Being a solution of a scalar-tensor theory, where the *breathing mode* polarisation exists apart from the standard GR + and × polarisations[12], it is plausible that scalar perturbations produce it. It can be shown that the scalar wave equation which we wrote earlier, when perturbed (i.e. $\phi \to \phi + \delta\phi$) yields, with a suitable gauge choice, an equation of the form $\Box\delta\phi = 0$. Therefore, by studying the scalar QNMs one can obtain information about the frequencies and damping rates of the ring-down process. Of course, gravitational perturbations must also be present, but here we focus only on the scalar breathing mode. The effective potential as a function of the tortoise coordinate $r_*$ is shown in Fig. 4.[13] Note the double barrier structure of the potential. The time-domain profiles for the ring-down are shown in Figs. 5, 6.[13]

### 3.1. *Scalar quasinormal modes–breathing mode*

We find the quasinormal modes (fundamentals) by using Prony Fit as well as by using direct integration[13]. The values found using the two methods do agree with each other. In Figs.7,8 the real and imaginary parts of the QNMs are shown as functions of $\lambda$, where we have chosen $\kappa + \lambda = 1$. In order to use the QNMs for evaluating the percentage errors we fit the QNM profiles using *NonlinearLeastSquareFit* in *Mathematica 10.0*. The fitted curves are shown as the continuous lines in Figs. 7, 8.

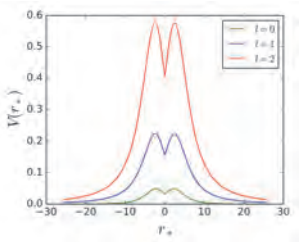

Fig. 4. The effective potential $V_{eff}(r_*)$.

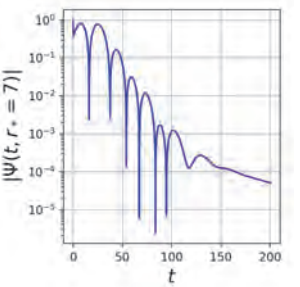

Fig. 5. Time domain profile

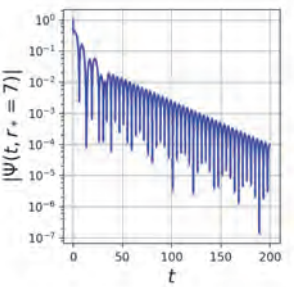

Fig. 6. Time domain profile

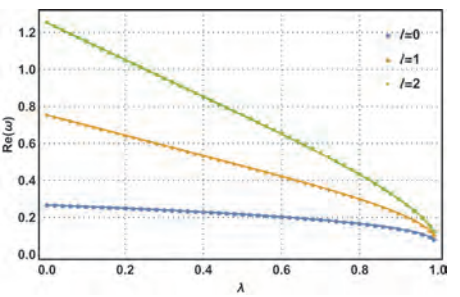

Fig. 7. Real part of QNM vs. $\lambda$.

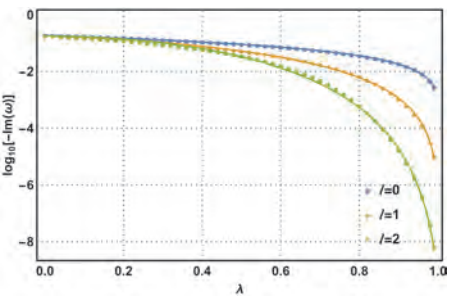

Fig. 8. Imaginary part of QNM vs $\lambda$.

An example of the fitted profile function is shown below. For $l = 0$, we have,

$$\nu = \frac{8628.13}{M}\left(1 - 0.29\frac{\lambda}{\lambda+\kappa}\right)\left(1 - \left(\frac{\lambda}{\lambda+\kappa}\right)^{2.36}\right)^{0.24} \tag{4}$$

$$\tau = \frac{M}{38908.58}\left(1 - 0.99\left(\frac{\lambda}{\lambda+\kappa}\right)^{0.94}\right)^{-1.02} \tag{5}$$

For $M = 68M_{sun}$ and $\frac{\kappa}{\lambda} = 0.1$ we obtain $\nu = 64$ Hz.

The breathing mode signal may be written as: $h(t) = A\sin(2\pi\nu t)e^{-t/\tau}$ where the strain amplitude $A$ contains the breathing-mode antenna pattern. Thus, knowing $\nu$ and $\tau$ from the extracted signal, one can find the $\frac{\kappa}{\lambda}$ and $M$, in principle. However, one must extract the signal from detector noise for which it is crucial to estimate errors.

### 3.2. *Error estimates*

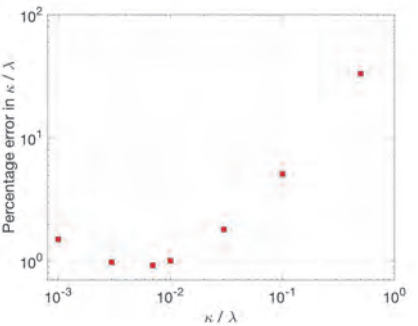

Fig. 9. Percentage error vs. $\frac{\kappa}{\lambda}$

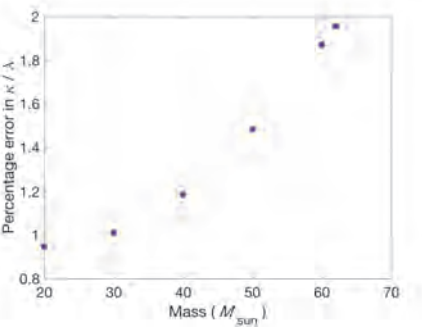

Fig. 10. Percentage error vs. $M$.

The percentage errors in $\frac{\kappa}{\lambda}$ can be calculated via the Fisher information matrix formalism. We estimate how accurately the wormhole parameters will be measurable using future interferometric detectors like aLIGO. To estimate the error in $\kappa/\lambda$, we compute that matrix for the damped-sinusoid signal in a single aLIGO detector at design sensitivity, for that parameter alone. The matrix is determined by the derivative of the signal $h$ with respect to $\kappa/\lambda$, which influences both the frequency and the damping time-constant of the signal.

We take $M$ to be known. For reference, the maximum QNM strain amplitude is assumed as $10^{-21}$, which is approximately the maximum amplitude (quadrupolar) of the GW150914 signal. Finally, we invert the information matrix to derive the estimated variance in the measured values of $\kappa/\lambda$. Its square-root gives the lower bound on the statistical error in $\kappa/\lambda$.

Fig. 9 shows the percentage errors in $\frac{\kappa}{\lambda}$ for $M = 30M_{sun}$. The error intially reduces as $\frac{\kappa}{\lambda}$ increases. The mode frequency gradually shifts to the more sensitive parts of the detector band. For higher values of $\frac{\kappa}{\lambda}$ (less than 1) the error increases due to decreasing time constant (heavy damping). Errors for $\frac{\kappa}{\lambda} > 1$ upto 10 have also been found using Einstein Telescope design sensitivities[13]. In Fig . 10, we have fixed $\frac{\kappa}{\lambda} = 0.01$. The error increases with increasing $M$ because the mode frequency decreases, placing the signal in the less sensitive part of the detector band. More details and other plots are available in[13].

### 3.3. *Summary and conclusions*

In the above, we have outlined a way of knowing, through GW observations, whether wormholes could exist. Earlier attempts towards detecting wormholes were largely using gravitational lensing. With new GW data, our proposal seems a better prospect. However, one really needs an astrophysical merger model. It is also necessary to study gravitational perturbations in order to obtain a more complete picture.

If we ever see the specific Lorentzian wormhole we proposed here, it will also be indirect evidence for extra dimensions and modified gravity. We hope that observations in the near future would be able to put better constraints and help decide the viability of Lorentzian wormholes in nature.

# Classical and quantum strong energy inequalities and the Hawking singularity theorem

P. J. Brown, C. J. Fewster and E.-A. Kontou*

*Department of Mathematics, University of York, Heslington, York, YO10 5DD, UK*
**E-mail: eleni.kontou@york.ac.uk*

Hawking's singularity theorem concerns matter obeying the strong energy condition (SEC), which means that all observers experience a non-negative effective energy density (EED). The SEC ensures the timelike convergence property. However, for both classical and quantum fields, violations of the SEC can be observed even in the simplest of cases, like the Klein-Gordon field. Therefore there is a need to develop theorems with weaker restrictions, namely energy conditions averaged over an entire geodesic and weighted local averages of energy densities such as quantum energy inequalities (QEIs). We present lower bounds of the EED for both classical and quantum scalar fields allowing nonzero mass and nonminimal coupling to the scalar curvature. In the quantum case these bounds take the form of a set of state-dependent QEIs valid for the class of Hadamard states. We also discuss how these lower bounds are applied to prove Hawking-type singularity theorems asserting that, along with sufficient initial contraction, the spacetime is future timelike geodesically incomplete.

*Keywords*: quantum fields, gravity, energy conditions, quantum inequalities, singularities

## 1. Introduction

A spacetime is defined to be singular if it possesses at least one incomplete geodesic. The question of whether or not cosmological models either originate or terminate in singularities has been an active subject of research since the formulation of the general theory of relativity. Initial efforts focused on models with high levels of symmetry, until Raychaudhuri's 1955 paper[1] paved the way to more general results. The Raychaudhuri equations in their modern form[2] present the evolution of geodesic congruences, and are the heart of most singularity theorems. For a timelike irrotational congruence with velocity field $U^\mu$, the expansion $\theta = \nabla \cdot U$ satisfies

$$\nabla_U \theta = R_{\mu\nu} U^\mu U^\nu - 2\sigma^2 - \theta^2/(n-1)\,, \tag{1}$$

where $n$ is the spacetime dimension, $\sigma$ is the shear scalar and $R_{\mu\nu}$ is the Ricci tensor. Senovilla[3] has described the singularity theorems in terms of a 'pattern theorem' with three ingredients: an energy condition establishes a focussing effect for geodesics, a causality condition removes the possibility of closed timelike curves, and a boundary or initial condition establishes the existence of some trapped region of spacetime. We divide singularity theorems into 'Hawking-type' after Hawking's original theorem[4] and 'Penrose-type' after Penrose's[5], depending on whether they demonstrate timelike or null geodesic incompleteness respectively. Hawking-type results, which concern us here, are based on the strong energy condition (SEC), which requires that the effective energy density (EED) is non-negative. The EED is defined as $\rho_U := T_{\mu\nu} U^\mu U^\nu - T/(n-2)$ and is easily made negative at individ-

ual points even for the classical minimally coupled scalar field. This situation is exacerbated in quantum field theory (QFT), in which none of the pointwise energy conditions can hold[6].

For these reasons there has long been interest in establishing singularity theorems under weakened energy assumptions, such as requiring the averaged energy along the geodesic to be non-negative. Examples of singularity theorems with such conditions include Refs. 7–9 but none of them address the case of a condition obeyed by quantum fields. Within a QFT the weakened energy conditions take the form of quantum energy inequalities (QEIs). These were introduced by Ford[10] and express a restriction on the possible magnitude and duration of any negative energy densities or fluxes. Our approach follows Ref. 11 which proved singularity theorems with energy conditions inspired by QEIs. For the Hawking-type theorem, it is assumed that

$$\int R_{\mu\nu}\dot{\gamma}^\mu\dot{\gamma}^\nu f^2(\tau)d\tau \geq -|||f|||^2\,, \tag{2}$$

on any timelike geodesic. Here $\dot{\gamma}^\mu$ is the tangent to the timelike geodesic $\gamma$, $|||\cdot|||^2$ is a Sobolev norm of the form $|||f|||^2 = \sum_{\ell=0}^{L} Q_\ell ||f^{(\ell)}||^2$ and $Q_\ell$ are non-negative constants. It is also assumed that there is a compact Cauchy hypersurface intersected by $\gamma$ at $\tau = 0$. Then the spacetime is future timelike geodesic incomplete provided that the required initial contraction obeys

$$\theta(0) \leq -\frac{c}{2} - \int_{-\tau_0}^{\infty} R_{\mu\nu}\dot{\gamma}^\mu\dot{\gamma}^\nu d\tau - |||f|||^2\,, \tag{3}$$

for some $c > 0$ and $f \in C^\infty(\mathbb{R})$ with $\operatorname{supp} f \subset [-\tau_0, \infty)$, $f(\tau) = e^{-c\tau/(n-1)}$ on $[0, \infty)$. It might seem strange at first that large positive values of $R_{\mu\nu}\dot{\gamma}^\mu\dot{\gamma}^\nu$ require larger initial contraction. The reason is that the average energy condition of Eq. (2) means that large positive energies in the past (before the $\theta(0)$ is measured) allow large negative energies in the future that can lead to a divergence of the congruence.

The purpose of this contribution is to describe bounds on the EED for classical and quantum fields, show that they are of the form of Eq. (2) and estimate the contraction needed to prove singularity theorems. In Sec. 2 we treat the classical Einstein-Klein-Gordon field while in Sec. 3 we present a bound on the renormalised expectation value of the EED for the non-minimally coupled quantum scalar field. In Sec. 4 we conclude with a summary and discussion of future work. Our geometrical conventions are those of Ref. 11 and we work on a globally hyperbolic manifold $M$.

## 2. A singularity theorem for the Einstein-Klein-Gordon field

The non-minimally coupled scalar field obeys the field equation $P_\xi\phi = 0$ with $P_\xi := \Box_g + m^2 + \xi R$, where $\xi$ is the coupling constant and

$$T_{\mu\nu} = (\nabla_\mu\phi)(\nabla_\nu\phi) + \frac{1}{2}g_{\mu\nu}(m^2\phi^2 - (\nabla\phi)^2) + \xi(g_{\mu\nu}\Box_g - \nabla_\mu\nabla_\nu - G_{\mu\nu})\phi^2\,. \tag{4}$$

For this stress-energy tensor, after some manipulation, the averaged EED on a timelike geodesic $\gamma$ is

$$\int_\gamma d\tau\, \rho_U\, f^2(\tau) = \int_\gamma d\tau \Bigg\{ -\frac{1-2\xi}{n-2} m^2 f^2(\tau) + \left(1 - 2\xi\frac{n-1}{n-2}\right)(\nabla_{\dot\gamma}\phi)^2 f^2(\tau) + \frac{2\xi}{n-2} h^{\mu\nu}(\nabla_\mu\phi)(\nabla_\nu\phi) f^2(\tau) + 2\xi[\nabla_{\dot\gamma}(f(\tau))\phi]^2 - 2\xi\phi^2(f'(\tau))^2 - \xi\mathcal{R}_\xi\phi^2 \Bigg\}, \quad (5)$$

where $\mathcal{R}_\xi = R_{\mu\nu}\dot\gamma^\mu\dot\gamma^\nu - 2\xi/(n-2)R$, and $h^{\mu\nu} = \dot\gamma^\mu\dot\gamma^\nu - g^{\mu\nu}$ is a positive definite metric. For $\xi \in [0, \xi_c]$, where $\xi_c$ is the conformal coupling constant, all the curvature independent terms have a definite sign, so

$$\int_\gamma d\tau\, \rho_U\, f^2(\tau) \geq -\int_\gamma d\tau \left\{ \frac{1-2\xi}{n-2} m^2 f^2(\tau) + \xi\left(2(f'(\tau))^2 + \mathcal{R}_\xi f^2(\tau)\right)\right\}\phi^2\,. \quad (6)$$

For a field obeying the Einstein's equation, we have that $8\pi\rho_U = R_{\mu\nu}\dot\gamma^\mu\dot\gamma^\nu$ and $(n/2-1)R = 8\pi T$. Moving the curvature terms to the left hand side of Eq. (6)

$$\int R_{\mu\nu}\dot\gamma^\mu\dot\gamma^\nu f(\tau)^2\, d\tau \geq -Q(\|f'\|^2 + \tilde{Q}^2\|f\|^2), \quad (7)$$

with $Q$ and $\tilde{Q}$ positive constants that depend on $\phi_{\max} \geq |\phi|$, $m$, $\xi$ and $n$. We can show that if

$$\theta(0) < -\tilde{Q}\sqrt{Q(n-1) + \frac{Q^2}{2}} - \frac{1}{2}QK\coth(K\tau_0)\,, \quad \text{with } K^2 \geq \tilde{Q}^2 + Q^{-1}R_{\mu\nu}\dot\gamma^\mu\dot\gamma^\nu \text{ on } (-\tau_0, 0]\,, \quad (8)$$

on a compact Cauchy surface, the spacetime is future timelike geodesic incomplete.

Finally, we want to estimate the necessary contraction for realistic scalar fields, using a hybrid model: a quantised scalar field in Minkowski spacetime of dimension 4, in a thermal state of temperature $T < T_m$, $T_m = mc^2/k$ with the maximum field value set by the expectation value of the Wick square at that temperature, $\phi^2_{\max} \sim \langle{:}\phi^2{:}\rangle_T$. As an example we consider the Higgs field with $m = 125\text{GeV}/c^2$, $\theta(0) \sim 10^{-14}\text{s}^{-1}$ for temperature up to $T = 10^{13}$K. Similar results are obtained for other examples. We conclude that when the field mass is taken equal to that of an elementary particle, and provided that the temperature stays below early universe levels we need very little initial contraction for geodesic incompleteness [a].

## 3. Strong quantum energy inequality

To quantise the EED we will follow the algebraic approach. We only consider quasifree, Hadamard states $\omega$, for which the two-point function $W(x,y) = \langle\Phi(x)\Phi(y)\rangle_\omega$ has a prescribed singularity structure so that the difference between two states is smooth.

[a] A detailed proof of the theorem and estimation of the initial contraction is given in Ref. 12.

We follow the methods of Hollands and Wald[13,14] to quantize the stress-energy tensor in a systematic and locally covariant way, and then define the EED as a quantum field by $\rho_U(f) = T_{\mu\nu}(U^\mu U^\nu - g^{\mu\nu}/(n-2)f)$. We are interested in expectation values of the quantized EED in state $\omega$, normal ordered relative to a reference Hadamard state $\omega_0$, $\langle{:}\rho_U{:}(f)\rangle_\omega = \langle\rho_U(f)\rangle_\omega - \langle\rho_U(f)\rangle_{\omega_0}$.

We now turn to the derivation of a quantum strong energy inequality (QSEI), a bound on the renormalised expectation value of EED averaged along a timelike geodesic $\gamma$. Choose any smooth $n$-bein $e_a$ $(a = 0, \ldots, n-1)$ on a tubular neighbourhood of $\gamma$, so that $U^\mu = e_0^\mu$ is everywhere timelike and agrees with $\dot\gamma^\mu$ on $\gamma$. The expectation values of the EED in Hadamard state $\omega$ can be written in terms of the coincidence limits, $[\![\cdot]\!]$ acting on $:W: = W - W_0$. Then we have

$$\langle{:}\rho_U{:}\rangle_\omega = [\![\hat\rho_1{:}W{:}]\!] + [\![\hat\rho_2{:}W{:}]\!] + \left(\xi\mathcal{R}_\xi - \frac{1-2\xi}{n-2}m^2\right)[\![{:}W{:}]\!] \text{ with} \tag{9}$$

$$\hat\rho_1 = \left(1 - 2\xi\frac{n-1}{n-2}\right)(\nabla_U \otimes \nabla_U) + \frac{2\xi}{n-2}\sum_{a=1}^{n-1}(\nabla_{e_a} \otimes \nabla_{e_a})\,, \tag{10a}$$

$$\hat\rho_2 = -2\xi(\mathbb{1} \otimes_{\mathfrak{s}} U^\mu U^\nu \nabla_\mu \nabla_\nu)\,, \tag{10b}$$

where $\otimes_{\mathfrak{s}}$ is the symmetrised tensor product $P \otimes_{\mathfrak{s}} P' = [(P \otimes P') + (P' \otimes P)]/2$. The contribution of the terms deriving from $\hat\rho_1$ to the averaged EED can be bounded from below, uniformly in $\omega$, using the methods of Ref. 15. By contrast, the mass term is negative definite for $\xi < 1/2$, while the geometric term $\mathcal{R}_\xi$ has no definite sign in general. This leaves $\hat\rho_2$, the contribution of which can be manipulated to a more convenient form. With these considerations we can prove

$$\langle{:}\rho_U{:} \circ \gamma\rangle_\omega(f^2) \geq -\left(\mathfrak{Q}_1[f] + \langle{:}\Phi^2{:} \circ \gamma\rangle_\omega(\mathfrak{Q}_2[f] + \mathfrak{Q}_3[f])\right) \text{ where} \tag{11}$$

$$\mathfrak{Q}_1[f] = \int_0^\infty \frac{d\alpha}{\pi}\left(\phi^*(\hat\rho_1 W_0)(\bar f_\alpha, f_\alpha) + 2\xi\alpha^2\phi^* W_0(\bar f_\alpha, f_\alpha)\right)\,, \tag{12a}$$

$$\mathfrak{Q}_2[f] = \frac{1-2\xi}{n-2}m^2 f^2(\tau) + 2\xi(f'(\tau))^2 \text{ and } \mathfrak{Q}_3[f] = \xi\mathcal{R}_\xi(\gamma(\tau))f(\tau)^2\,. \tag{12b}$$

Here $\phi^*$ is the distributional pull-back on the geodesic. An important feature of the QEI (11), is that the lower bound depends on the state of interest $\omega$. We should note however, that the only nontrivial quantum field appearing in the bound is the Wick square $:\Phi^2:$ which enables us to show that the QEI derived is nontrivial (see Ref. 16 for more details).

The establishment of a QSEI is a first step towards a Hawking-type singularity theorem result employing QEI hypotheses. Here we outline a method of obtaining such a result, part of an ongoing work to appear elsewhere. The singularity theorems require a geometric assumption, a condition on the curvature rather than the stress-energy tensor. In the case of classical fields we can use the Einstein equation while when we are treating quantum fields on a classical curved background we can instead use the semiclassical Einstein equation (SEE), $\langle T_{\mu\nu}\rangle_\omega = 8\pi G_{\mu\nu}$. In order to use the

QSEI and the SEE for general curved spacetimes the EED needs to be renormalised by subtracting the Hadamard parametrix instead of a reference state. To overcome this problem we note there is evidence (see e.g. Ref. 17) that in situations where the curvature is bounded we can find a uniform length $\tau_0$ which is small compared to local curvature. Then the Hadamard parametrix on $\tau_0$ approximates that of flat spacetime. Following, we can use Eq. (11) for $f \in C_0^\infty$ supported only to intervals with lengths at most $2\tau_0$. Choosing a state $\omega$ and a metric $g_{\mu\nu}$ that satisfy the EED and the stress energy tensor renormalised with respect to the Minkowski vacuum,

$$\int d\tau f^2(\tau) R_{\mu\nu} U^\mu U^\nu \geq -8\pi \left[ \int_0^\infty \frac{d\alpha}{\pi} \phi^* ((\nabla_U \otimes \nabla_U) W_0)(\bar{f_\alpha}, f_\alpha) + \frac{\mu^2 \phi_{\max}^2 ||f||^2}{n-2} \right], \tag{13}$$

where we also set $\xi = 0$, $\mu$ is the mass of the field and we restrict to a class of Hadamard states for which $|(:\Phi^2:\gamma)_\omega| \leq \phi_{\max}^2$.

To discuss averages over long timescales we will use a partition of unity. We define bump functions each supported on $(-\tau_0, \tau_0)$ and thus obtain a sum of integrals, each of which can be bounded by Eq. (13). Then for even numbers of spacetime dimensions ($m = n/2$), we can show that for $f$ supported on $(-\infty, \infty)$ we have

$$\int_{-\infty}^{\infty} d\tau f^2(\tau) R_{\mu\nu} U^\mu U^\nu \geq -Q_m (||f^{(m)}||^2 + \tilde{Q}_m^2 ||f||^2), \tag{14}$$

where the $Q_m$ and $\tilde{Q}_m$ depend on $\phi_{\max}$, $\mu$, and the maximum values of the chosen bump function and its derivatives. This is an inequality of the form of Eq. (2) so it can be used as a condition to a Hawking-type singularity theorem.

## 4. Conclusions

In this work we presented the derivation of lower bounds on EED for the classical and quantum non-minimally coupled scalar field. In the classical case we presented the proof of a Hawking-type singularity theorem for the Einstein-Klein-Gordon field and estimated the required initial contraction to have future timelike geodesic incompleteness. In the quantum case, using the SEE we showed that we can obtain a condition on the curvature to be used as a hypothesis for a singularity theorem.

Apart from estimating the required initial contraction for the quantum case, the obvious extension of this work is the derivation of an absolute (Hadamard renormalised) QSEI for spacetimes with curvature. Another direction is the derivation of a Penrose-type singularity theorem with a condition obeyed by quantum fields. Finally we should note that similar proofs with weakened energy conditions seem to be possible for other classical relativity theorems.

We consider Ellis wormholes immersed in rotating matter in the form of an ordinary complex boson field. The resulting wormholes may possess full reflection symmetry with respect to the two asymptotically flat spacetime regions. However, there arise also wormhole solutions where the reflection symmetry is broken. The latter always appear in pairs. We analyse the properties of these rotating wormholes and show that their geometry may feature single throats or double throats. We also discuss the ergoregions and the lightring structure of these wormholes.

*Keywords*: wormholes, boson stars, lightrings

## 1. Introduction

The non-trivial topology of wormholes requires the presence of exotic matter in Einstein's General Relativity (see e.g. the recent review[1] of the field). Choosing a massless phantom (scalar) field for the exotic matter, Ellis[2,3] and Bronnikov[4] found static spherically symmetric wormhole solutions, which connect two asymptotically flat regions of space-time.

Their rotating generalizations were first constructed perturbatively for slow rotation[5,6] and later numerically for rapid rotation[7]. In these wormhole solutions the rotation of the throat and thus the spacetime is achieved by an appropriate choice of the boundary conditions. However, this results in the fact that the two asymptotic regions are rotating with respect to one another. Thus while both asymptotic regions are asymptotically flat, the spacetime is not symmetric with respect to reflection at the throat.

In order to obtain rotating wormholes that exhibit a reflection symmetry at the throat, one can immerse the throat inside rotating matter[8,9]. Then the rotation of the matter will drag the spacetime and thus the throat of the wormhole.

## 2. Wormholes Immersed in Rotating Matter

A nice model to study such wormholes immersed in rotating matter is obtained by adding an ordinary massive complex scalar field to the real phantom scalar field into the action, coupling both to gravity. Without the phantom scalar field the model would yield non-rotating and rotating boson stars. The combination of both scalar fields then allows for rotating wormholes immersed in scalar matter, that are

reflection symmetric. Moreover, a new type of non-symmetric wormholes emerges. In the following we will briefly discuss the model and present its rotating wormhole solutions and analyze their properties[8–11].

### 2.1. *Theoretical Setting*

We consider the action $S$

$$S = \int \left[\frac{1}{2\kappa}\mathcal{R} + \mathcal{L}_{\rm bs} + \mathcal{L}_{\rm ph}\right] \sqrt{-g}\; d^4x \tag{1}$$

with the Einstein-Hilbert term, the Lagrangian $\mathcal{L}_{\rm bs}$ of the complex scalar field $\Phi$

$$\mathcal{L}_{\rm bs} = -\frac{1}{2} g^{\mu\nu} \left(\partial_\mu \Phi^* \partial_\nu \Phi + \partial_\nu \Phi^* \partial_\mu \Phi\right) - m_{\rm bs}^2 |\Phi|^2 \ , \tag{2}$$

and the Lagrangian $\mathcal{L}_{\rm ph}$ of the phantom field $\Psi$,

$$\mathcal{L}_{\rm ph} = \frac{1}{2} \partial_\mu \Psi \partial^\mu \Psi \ . \tag{3}$$

The field equations then consist of the Einstein equations

$$G_{\mu\nu} = \mathcal{R}_{\mu\nu} - \frac{1}{2} g_{\mu\nu} \mathcal{R} = \kappa T_{\mu\nu} \tag{4}$$

and the matter field equations

$$\nabla^\mu \nabla_\mu \Psi = 0 \tag{5}$$

and

$$\nabla^\mu \nabla_\mu \Phi = m_{\rm bs}^2 \Phi \ . \tag{6}$$

An appropriate Ansatz for the metric is given by

$$ds^2 = -e^f dt^2 + e^{q-f} \left[e^b (d\eta^2 + h d\theta^2) + h \sin^2\theta (d\varphi - \omega dt)^2\right] \ , \tag{7}$$

where $f$, $q$, $b$ and $\omega$ are functions of $\eta$ and $\theta$, $h = \eta^2 + \eta_0^2$ with throat parameter $\eta_0$, and $\eta$ takes positive and negative values, $-\infty < \eta < \infty$. The ansatz for the rotating bosonic matter is taken as for boson stars

$$\Phi(t, \eta, \theta, \varphi) = \phi(\eta, \theta)\; e^{i\omega_s t + i n \varphi} \ , \tag{8}$$

where $\phi(\eta, \theta)$ is a real function, $\omega_s$ is the boson frequency, $n$ is a rotational quantum number, and the ansatz for the phantom field $\Psi$ is simply

$$\Psi(t, \eta, \theta, \varphi) = \psi(\eta, \theta) \ . \tag{9}$$

The resulting set of six coupled non-linear partial differential equations is then solved numerically subject to an appropriate set of boundary conditions in the two asymptotic regions $\eta \to \pm\infty$, on the axis of rotation $\theta = 0$, and in the equatorial plane $\theta = \pi/2$.

### 2.2. *Symmetric Wormholes*

Let us now discuss the properties of the symmetric wormholes immersed in bosonic matter. In Fig.1a and b we show their mass $M$ and particle number $Q$ versus the boson frequency $\omega_s$ for a typical set of such wormholes ($\eta_0 = 1$, $n = 0, 1, 2$). Their angular momentum $J$ is given by $J = nQ$.

Clearly, the domain of existence is limited by a maximal value $\omega_{\max} = m_b$, where a vacuum configuration with $M = 0 = Q$ is reached, analogous to boson stars. For large values of $\omega_s$ the global charges of the wormholes follow those of boson stars (see the thin black lines in the figures). However, for small $\omega_s$ the spiralling behaviour present in boson stars is basically lost. In fact, the would-be spirals unwind with respect to the frequency and continue to lower frequencies (possibly reaching a singular configuration[10]).

We emphasize that these solutions satisfy the same boundary conditions in both asymptotic regions. Thus in the case of rotation, it is the complex scalar field with its finite rotational quantum number $n$ that imposes the rotation on the configuration. Then the rotation of the scalar field is reflected in the rotation of the

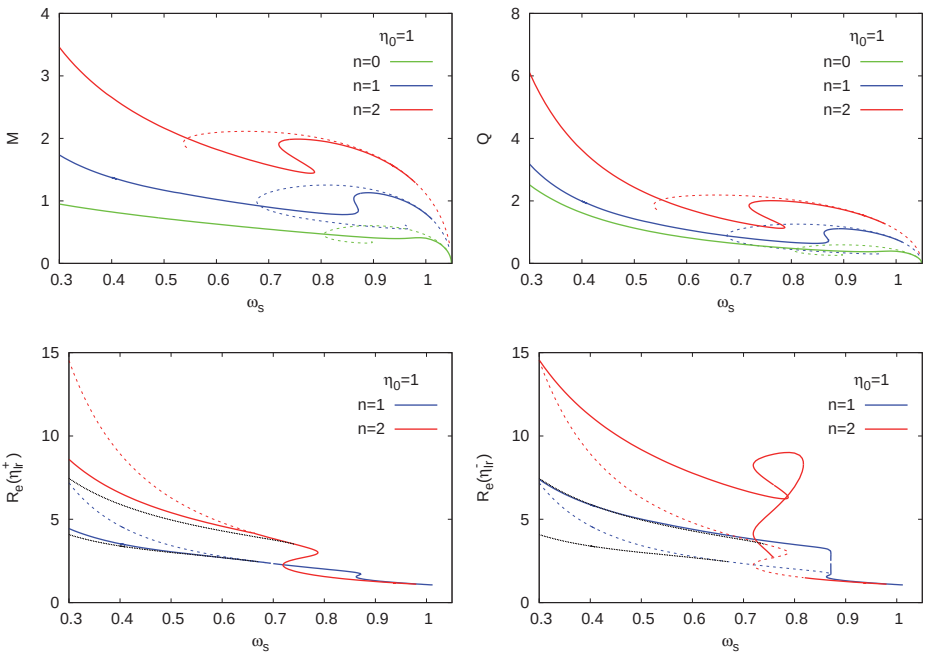

Fig. 1. Properties of symmetric wormhole solutions (throat parameter $\eta_0 = 1$, rotational quantum numbers $n = 0, 1, 2$) versus the boson frequency $\omega_s$: (a) the mass $M$; (b) the particle number $Q$; the dashed lines indicate the respective boson star solutions; (c) the corotation lightring circumferential radius $R_e(\eta_{lr}^+)$; (d) the counterrotation lightring circumferential radius $R_e(\eta_{lr}^-)$; also shown are the circumferential radii of the ergosurfaces (black lines).

spacetime, leading to a rotating throat and frame dragging. Not too surprisingly therefore a sufficiently fast rotation will lead to ergoregions in the wormhole spacetimes. The circumferential radii of the ergoregions are exhibited by the black lines in Fig. 1c and d.

When we consider the geometry of the wormhole solutions we realize that there arises a transition from ordinary single throat wormholes to double throat wormholes with an equator in between, as the frequency $\omega_s$ is decreased. At the transition value the throat degenerates to an inflection point, i.e., the circumferential radius at the center $\eta = 0$ has vanishing first and second derivative.

Of interest are also the lightrings of these spacetimes, as exhibited in Fig. 1c and d for corotating and counterrotating photon orbits, respectively. In particular, we show their circumferential radii $R_e(\eta_{lr}^+)$ and $R_e(\eta_{lr}^-)$. We note that a single lightring exists for large $\omega_s$. For smaller $\omega_s$ two more lightrings emerge. One lightring is always located at $\eta = 0$ (i.e., at the throat or equator), and the additional ones are located symmetrically w.r.t. $\eta = 0$. In the $n = 2$ case up to five lightrings of counterrotating massless particles exist.

### 2.3. *Asymmetric Wormholes*

Let us now focus on another new aspect, namely the presence of symmetric and asymmetric wormhole solutions immersed in bosonic matter. Whereas the field equations are symmetric with respect to reflection of the radial coordinate at the center, and the same boundary conditions are employed in both asymptotically flat regions, the solutions may, however, still be either symmetric or asymmetric with respect to such a reflection. It is the non-trivial topology, which allows for asymmetric solutions, as well.

Starting again the discussion with the global charges, we exhibit the mass and the particle number of these asymmetric solutions in Fig. 2, and compare to the

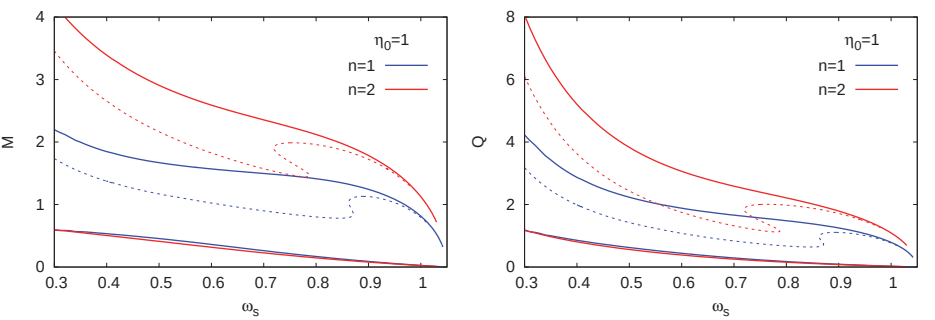

Fig. 2. Properties of asymmetric wormhole solutions (throat parameter $\eta_0 = 1$, rotational quantum numbers $n = 1, 2$) versus the boson frequency $\omega_s$: (a) the mass $M$; (b) the particle number $Q$; the dashed lines indicate the respective symmetric solutions.

corresponding symmetric solutions. Because of the asymmetry the boson field is different in both regions of the spacetime, resulting in different global charges, read off asymptotically. Thus for a given $n$ there is one curve for the symmetric wormholes, but there are two curves for the asymmetric wormholes. Note, that for these asymmetric solutions the angular momentum no longer satisfies $J = nQ$.

As in the case of the symmetric wormholes, there arise double throat wormholes, but now the equator will not reside at $\eta = 0$, but instead arise somewhere in one of the regions. Of course, for each asymmetric solution there exists a second solution, obtained for $\eta \to -\eta$. The asymmetric wormholes may also possess ergoregions and multiple lightrings.

## 3. Conclusions and Outlook

We have obtained a new type of rotating wormhole by immersing the throat in rotating bosonic matter, adopting some features from boson stars. We have studied various physical properties of these solutions, like their global charges, their ergoregions, and their lightrings. To conclude, let us illustrate these new wormhole solutions immersed in rotating matter, via embeddings of a symmetric and an asymmetric double throat wormhole in Fig. 3.

Fig. 3. Embeddings of symmetric (a) and asymmetric (b) wormhole solutions.

All these wormholes are based on General Relativity and therefore need exotic matter for their existence. It will be interesting to consider this new type of wormhole solutions in generalized theories of gravity, which allow for wormholes without the need for exotic matter. Another point of interest will be the study of the stability of these solutions.

This report is based on the Parallel Session AT3 "Wormholes, Energy Conditions and Time Machines" of the Fifteenth Marcel Grossmann Meeting - MG15, held at the University of Rome "La Sapienza" – Rome, in 2018.

*Keywords*: Wormholes; energy conditions; time machines.

## 1. Introduction

Traditionally, the solutions of General Relativity (GR) are obtained by first considering a plausible distribution of mass and energy, described by a stress-energy tensor, and through the Einstein field equations (EFE) one obtains the spacetime metric. However, one may adopt the reverse philosophy and engineer an interesting metric and then solve the EFE to find the matter sources that sustain the corresponding geometry. In this manner, in wormhole physics, the tunnel-like structure imposes the so-called flaring-out condition at the wormhole throat, the latter being the location of the minimum radius of the geometry. Thus, from this flaring-out condition, and using the EFE, in GR one discovers that the null energy condition (NEC) is violated[1]. In fact, all of the pointwise energy conditions are violated. Another interesting feature of these spacetimes is that they allow "effective" superluminal travel, and consequently generate closed timelike curves[2], although locally the speed of light is not surpassed. One may mention that, in fact, these solutions are primarily useful as "gedanken-experiments" and as a theoretician's probe of the foundations of GR. We refer the reader to the books[3,4] for an extensive review on the subject.

The AT3 Parallel Session, "Wormholes, Energy Conditions and Time Machines", was dedicated to the state-of-art contributions on this fascinating branch of research. In this report, we find it useful to organise the following sections, which reflect the internal schedule that was adopted during the session.

## 2. Traversable wormholes: Mathematical structure and applications

Ever since their revival, three decades ago, in the seminal work of Morris and Thorne[1,2], Lorentzian wormholes in GR have led an uncomfortable existence as they require matter which violates the well known energy conditions. However, in other theories of gravity beyond GR wormholes can indeed exist supported by "standard matter" satisfying the energy conditions[5].

Sayan Kar illustrated this fact with some known examples and also by explicitly constructing a zero Ricci scalar wormhole in a four dimensional scalar-tensor, on-brane gravity theory arising from the two-brane Randall-Sundrum model with one extra dimension[6]. If such a wormhole could arise as the end-state of some astrophysical process, its ringdown may be studied using gravitational waves. With this aim, the scalar quasinormal modes in this class of wormholes were obtained and identified as the 'breathing mode' associated with gravitational waves in scalar-tensor theories. Moreover, using the frequencies and time constants of the breathing mode as well as the results arising out of the GW150914 event, the size of the wormhole parameters using standard tools were estimated. The analysis suggests that it may be possible to constrain wormholes and distinguish them from black holes using this kind of observations.

Jutta Kunz considered Ellis-Bronnikov wormholes immersed in rotating matter in the form of an ordinary complex boson field[7,8]. The resulting wormholes may possess full reflection symmetry with respect to the two asymptotically flat spacetime regions. However, wormhole solutions also arise where the reflection symmetry is broken, and in such a case they always appear in pairs. The properties of these rotating wormholes were analysed and it was shown that their geometry may feature single throats or double throats. The ergoregions and the light ring structure of these wormholes were also discussed.

Kirill Bronnikov analysed spherically symmetric configurations in GR, supported by nonlinear electromagnetic fields with gauge-invariant Lagrangians[9] depending on the single invariant $f = F_{\mu\nu}F^{\mu\nu}$. Considering metrics with two independent functions of time, a natural generalization of the class of wormholes previously introduced by Arellano and Lobo with a time-dependent conformal factor was found[10]. Such wormholes are shown to be only possible for some particular choices of the Lagrangian function $L(f)$, having no Maxwell weak-field limit. Their time evolution contains cosmological-type singularities. For general non-Maxwell $L(f)$, instead of the usual electric-magnetic duality there exists the so-called FP duality, connecting theories with different $L(f)$; accordingly, for some of the wormhole solutions naturally emerging with magnetic fields, the electric counterparts with the same metric are ill-defined from the viewpoint of the Lagrangian formalism.

Gonzalo Olmo showed that the field equations of metric-affine theories of gravity whose Lagrangian is a nonlinear function of the Ricci tensor can be written in an Einstein form introducing both an auxiliary metric and auxiliary matter fields[11,12]. In this way the resolution of the equations can be done directly from within the framework of GR coupled to nonlinear matter fields. In other words, the nonlinearities of the gravity sector can be transferred to the matter sector. The correspondence with the original nonlinear gravity theory only involves algebraic manipulations. Standard analytical and numerical methods can thus be used to find solutions of these theories starting from GR ones.

Rajibul Shaikh studied shadows cast, under some circumstances, by a certain class of rotating wormholes, and explored the dependence of the shadows on the wormhole spin[13]. The results were then compared with that of a Kerr black hole. For small spin, the shapes of the shadows cast by a wormhole and a black hole are nearly identical. However, with increasing values of the spin, the shape of a wormhole shadow starts deviating considerably from that of a Kerr black hole. Detection of such a considerable deviation in future observations may possibly indicate the presence of a wormhole. In other words, the results indicate that the wormholes considered in this work, and that have reasonable spin, can be distinguished from a black hole through the observation of their shadows.

João Rosa presented wormhole solutions in the scalar-tensor representation of the generalized hybrid metric-Palatini matter theory, given by a gravitational Lagrangian density $f(R, \mathcal{R})$, where $R$ is the metric Ricci scalar, and $\mathcal{R}$ is a Palatini scalar curvature defined in terms of an independent connection[14]. The main interest in the solutions found is that the matter field obeys the NEC everywhere, including the throat and up to infinity, so that there is no need for exotic matter. The wormhole geometry with its flaring out at the throat is supported by the higher-order curvature terms, which can be interpreted as a gravitational fluid. Thus, in this theory, in building a wormhole, it is possible to exchange the exoticity of matter by the exoticity of the gravitational sector.

Sung-Won Kim presented recent work on the exact solution of the cosmological model, in an expanding Friedmann-Lemaitre-Robertson-Walker universe, from the isotropic form of the Morris-Thorne type wormhole[15]. Matter, radiation, and the cosmological constant $\Lambda$ were considered as the single component of the universe. For the multi-component universe case, the $\Lambda$CDM universe with matter and $\Lambda$ was adopted. In the case of the single-component universe, the apparent horizons coincide at a certain time. However, they have two coincidence times in the multi-component universe, which means that they start at early times and finish at late times like the combination of two single-component universes.

Mikhail Volkov applied duality rotations and complexifications to the vacuum Weyl metrics generated by massive rods or by point masses[16]. As a first step this gives families of prolate and oblate vacuum metrics. Further duality transformations produce a scalar field from the vacuum, which can be either the conventional scalar or the phantom field with negative kinetic energy. This gives rise to large classes of axially symmetric solutions, presumably including all previously known solutions for gravity-coupled massless scalar fields. Particularly interesting are the oblate solutions which, irrespectively of whether they are coupled to a scalar field or not, describe wormholes connecting several asymptotic regions. In the one-wormhole sector they reduce to the ring wormholes in the vacuum case and to the Bronnikov-Ellis wormhole in the phantom one. The two-wormhole solutions were also studied and it was found that two of their four asymptotic regions are completely regular while two others contain an infinitely long strut along the symmetry axis.

Remo Garattini argued that, since Yukawa corrections to Newtonian potentials appear in some modified theories of gravity, it is worth exploring some aspects of traversable wormholes with a shape function having a Yukawa-like profile and related generalizations[17]. These aspects also include the introduction of some equations of state. More specifically, an equation of state was considered in which the sum of the energy density and radial pressure is proportional to a Yukawa profile. In some cases, it was shown that the specific wormhole solution has an asymptotic behaviour corresponding to a global monopole.

Fayçal Hammad presented the behavior of black hole horizons and wormholes under Weyl conformal transformations[18]. First, a shorter, but more general, derivation of the Weyl transformation of the simple prescription for detecting horizons and wormholes given recently in the literature for spherically symmetric spacetimes was provided. Then, the conformal behavior of black hole horizons and wormholes in more general spacetimes, based on more "sophisticated" definitions, was presented. The study showed that black holes and wormholes might always arise in the new frame even if they were absent in the original frame. Moreover, it was shown that the various definitions found in the literature might be transformed into one another under such transformations. Finally, the conformal behavior of the required energy conditions for wormholes was discussed.

Jin Young Kim considered a new approach to construct wormholes without introducing exotic matter in Einstein-Born-Infeld gravity with a cosmological constant[19]. It was argued that the exoticity of the energy-momentum tensor is not essential to sustain the wormhole. The stability of the new wormholes with a scalar perturbation was also investigated, and it was confirmed that the Breitenlohner-Freedman bound holds in Einstein-Born-Infeld gravity.

Elisa Maggio discussed that gravitational wave astronomy can give us access to the structure of black holes, and to potentially probing microscopic corrections at the horizon scale[20]. A general model of a exotic compact object consisting of a Kerr geometry with a reflective surface near the horizon was investigated. This framework can be applied to thin-shell wormholes when the surface is perfectly reflecting. The stability of these geometries under scalar and electromagnetic perturbations was analysed. It was shown that exotic compact objects with a perfectly reflecting surface are affected by the an ergoregion instability when spinning sufficiently fast. This instability might have a crucial impact on their phenomenology. On the other hand, it was found that a partial absorption at the surface is sufficient to quench the ergoregion instability completely. This finding has important consequences for the viability of exotic compact objects and it suggests that they are not necessarily ruled out by the ergoregion instability.

## 3. Energy conditions

Eleni-Alexandra Kontou presented a theme related to the strong quantum energy inequality and the Hawking singularity theorem[21]. The latter concerns matter

obeying the strong energy condition (SEC), which means that all observers experience a nonnegative effective energy density thereby guaranteeing the timelike convergence property. However, for both classical and quantum fields, violations of the SEC can be observed in some of the simplest cases, for example, in the massive Klein-Gordon field. Therefore, there is a need to develop theorems with weaker restrictions, namely, energy conditions averaged over an entire geodesic and quantum inequalities, weighted local averages of energy densities. In fact, lower bounds of the effective energy density were derived in the presence of both classical and quantum scalar fields allowing a nonzero mass and nonminimal coupling to the scalar curvature. In the quantum case these bounds take the form of a set of state-dependent quantum energy inequalities valid for the class of Hadamard states. Finally, it was discussed how the classical and quantum inequalities derived can be used as an assumption to a modified Hawking-type singularity theorem.

## 4. Causal structure of spacetime

Sandipan Sengupta presented, in classical gravity theory, explicit examples of vacuum solutions that admit the possibility of time travel (to the past) through their geodesics[22]. These geometries are built upon metrics whose determinant can continuously go to zero over some extended region of the spacetime. These solutions to the first order field equations satisfy the energy conditions. One may see the existence of these solutions as a motivation to revisit the status of causality in the formulation of classical gravity.

Vaishak Prasad presented the possibility of resolving the chronology protection problem due to the existence of closed time-like curves in Kerr-Newman black holes using modified gravity[23]. First, the details of the causality violation in the Kerr-Newman spacetime were revisited and quantified. It was then shown that the issue also extends onto two of the modified Kerr-Newman solutions: non-commutative geometry inspired and $f(R)$ gravity solutions. The geodesic connectivity of the causality violating region was discussed in both scenarios and the existence of null geodesics was proved. The possibility of preventing causality violation was also explored. It was shown that although in both models the parameters can be chosen such that the causality violating region is removed, the $f(R)$ case is not consistent with cosmological observations. In the case of the non-commutative geometry inspired solution, it was shown that the chronology protection can be ensured by choosing suitable values for the non-commutative parameter, thereby eliminating the causality violating region and the Cauchy horizon.

Ilia Musco showed that in the gravitational collapse to form black holes, trapping horizons (foliated by marginally trapped surfaces) make their first appearance either within the collapsing matter or where it joins on to a vacuum exterior. Those which then move outwards with respect to the matter have been proposed for use in defining black holes, replacing the global concept of an event horizon, which has some serious drawbacks for practical applications. Results were presented from a

study of the properties of both outgoing and ingoing trapping horizons, assuming strict spherical symmetry throughout [24]. The causal nature was investigated following two different approaches, namely, one using a geometrical quantity related to expansions of null geodesic congruences, and the other using the horizon velocity measured with respect to the collapsing matter. The models treated are simplified, but do include pressure effects in a meaningful way, and the behavior of the horizon evolution was analysed depending on the initial conditions of energy density and pressure of the collapse.

Gravitational waves are probes of gravity in the strong-field regime that allow to understand the nature of compact objects. Several families of exotic compact objects have been conceived in order to overcome some paradoxes associated to black holes, particularly the existence of the event horizon. Some models of exotic compact objects are characterized by microscopic or even Planckian corrections at the horizon scale. In particular, the wormhole solution has a perfectly reflecting surface instead of the event horizon. Spinning horizonless compact objects may be unstable against an "ergoregion instability" when spinning sufficiently fast. We analyse the instability and its astrophysical impact for the viability of exotic compact objects.

## 1. Introduction

Recently, there has been a growing interest in investigating the nature of compact objects and testing the existence of horizons.[1,2] Following the recent detections of gravitational waves (GWs) from compact binary coalescences,[3] it is reasonable to enquire whether the compact remnant is compatible with the predictions of General Relativity. Several quantum-gravity models of exotic compact objects (ECOs) have been proposed as alternatives to black holes (BHs).[4–6] ECOs are horizonless compact objects which can overcome some paradoxes associated to BHs, such as their thermodynamical instability and their entropy which is far in eccess of a typical stellar progenitor.[7] ECO models have a unique fingerprint in the postmerger ringdown phase of a GW signal that allow to distinguish them from canonical BH solutions.[1,8]

In the following, we analyse the wormhole model as a horizonless compact object supported by an exotic distribution of matter.[9] Spinning wormhole solutions are prone to the so-called *ergoregion instability* when spinning sufficiently fast.[10] The latter is an instability that develops in any spacetime featuring an ergoregion but without an event horizon in the absence of dissipation mechanisms. The ergoregion instability could have a crucial impact on the dynamics of the ECO and provide a strong theoretical argument in favour of the BH paradigm.

## 2. Gravitational waves as probes of strong gravity

The recent detections of GWs provide the opportunity to analyse the two-body motion in the strong-field and large-velocity regime of gravity.[11] The detected GW signals are characterized by three phases: (i) the inspiral, when the two bodies have large separations and the GW emission decreases the binary's orbital period; (ii) the

merger, when the two bodies coalesce; (iii) the ringdown, when the final remnant relaxates to a stationary and equilibrium solution.

The ringdown stage is dominated by a superposition of the characteristic frequencies of the remnant, the so-called *quasi-normal modes* (QNMs). The latter are complex frequencies, $\omega = \omega_R + i\omega_I$, which describe the response of the compact object to a perturbation.[12] The emitted ringdown signal is a sum of exponentially damped sinusoids whose frequencies are proportional to the real part of the QNMs ($f_{\rm GW} = \omega_R/2\pi$) and whose damping times are proportional to the imaginary part of the QNMs ($\tau_{\rm damp} = -1/\omega_I$.)[13] According to our convention, a mode with $\omega_I < 0$ describes a stable remnant, whereas a mode with $\omega_I > 0$ describes an unstable one.

From the detection of the ringdown stage of a binary coalescence, the QNMs of the remnant can be inferred, leading to an understanding of the nature of the remnant. Solely in the first event GW150914, the least-damped QNM of the remnant has been observed.[14] The latter is consistent with a Kerr BH of mass $62^{+4}_{-4}\ M_\odot$ and spin $0.67^{+0.05}_{-0.07}$ at 90% confidence.[15] However alternatives to BHs are not excluded and the characterization of the remnant is still an open problem.[16–18] A precise modeling of the gravitational waveform in a variety of strong gravity processes is necessary, including the signal emitted by alternatives to BHs.

## 3. Exotic compact objects

Several arguments have recently been put forward, suggesting that new physics at the horizon scale might alter the formation of BHs during the gravitational collapse.[5,19,20] In this context, several families of ECOs have been proposed as near-horizon quantum structures.[4,7,21] ECOs are theoretical compact objects that can mimic the features of BHs by means of electromagnetic observations since they can be as compact as BHs. However, ECOs are not endowed with an event horizon nor a curvature singularity.

In the following, we consider rotating solutions described by the Kerr metric and characterized by microscopic corrections at the horizon scale.[22,23] The surface of the compact object is located at $r_0 = r_+(1+\epsilon)$, where $r_+$ is the location of the would-be horizon and $0 < \epsilon \ll 1$ is a parameter related to the compactness of the object. The properties of the object's interior are parametrized in terms of a surface reflection coefficient $\mathcal{R}$.[24] A perfectly reflecting surface is described by $|\mathcal{R}|^2 = 1$, whereas a partially absorbing surface (e.g. due to dissipation, viscosity, fluid mode excitations) is described by $|\mathcal{R}|^2 < 1$.

### 3.1. *Wormholes*

In the static limit, the wormhole solution can be constructed by taking two copies of the Schwarzschild metric with $r > r_0$ and by pasting them at $r = r_0$, which is the location of the wormhole throat. This procedure is called *Schwarzschild surgery* and is analogous to considering one Schwarzschild metric with $r > r_0$ and a perfectly reflecting surface at $r = r_0$.[9]

According to Birkhoff's theorem, the Schwarzschild metric is the only solution of Einstein's field equations in vacuum which describes a spherically symmetric spacetime. As a consequence, the wormhole solution must be sustained by a distribution of matter. In this case, a thin shell of matter is located at the wormhole throat.[25] Furthermore, the distribution is exotic since it violates the weak energy condition according to which the surface energy density is negative.[25]

## 4. Ergoregion instability

Spinning wormhole solutions might turn unstable above a critical threshold of the spin due to the *ergoregion instability*.[10] Since physical negative-energy states can exist inside the ergoregion – which is key ingredient of the Penrose's process–[26] it is energetically favorable to cascade toward more negative states. The only way to prevent such an infinite cascade is by absorbing negative-energy states. For this reason, Kerr BHs are stable against the ergoregion instability. Whereas, ECOs suffer from the instability in the absence of dissipation mechanisms.

### 4.1. *Linear perturbations*

In order to analyse the stability of ECOs, let us consider a massless scalar field governed by the Klein-Gordon equation in Kerr geometry. By decomposing the scalar field in Boyer-Lindquist coordinates, the Klein-Gordon equation can be separated in terms of Teukolsky's master equations.[27]

By imposing physically motivated boundary conditions at infinity and at the surface of the ECO, the equations define an eigenvalue problem whose (complex) eigenvalues are the QNMs of the system. In particular, at infinity the proper vibrations of the object require only outgoing waves.[28] In the the BH case, at $r = r_+$ the presence of the horizon would require purely ingoing waves. Whereas, in the ECO case, at $r = r_0$ there is a superposition of ingoing and outgoing waves such that the flux of energy is conserved.[22,23]

### 4.2. *Quasi-normal mode spectrum*

In the static case, the QNMs of the wormhole are stable since $\omega_I < 0$. As discussed in Ref. 8, in the BH limit (as $\epsilon \to 0$) the QNM frequencies approaches zero and the damping time becomes infinite, thus the modes become extremely long lived. The fact that the imaginary part of the modes vanishes as $\epsilon \to 0$ suggests that the modes might turn unstable in the spinning case, due to the Zeeman splitting of the frequencies with different azimuthal numbers. This expectation is confirmed by our results for an ECO with a perfectly reflecting surface. In particular, the QNM frequencies have a zero crossing at a critical value of the spin where the ECO turns from stable into unstable against the ergoregion instability.[22]

### 4.3. *Astrophysical impact of the instability*

The onset of the ergoregion instability depends on the compactness of the ECO. In particular, in the BH limit ($\epsilon \to 0$) the critical value of the spin approaches zero. Thus, even slowly spinning ECOs suffer from the ergoregion instability.

The instability time scale is extremely short compared to typical astrophysical time scales. For example, for a stellar mass ECO the instability occurs after few seconds the formation of the object.[22] Thus, for a perfectly reflecting surface the ergoregion instability plays an important role in the dynamics of the ECO.

### 4.4. *The role of absorption*

The case of a perfectly reflecting surface is an idealization and it is expected that the compact object would absorb part of the ingoing radiation, e.g., through viscosity, dissipation. In this case, at $r = r_0$ there is a superposition of ingoing and outgoing waves such that a certain fraction of the incident flux of energy is absorbed at the surface of the ECO.

By deriving the QNMs of the compact object, we obtain that an absorption rate of 0.4% is sufficient to quench the ergoregion instability completely.[22] Thus, any ECO with at least this level of absorption is stable under scalar field perturbations.

An indicative estimate shows that this level of absorption can be naturally achieved by a viscous fluid in the ECO. The dissipation can occur through sound waves which propagate into the interior of the fluid and through shear waves which heat the surface of the ECO.[29,30]

## 5. Conclusions and future prospectives

In the newly-born era of GWs, we have the first opportunity to look for new physics at the horizon scale. We analysed the stability of an ECO described by the Kerr metric whose surface is at a Planckian distance from the would-be event horizon. We analysed a test scalar field perturbation and we showed two interesting properties:

i. An ECO with a perfectly reflecting surface suffers from the ergoregion instability above a critical value of the spin. The instability time scale is short compared to astrophysical time scales.
ii. An absorption rate of 0.4% at the surface of the ECO is sufficient to quench the ergoregion instability completely.

An extension of this work is the analysis of gravitational perturbations. It has been recently computed in Ref. 23 that an absorption rate of 0.3% (6%) is necessary in order to have a stable ECO with spin $\chi \lesssim 0.7$ ($\chi \lesssim 0.9$) for any perturbation.

Finally, an understanding of the evolution and the end point of the instability – including possible nonlinearities – remain interesting open problems.

Wormhole solutions in a generalized hybrid metric-Palatini matter theory, given by a gravitational Lagrangian density $f(R, \mathcal{R})$, where $R$ is the metric Ricci scalar, and $\mathcal{R}$ is a Palatini scalar curvature defined in terms of an independent connection, and a matter Lagrangian, are found. The solutions are worked out in the scalar-tensor representation of the theory, where the Palatini field is traded for two scalars, $\varphi$ and $\psi$, and the gravitational term $R$ is maintained. The main interest in the solutions found is that the matter field obeys the null energy conditions everywhere, including the throat and up to infinity, so that there is no need for exotic matter. The wormhole geometry with its flaring out at the throat is supported by the higher-order curvature terms, or equivalently, by the two fundamental scalar fields, which either way can be interpreted as a gravitational fluid. Thus, in this theory, in building a wormhole, it is possible to exchange the exoticity of matter by the exoticity of the gravitational sector.

*Keywords*: Wormholes; modified gravity; hybrid metric-Palatini gravity.

## 1. Introduction

The flaring-out condition is the fundamental ingredient in wormhole physics[1–5], and in general relativity this geometric condition entails the violation of the null energy condition (NEC). The latter states that $T_{ab}\, k^a k^b \geq 0$, where $T_{ab}$ is the matter stress-energy tensor and $k^a$ is any null vector. Matter that violates the NEC is denoted as exotic matter. In fact, in the context of modified theories of gravity[6], it has been shown in principle that normal matter may thread the wormhole throat[7], and it is the higher-order curvature terms, which may be interpreted as a gravitational fluid, that support these nonstandard wormhole geometries. Indeed, it was shown explicitly that in $f(R)$ theories[8] and extensions[9–11], wormhole throats can be theoretically constructed without the presence of exotic matter, where the throat is solely sustained by the geometric fields presented in modified gravity.

The main aim of this work is to theoretically construct wormhole solutions in generalized hybrid metric-Palatini gravity[12–14], where the matter obeys the NEC throughout the geometry. In the scalar representation of generalized hybrid metric-Palatini gravity we are studying, the gravitational field is complemented by the two other fundamental scalar fields[14,15], whereas the matter fields in this theory are still encoded in the stress-energy tensor $T_{ab}$. Thus, to allow for a mandatory

flaring-out condition, the matter $T_{ab}$ can obey the NEC, as long as some appropriate combination of $T_{ab}$ with the other fundamental fields violates the NEC. We will make use of the junction conditions for the generalized hybrid theory[16].

## 2. Scalar-tensor representation of the generalized hybrid metric-Palatini gravity

Consider the general hybrid action $S$ given by

$$S=\frac{1}{2\kappa^2}\int\sqrt{-g}f\left(R,\mathcal{R}\right)d^4x+\int\sqrt{-g}\,\mathcal{L}_m d^4x, \tag{1}$$

where $\kappa^2\equiv 8\pi G$, $g$ is the determinant of the spacetime metric $g_{ab}$, $R$ is the metric Ricci scalar, $\mathcal{R}\equiv\mathcal{R}^{ab}g_{ab}$ is the Palatini Ricci scalar, which is defined in terms of an independent connection $\hat{\Gamma}^c_{ab}$ as, $\mathcal{R}_{ab}=\partial_c\hat{\Gamma}^c_{ab}-\partial_b\hat{\Gamma}^c_{ac}+\hat{\Gamma}^c_{cd}\hat{\Gamma}^d_{ab}-\hat{\Gamma}^c_{ad}\hat{\Gamma}^d_{cb}$, $\partial_a$ denotes partial derivative; $f\left(R,\mathcal{R}\right)$ is a well-behaved function of $R$ and $\mathcal{R}$, and $\mathcal{L}_m$ is the matter Lagrangian density minimally coupled to the metric $g_{ab}$.

It is useful to express the action (1) in a scalar-tensor representation, given by[14]

$$S=\frac{1}{2\kappa^2}\int\sqrt{-g}\left[\left(\varphi-\psi\right)R-\frac{3}{2\psi}\partial^a\psi\partial_a\psi-V\left(\varphi,\psi\right)\right]d^4x+\int\sqrt{-g}\,\mathcal{L}_m d^4x\,, \tag{2}$$

where $\varphi$ and $\psi$ are two scalar fields and $V=V(\varphi,\psi)$ is the potential. Varying the action (2) with respect to the metric $g_{ab}$ gives[15]

$$\begin{aligned}\left(\varphi-\psi\right)G_{ab}=&\,\kappa^2T_{ab}+\nabla_a\nabla_b\varphi-\nabla_a\nabla_b\psi+\frac{3}{2\psi}\partial_a\psi\partial_b\psi\\&-\left(\Box\varphi-\Box\psi+\frac{1}{2}V+\frac{3}{4\psi}\partial^c\psi\partial_c\psi\right)g_{ab}\,,\end{aligned} \tag{3}$$

where $\nabla_a$ is the covariant derivative and $\Box=\nabla^a\nabla_a$ the d'Alembertian. Varying the action with respect to the field $\varphi$ and to the field $\psi$ yields[15],

$$\Box\varphi+\frac{1}{3}\left(2V-\psi V_\psi-\varphi V_\varphi\right)=\frac{\kappa^2T}{3}\,, \tag{4}$$

$$\Box\psi-\frac{1}{2\psi}\partial^a\psi\partial_a\psi-\frac{\psi}{3}\left(V_\varphi+V_\psi\right)=0\,, \tag{5}$$

respectively. In this work, we are interested in finding wormhole solutions that satisfy the NEC throughout the spacetime geometry.

## 3. Wormhole geometries in the generalized hybrid metric-Palatini gravity

### 3.1. *Gravitational field equations*

We impose that the wormhole solutions are described by a static and spherically symmetric metric where the line element is given by[1]

$$ds^2=-e^{\zeta(r)}dt^2+\left[1-\frac{b\left(r\right)}{r}\right]^{-1}dr^2+r^2\left(d\theta^2+\sin^2\theta d\phi^2\right)\,, \tag{6}$$

where $\zeta(r)$ is the redshift function and $b(r)$ is the shape function. The latter obeys the boundary condition $b(r_0) = r_0$, where $r_0$ is the radius of the wormhole throat. The flaring-out condition at the throat vicinity is given by $(b - b'r)/b^2 > 0$. This imposes that at the throat $b'(r_0) < 1$. The redshift function must be finite everywhere to avoid the presence of horizons. We also assume that $\varphi = \varphi(r)$ and $\psi = \psi(r)$.

The three independent components of Eq. (3) are given by

$$(\varphi-\psi)\frac{b'}{r^2} - \frac{(\varphi-\psi)'}{2r}(1-b') - \frac{V}{2} - \left(1-\frac{b}{r}\right)\left[(\varphi-\psi)'' + \frac{3(\varphi-\psi)'}{2r} + \frac{3\psi'^2}{4\psi}\right] = \kappa^2\rho\,, \tag{7}$$

$$(\varphi-\psi)\left[\frac{\zeta'}{r}\left(1-\frac{b}{r}\right) - \frac{b}{r^3}\right] + \left(1-\frac{b}{r}\right)\times \times\left[-\frac{3\psi'^2}{4\psi} + \frac{2(\varphi-\psi)'}{r} + \frac{\zeta'(\varphi-\psi)'}{2}\right] + \frac{V}{2} = \kappa^2 p_r, \tag{8}$$

$$(\varphi-\psi)\left[\left(1-\frac{b}{r}\right)\left(\frac{\zeta''}{2} + \frac{\zeta'^2}{4} + \frac{\zeta'}{2r}\right) + \frac{b-rb'}{2r^3}\left(1+\frac{\zeta' r}{2}\right)\right] + \frac{\phi'}{2r}(1-b') + \frac{V}{2} + \left(1-\frac{b}{r}\right)\left[(\varphi-\psi)'' + \frac{\zeta'(\varphi-\psi)'}{2} + \frac{3\psi'^2}{4\psi} + \frac{(\varphi-\psi)'}{2r}\right] = \kappa^2 p_t\,, \tag{9}$$

where $\rho = \rho(r)$ is the energy density, $p_r = p_r(r)$ is the radial pressure, and $p_t = p_t(r)$ is the transverse pressure. The equation for $\varphi(r)$, Eq. (4), can be written as

$$\left(1-\frac{b}{r}\right)\left(\zeta'' + \frac{\zeta'^2}{2} + \frac{2\zeta'}{r}\right) - \frac{b+rb'}{r^3} + \frac{b-rb'}{r^3}\left(1+\frac{r\zeta'}{2}\right) + V_\varphi = 0\,, \tag{10}$$

and the equation for $\psi(r)$, Eq. (5), yields

$$\left(1-\frac{b}{r}\right)\left(\psi'' + \frac{\zeta'\psi'}{2} + \frac{3\psi'}{2r} - \frac{\psi'^2}{2\psi}\right) + \frac{\psi'}{2r}(1-b') - \frac{\psi}{3}(V_\varphi + V_\psi) = 0\,. \tag{11}$$

The fundamental gravitational fields are the metric fields, $\zeta(r)$ and $b(r)$, and the scalar fields $\varphi(r)$ and $\psi(r)$ that form the potential $V$. The scalar fields $\varphi$ and $\psi$ should be well-behaved throughout $r$.

### 3.2. *Interior solution*

We have the freedom to choose three functions out of the eight variables, $\zeta(r)$, $b(r)$, $\varphi(r)$, $\psi(r)$, $V(r)$, $\rho(r)$, $p_r(r)$, and $p_t(r)$, since there are only five independent equations (7)-(10). The three functions that we choose are $\zeta(r)$, $b(r)$, and $V(\varphi, \psi)$.

Consider, for simplicity, the following metric functions

$$\zeta(r) = \zeta_0\,, \qquad b(r) = \frac{r_0^2}{r}\,. \tag{12}$$

Let $V_0$ be a constant and consider further a power-law potential of the form

$$V(\varphi,\psi)=V_0\left(\varphi-\psi\right)^2 . \tag{13}$$

The gravitational field equations (7)–(9), yield the following solutions

$$\rho=\frac{r_0^2}{2r^6V_0\kappa^2}\left(24-31\frac{r_0^2}{r^2}\right), \qquad p_r=\frac{r_0^2}{2r^6V_0\kappa^2}\left(16-13\frac{r_0^2}{r^2}\right), \tag{14}$$

$$p_t=\frac{r_0^2}{2r^6V_0\kappa^2}\left(-32+39\frac{r_0^2}{r^2}\right), \tag{15}$$

respectively. The solutions for the scalar fields, $\varphi(r)$ and $\psi(r)$, are given by

$$\varphi(r)=\psi_0-\frac{r_0^2}{r^4V_0}, \qquad \psi(r)=\psi_0 . \tag{16}$$

From Eqs. (16), we see that both scalar fields are finite for $r$ at the throat $r_0$, and for values of $r$ in its vicinity, and indeed for all $r$.

The expressions for the NEC are given by

$$\rho+p_r=\frac{2r_0^2}{r^6V_0\kappa^2}\left(10-11\frac{r_0^2}{r^2}\right), \qquad \rho+p_t=\frac{4r_0^2}{r^6V_0\kappa^2}\left(-1+\frac{r_0^2}{r^2}\right). \tag{17}$$

We impose that $V_0$ negative, i.e., $V_0<0$, so that the NEC is valid in the throat's neighborhood up to to the radius $r=r_0\sqrt{11/10}$.

### 3.3. *Exterior vacuum solution*

Now, in order to guarantee that the complete solution obeys the NEC for all values of $r$, we match the interior solution at some $r_\Sigma$, to an external vacuum and asymptotically flat spherically symmetric solution, i.e., $T_{ab}=0$. Consider that the scalar fields are constant in the exterior solution, i.e., $\varphi\left(r\right)=\varphi_e$ and $\psi\left(r\right)=\psi_e$ with $\varphi_e$ and $\psi_e$ constants, $\varphi_e\neq\psi_e$, where the subscript $e$ stands for exterior.

It was shown that the Schwarzschild solution with a cosmological constant[14] of general relativity is a vacuum solution of the generalized hybrid theory we are studying[14]. These solutions are known as Schwarzschild-de Sitter, Schwarzschild-dS for short, if the constant cosmological term is positive, and Schwarzschild-anti-de Sitter, Schwarzschild-AdS for short, if the constant cosmological term is negative. The metric fields $\zeta(r)$ and $b(r)$ for the exterior region outside some radius $r_\Sigma$, i.e., $r>r_\Sigma$, are then

$$e^{\zeta(r)}=\left(1-\frac{2M}{r}-\frac{V_0\left(\varphi_e-\psi_e\right)r^2}{6}\right)e^{\zeta_e}, \qquad b\left(r\right)=2M+\frac{V_0\left(\varphi_e-\psi_e\right)r^3}{6}, \tag{18}$$

respectively, where $M$ is a constant of integration and represents the mass, and the factor $e^{\zeta_e}$ is a useful constant.

The sign of the term $V_0\left(\varphi_e-\psi_e\right)/2$ will determine whether the solution is Schwarzschild-dS or Schwarzschild-AdS[3]. This sign will be determined by the

matching surface and the imposition that the NEC holds everywhere. Thus, exterior solution, in addition to Eqs. (18), has the following expressions, $\varphi(r) = \varphi_e$, $\psi(r) = \psi_e$, $V = V_0(\varphi_e - \psi_e)^2$, and $\rho(r) = p_r(r) = p_t(r) = 0$.

### 3.4. *Surface stresses at the junction interface*

To match the interior to the exterior solution we need the junction conditions at the hypersurface $\Sigma$, which is located at the junction radius $r_\Sigma$, for the generalized hybrid metric-Palatini gravity[16]. These conditions are

$$[h_{\alpha\beta}] = 0\,, \qquad [\varphi] = 0\,, \qquad [\psi] = 0\,, \qquad n^a\,[\partial_a \psi] = 0\,, \tag{19}$$

$$n^a\,[\partial_a \varphi] = \frac{\kappa^2}{3} S\,, \qquad S^\beta_\alpha - \frac{1}{3}\delta^\beta_\alpha S = -\frac{(\varphi_\Sigma - \psi_\Sigma)}{\kappa^2}\left[K^\beta_\alpha\right]\,, \qquad [K] = 0\,, \tag{20}$$

where $h_{\alpha\beta}$ is the induced metric at the junction hypersurface $\Sigma$, with Greek indexes standing for $(0, 2, 3)$, the brackets $[X]$ denote the discontinuity of $X$ across $\Sigma$, $n^a$ is the unit normal vector to $\Sigma$, $K = K^\alpha_\alpha$ is the trace of the extrinsic curvature $K_{\alpha\beta}$ of the surface $\Sigma$, $S = S^\alpha_\alpha$ is the trace of the stress-energy tensor $S_{\alpha\beta}$ of the thin shell, and the subscripts $\Sigma$ indicate the value computed at the junction interface.

The second condition in Eq. (20) yield the field equations at the hypersurface

$$\sigma = \frac{4r_0^2}{\kappa^2 V_0 r_\Sigma^5}\left(1 - \frac{1}{4}\, r_\Sigma \left[K_0^0\right]\right)\,, \qquad p = -\frac{4r_0^2}{\kappa^2 V_0 r_\Sigma^5}\left(1 + \frac{1}{8}\, r_\Sigma \left[K_0^0\right]\right)\,, \tag{21}$$

respectively, where $\sigma = -S_0^0$ the surface energy density and $p = S_1^1$ and the surface transverse pressure. with

$$\left[K_0^0\right] = \frac{r_0 \zeta_0}{2r_\Sigma^2}\sqrt{1 - \frac{r_0^2}{r_\Sigma^2}} + \frac{\frac{r_0^2}{r_\Sigma} - 6M}{6r_\Sigma^2\sqrt{1 - \frac{2M}{r_\Sigma} + \frac{r_0^2}{6r_\Sigma^2}}}\,. \tag{22}$$

We also impose that the matter NEC should be satisfied at the thin shell[4,5], so that $\sigma + p \geq 0$ and the formulas given in Eq. (21) imply

$$\sigma + p = -\frac{3r_0^2}{2\kappa^2 V_0 r_\Sigma^4}\left[K_0^0\right]\,. \tag{23}$$

Finding a combination of parameters that fulfills all the junction conditions, plus the matter NEC everywhere, is a problem that requires some fine-tuning, and was analysed in detail[14].

## 4. Conclusions

In this work, we found traversable asymptotically AdS wormhole solutions that obey the NEC everywhere in the generalized hybrid metric-Palatini gravity theory, so there is no need for exotic matter. The interior wormhole solution obtained verifies the NEC near and at the throat of the wormhole. The matching of the interior solution to an exterior vacuum solution yields a thin shell respecting also

the NEC. We showed that it is possible to build the full wormhole solution, where the matter satisfies the NEC throughout the wormhole geometry, and found that it is asymptotically AdS.

**E-mail: sandipan@phy.iitkgp.ac.in*

We explore the possibility of 'time travel' through geodesics in the first order formulation of classical gravity theory. The analysis is developed around a few vacuum solutions to the field equations, constructed such that the proper time exhibits a non-monotonic flow along the geodesic. These geometries are built upon metrics whose determinant vanish over some region. The associated spacetimes are smooth and the curvature two-form fields are finite everywhere.

*Keywords*: Time machine, Degenerate metric, Causality violation; MG15 Proceedings; World Scientific Publishing.

## 1. Introduction

The possibility of obtaining theoretical models of time machine spacetimes within Einstein's theory of general relativity, as well as the practical feasibility of such a potential construction, have been and still is a matter of open debate. Whereas Einstein's equations (with or without matter) have been shown to admit spacetime solutions that exhibit closed timelike curves (and hence implying a possible realization of time travel), they seem to violate at least one or more of the stability criteria motivated from classical and quantum physics. To emphasize, while some of them fail to satisfy the energy conditions, others are either unstable against quantum fluctuations or are supported by matter fields which have no realization in nature[1–8].

Here we discuss vacuum spacetime solutions of gravity theory, with the special property that the associated metric is degenerate over a region (but not everywhere) and the (non-spacelike) geodesics are characterized by nonmonotonic proper time[9]. This could possibly imply 'time travel', provided there is a way to go across the turning points of the affine parameter along the geodesic.

These configurations satisfy the energy conditions at the invertible phase. At the noninvertible phase, there is no exotic matter. Although it is beyond the scope of this article to provide a precise formulation of the energy conditions for the degenerate metric phase, there are reasons to believe that the energy conditions are satisfied there as well[10]. In addition, these solutions are free of any divergence either in the curvature two-form fields or in the lower dimensional curvature scalars that could be associated with the zero-determinant phase. Even though it is not clear whether such solutions could be realized in nature, their very existence as classical solutions is intriguing.

## 2. Solutions of first order gravity

Spacetimes with degenerate metrics[11] appear naturally in the context of first order formulation of gravity theory, described by the Hilbert-Palatini action[12–14]. The corresponding equations of motion are obtained through the variation with respect to the tetrad and connection fields:

$$e^{[K}_{[\mu} D_\nu(\omega) e^{L]}_{\alpha]} = 0, e^{[J}_{[\nu} R_{\alpha\beta]}^{\ \ KL]}(\omega) = 0 \ . \tag{1}$$

Here we shall present three solutions to these equations with the properties mentioned earlier. Whereas the connection fields are flat for the first two, the last example corresponds to a nontrivial curvature two-form.

### 2.1. *Solution-I: Extension of Rindler metric*

Let us introduce a metric which divides the spacetime into three regions; The determinant being zero at the intermediate region and non-zero everywhere else:

$$\begin{aligned} ds^2 &= -f^2(x)dt^2 + f'^2(x)dx^2 + dy^2 + dz^2 \ \text{ at } |x| > x_0, \\ &= 0 - F^2(x)dx^2 + dy^2 + dz^2 \ \text{ at } |x| \leq x_0 \end{aligned} \tag{2}$$

where, each of the coordinates $(t, x, y, z)$ spans the whole real line $(-\infty, \infty)$ and the functions $f(x)$ & $F(x)$ satisfy:

$$f(\pm x_0) = 0 = f'(\pm x_0), \ F(x_0) = 0. \tag{3}$$

The internal metric used to raise or lower the $SO(3,1)$ indices is given by $\eta_{IJ} = diag[-1,1,1,1]$ everywhere. At the two regions $|x| > x_0$, the spacetime metric becomes equivalent to the Rindler metric upon a reparametrization $x \to u = f(x)$. The only nonvanishing component of the torsionless spin connection is $\omega_t^{\ 01} = 1$. Within the patch $|x| \leq x_0$, the spin-connection fields are chosen to be:

$$\hat{\omega}_\mu^{\ IJ} = 0, \tag{4}$$

leading to trivial $\hat{R}_{\mu\nu}^{\ \ IJ}$. Note that although the spin-connection fields as given above are not manifestly continuous across $x = x_0$, they may be made to be so through a $SO(3,1)$ gauge transformation on the fields:

$$\hat{e}'^I_\mu = \Lambda^I_{\ L} \hat{e}^L_\mu, \ \hat{\omega}'^{\ IJ}_\mu = \Lambda^I_{\ K} \hat{\omega}_\mu^{\ KL} \left(\Lambda^{-1}\right)^{\ J}_L + \Lambda^I_{\ K} \partial_\mu \left(\Lambda^{-1}\right)^{KJ}.$$

where transformation $\Lambda$ is a boost:

$$\Lambda^I_{\ J} = \begin{pmatrix} \cosh t & \sinh t & 0 & 0 \\ \sinh t & \cosh t & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}.$$

As is straightforward to verify, both the configurations $(e^I_\mu, \omega_\mu^{\ IJ})$ and $(\hat{e}^I_\mu, \hat{\omega}_\mu^{\ IJ})$ are solutions to the first order equations of motion (1). Also, the gauge-covariant

fields (i.e. tetrad, torsion and field-strength) are continuous at the phase boundaries $x = \pm x_0$.

For the invertible and noninvertible metric phases, the (torsionless) affine connection components are defined as, respectively:

$$\Gamma_{\alpha\beta\rho} = g_{\rho\sigma}\Gamma_{\alpha\beta}^{\ \ \sigma} = \frac{1}{2}\left[\partial_\alpha g_{\beta\rho} + \partial_\beta g_{\alpha\rho} - \partial_\rho g_{\alpha\beta}\right],$$
$$\hat{\Gamma}_{\alpha\beta\rho} = \hat{g}_{\rho\sigma}\hat{\Gamma}_{\alpha\beta}^{\ \ \sigma} = \frac{1}{2}\left[\partial_\alpha \hat{g}_{\beta\rho} + \partial_\beta \hat{g}_{\alpha\rho} - \partial_\rho \hat{g}_{\alpha\beta}\right] \tag{5}$$

The noninvertibility of the metric with $\hat{g}_{t\mu} = 0$ gets reflected through the indeterminacy of the affine connection components $\hat{\Gamma}_{\alpha\beta}^{\ \ t}$. This essentially implies that within the degenerate region, the null coordinate (t) becomes nondynamical and any evolution along that is equivalent to a gauge motion.

The geodesic equations at the region $x > x_0$ are defined as $u^\alpha \mathcal{D}_\alpha u^\beta := u^\alpha \partial_\alpha u^\beta + \Gamma_{\alpha\rho}^{\ \ \beta} u^\alpha u^\rho = 0$, leading to:

$$f^2(x)\dot{t}^2 - f'^2(x)\dot{x}^2 - \dot{y}^2 - \dot{z}^2 = k,\ f^2(x)\dot{t} = E,\ \dot{y} = k_y,\ \dot{z} = k_z \tag{6}$$

where $E, k_y, k_z$ are constants of motion and $k = 1, 0, -1$ characterise the timelike, null and spacelike geodesics, respectively. The affine parameter is solved as:

$$\lambda = \pm\frac{1}{(k + k_y^2 + k_z^2)}\left[E^2 - (k + k_y^2 + k_z^2)f^2(x)\right]^{\frac{1}{2}} + const. \tag{7}$$

Within the degenerate region $x \leq x_0$, the equations for the physical degrees of freedom read (the equation for the null coordinate $t$ being redundant):

$$F^2(x)\dot{x}^2 - \dot{y}^2 - \dot{z}^2 = k,\ \dot{y} = k_y,\ \dot{z} = k_z \tag{8}$$

with the solution:

$$\lambda = \pm\frac{1}{(k + k_y^2 + k_z^2)^{\frac{1}{2}}}\int dx\ F(x) + const. \tag{9}$$

In the above expressions, one could choose the smooth function $F(x)$ such that the proper time is monotonic at the degenerate region. However, it is also possible to do otherwise, leading to a turning point of the proper time. For instance, a possible set of such functions is given by:

$$f(x) = \alpha x^2 exp\left[-\frac{x_0^2}{x^2 - x_0^2}\right],\ F(x) = f'(x),$$

where $\alpha$ is a constant. This corresponds to a motion along the geodesic where a massive particle apparently can come back to the same value of proper time after a trip within the degenerate core.

### 2.2. *Solution-II: Extension of Kasner metric*

In our next example, the invertible phase of the spacetime corresponds to a particular cosmological solution of the Kasner family. Here, the null eigenvalue at the noninvertible phase lies along the $x$-direction, unlike in the previous example:

$$\begin{aligned} ds^2 &= -dt^2 + t^2 dx^2 + dy^2 + dz^2 \ \text{ at } t > 0, \\ &= -F^2(t)dt^2 + 0 + dy^2 + dz^2 \ \text{ at } t \leq 0, \end{aligned} \tag{10}$$

The function $F(t)$ obeys the boundary conditions: $F(0) = 1,\ \dot{F}(0) = 0$. The internal metric is given by $\eta_{IJ} = diag[-1, 1, 1, 1]$.

Using the affine connection components, the geodesic equations for timelike and null geodesics at $t > 0$ become:

$$\dot{t}^2 - t^2\dot{x}^2 - \dot{y}^2 - \dot{z}^2 = k,\ t^2\dot{x} = k_x,\ \dot{y} = k_y,\ \dot{z} = k_z; \tag{11}$$

Which are solved as:

$$\lambda = \pm\frac{1}{(k + k_y^2 + k_z^2)}[(k + k_y^2 + k_z^2)t^2 + k_x^2]^{\frac{1}{2}} + const. \tag{12}$$

At the degenerate phase $t \leq 0$, the physical motion is described by the remaining three coordinates through the respective geodesic equations (while the dynamics happens to be trivial along the $x$-direction as expected):

$$F^2(t)\dot{t}^2 - \dot{y}^2 - \dot{z}^2 = k,\ \dot{y} = k_y,\ \dot{z} = k_z, \tag{13}$$

These imply:

$$\lambda = \pm\frac{1}{(k + k_y^2 + k_z^2)^{\frac{1}{2}}}\int dt\ F(t) + const. \tag{14}$$

As earlier, a suitable choice of the smooth function $F(t)$ may now be made so that the proper time is nonmonotonic at $t \leq 0$.

### 2.3. *Solution III: Extension of Schwarzschild metric*

Our final example is based on a degenerate extension of the Schwarzschild exterior geometry. In terms of the chart ($t \in (-\infty, \infty),\ u \in (-\infty, \infty),\ \theta \in [0, \pi]$, $\phi \in [0, 2\pi]$), the spacetime metric at the two phases are given by:

$$\begin{aligned} ds^2 &= -\left[1 - \frac{2M}{f(u)}\right]dt^2 + \frac{f'^2(u)}{\left[1 - \frac{2M}{f(u)}\right]}du^2 + f^2(u)\left[d\theta^2 + \sin^2\theta d\phi^2\right]\ (u > u_0), \\ &= 0 - F^2(u)du^2 + H^2(u)\left[d\theta^2 + \sin^2\theta d\phi^2\right]\ (u \leq u_0), \end{aligned} \tag{15}$$

where we impose the boundary conditions:

$$f(u_0) = 2M,\ f'(u_0) = 0,\ F(u_0) = 0 \tag{16}$$

and also the constraint:

$$\left(1+\frac{H'^2(u)}{F^2(u)}\right)F(u)+2H(u)\left(\frac{H'(u)}{F(u)}\right)'=0 \tag{17}$$

The field-strength at $u > u_0$ is completely determined by the associated (torsionless) spin-connection fields $\omega_\alpha{}^{IJ}(e)$. At the region $u \leq u_0$ with a degenerate phase, we assume the nonvanishing spin-connection components to be:

$$\hat{\omega}_\theta{}^{12}=i\frac{H'(u)}{F(u)},\ \hat{\omega}_\phi{}^{23}=-\cos\theta,\ \hat{\omega}_\phi{}^{31}=-i\frac{H'(u)}{F(u)}\sin\theta \tag{18}$$

The corresponding $SO(3,1)$ field strength components read:

$$\hat{R}_{u\theta}{}^{12}=i\left[\frac{H'(u)}{F(u)}\right]',\ \hat{R}_{\theta\phi}{}^{23}=\left[1+\left(\frac{H'(u)}{F(u)}\right)^2\right]\sin\theta,\ \hat{R}_{\phi u}{}^{31}=i\left[\frac{H'(u)}{F(u)}\right]'\sin\theta, \tag{19}$$

all other components being zero. Note that even though some of the field-strength components are imaginary, the physical fields, given by their $SO(3,1)$ gauge-invariant counterparts $\hat{R}_{\mu\nu\alpha\beta}=\hat{R}_{\mu\nu}{}^{IJ}\hat{e}_{\alpha I}\hat{e}_{\beta J}$, are all real.

It is easy to verify that the configuration above satisfies the vacuum equations of motion of first order gravity everywhere. For definiteness, we shall consider the following set of functions $F(u)$ and $H(u)$ which solve the boundary conditions and the constraint:

$$F(u)=-\frac{f'(u)}{\left(\frac{2M}{f(u)}-1\right)^{\frac{1}{2}}},\ H(u)=f(u) \tag{20}$$

With this, one may now solve the geodesic equations explicitly, the procedure being exactly similar to the earlier cases. Without going into any further detail of these solutions [a], it is sufficient to note that the affine parameter $\lambda$ is characterized completely by the (smooth) function $f(u)$. An appropriate choice of $f(u)$ can be made so that the spacetime is smooth and the proper time $\lambda(u)$ exhibits turning point(s) within the degenerate region. If an observer is able to cross any such point along the geodesic, the proper clock would start running backwards.

## 3. Conclusions

Here we have constructed smooth vacuum solutions of first-order gravity where the geodesics correspond to a non-monotonic motion of the proper time. While this feature is intriguing, it is certainly not clear if this could imply a 'time travel' in reality. One should note that the turning points of the proper time precisely corresponds to those points where there exists no orientability of time. Thus, even though there is no divergence in the associated curvature two-form fields, these degenerate metric solutions are not completely satisfactory in a strict sense, at least

[a] The reader is referred to ref. [9] for more details in this regard.

classically. Rather, the appropriate habitat of such solutions should be the quantum theory, which could provide a meaningful interpretation of this non-orientability, and of the acausal features associated with these in general. A deeper understanding of such issues is essential in order to answer the question as to whether these could be seen as vacuum time machine solutions, without having to bring in additional features such as exotic matter or else.

# Shadows cast by rotating wormholes

Rajibul Shaikh

*Department of Astronomy & Astrophysics, Tata Institute of Fundamental Research, Mumbai, Maharashtra 400005, India*
** E-mail: rajibul.shaikh@tifr.res.in, rshaikh@iitk.ac.in*

We study shadows cast, under some circumstances, by a certain class of rotating wormholes and explore the dependence of the shadows on the wormhole spin. We compare our results with that of a Kerr black hole. For small spin, the shapes of the shadows cast by a wormhole and a black hole are nearly identical to each other. However, with increasing values of the spin, the shape of a wormhole shadow start deviating considerably from that of a Kerr black hole. Detection of such considerable deviation in future observations may possibly indicate the presence of a wormhole. In other words, our results indicate that the wormholes which are considered in our work and have reasonable spin can be distinguished from a black hole, through the observation of their shadows.

*Keywords*: General Relativity; Shadow; Wormhole; Black Hole; Gravitational Lensing.

## 1. Introduction

It is commonly believed that the central suppermassive compact region of our Galaxy as well as those of many other galaxies contain suppermassive black holes. Typically, the event horizon of a black hole, together with a set of unstable light rings (or a photon sphere in the case of a static, spherically symmetric black hole) present in its exterior geometry, creates a characteristic shadow-like image (a darker region over a brighter background) of the photons emitted by nearby photon sources or of the radiation emitted by an accretion flow around it. With the purpose of detecting this shadow in the image of the suppermassive compact object Sagittarius A$^*$ (Sgr A$^*$) present at our Galactic Center and in the image of that present at the center of the nearby galaxy M87, the event horizon telescope (EHT)[1–3] is being constructed and has begun collecting data.

While the intensity map of an image depends on the details of the emission mechanisms of photons, the boundary (silhouette) of the shadow is determined only by the spacetime metric itself, since it corresponds to the apparent shape of the photon capture orbits as seen by a distant observer. Shadows and images cast by different black holes have been studied by several researchers in the past. See Ref. 4 for a recent brief review on this subject. Some recent studies, however, suggest that the presence of a shadow does not by itself prove that it is being necessarily cast by a black hole. Other horizonless compact objects[5–12] can also cast similar shadows. In case of a wormhole, the throat plays very crucial role in casting a shadow[9]. This crucial role was overlooked in Ref. 6, resulting in incomplete results. Later, this problem was revisited in Ref. 9 where the correct and complete shapes of rotating wormhole shadows were obtained by incorporating the crucial role of a wormhole throat. In what follows, we summarize the main results obtained in Ref. 9.

## 2. The rotating wormhole spacetime and null geodesics

The spacetime geometry of a stationary, axisymmetric spacetime metric describing a rotating traversable wormhole of Teo class is given by[13]

$$ds^2 = -N^2dt^2 + \frac{dr^2}{1-\frac{b}{r}} + r^2K^2\left[d\theta^2 + \sin^2\theta(d\varphi - \omega dt)^2\right], \tag{1}$$

where $-\infty < t < \infty$, and $r_0 \leq r < \infty$, $0 \leq \theta \leq \pi$ and $0 \leq \phi \leq 2\pi$ are spherical coordinates. The functions $N$, $b$, $K$, and $\omega$ depend on $r$ and $\theta$. $N$ and $b$ are, respectively, known as analog redshift function and shape function. $K$ determines the area radius through $R = rK$ and $\omega$ measures the angular velocity of the wormhole. To ensure that there are no curvature singularities or event horizons, the above metric functions have to satisfy certain conditions (see Ref. 13 for details). The spacetime describes two identical, asymptotically flat regions connected together at the throat $r = r_0 = b > 0$.

We choose the following form of the metric functions which are frequently used in the literature[6,14,15]:

$$N = \exp\left[-\frac{r_0}{r} - \gamma\left(\frac{r_0}{r}\right)^{\delta}\right], \quad b(r) = r_0, \quad K = 1, \quad \omega = \frac{2J}{r^3}, \tag{2}$$

where $J$ is the angular momentum of the wormhole and $\gamma$ and $\delta$ ($> 1$) are real constants. Also, we can write $r_0 = 2M$, $M$ being the mass of the wormhole[9].

Null geodesics in the spacetime of the wormholes given in Eq. (1) have been studied in Ref. 6. The radial part of the geodesic equation for a photon is given by[6,9]

$$\left(\frac{dr}{d\tilde{\lambda}}\right)^2 + V_{eff} = 0, \quad V_{eff} = -\frac{1}{N^2}\left(1 - \frac{b}{r}\right)R(r), \tag{3}$$

$$R(r) = (1-\omega\xi)^2 - \eta\frac{N^2}{r^2K^2}, \tag{4}$$

where $V_{eff}$ is the effective potential, and $\xi$ and $\eta$ are impact parameters defined by

$$\xi = \frac{L}{E}, \quad \eta = \frac{Q}{E^2}. \tag{5}$$

Here, $E$, $L$ and $Q$ are three constants of motion and represent, respectively, the energy, the angular momentum (about the axis of symmetry) of the photon and the Carter constant.

## 3. Shadows

A wormhole connects two regions of spacetime through its throat. To obtain the shadow cast by a wormhole, we consider that the wormhole is illuminated by photons coming from an extended light source situated in one of the regions (first region), and no light sources are present in the vicinity of the throat in the other region (second region). Depending on the impact parameters, some of the photons from

the light source get captured by the wormhole, and some get scattered away to a faraway observer situated in the first region. In the observer's sky, the scattered photons which are received by him/her form bright spots. On the other hand, the captured photons plunge through the wormhole and go to the other region, thereby forming dark spots in the observer's sky. The union of the dark spots in the observer's sky constitute what we call shadow.

A set of unstable circular orbits of photons, which are also known as unstable light rings, separate the escaping and plunging photons and are characterized by certain critical values of the impact parameters $\xi$ and $\eta$. These critical impact parameters define the boundary of the shadow. The unstable circular photon orbits correspond to the maximum of the effective potential $V_{eff}$ and are determined by the standard conditions

$$V_{eff} = 0, \quad \frac{dV_{eff}}{dr} = 0, \quad \frac{d^2V_{eff}}{dr^2} \leq 0. \tag{6}$$

The unstable circular orbits may lie outside as well as at the wormhole throat[12]. For the unstable circular orbits whose radii do not coincide with the throat radius $r_0$ (i.e. for the unstable circular orbits which lie outside the throat such that $(1-\frac{b}{r}) \neq 0$ on the orbits), in terms of $R(r)$, the above set of conditions can be rewritten as

$$R(r) = 0, \quad \frac{dR}{dr} = 0, \quad \frac{d^2R}{dr^2} \geq 0. \tag{7}$$

Using $R = 0$ and $dR/dr = 0$, we obtain[6]

$$\eta = \left[\frac{r^2K^2}{N^2}(1-\omega\xi)^2\right]_{r=r_{ph}}, \quad \xi = \frac{\Sigma}{\Sigma\omega - \omega'}\Big|_{r=r_{ph}}, \quad \Sigma = \frac{1}{2}\frac{d}{dr}\ln\left(\frac{N^2}{r^2K^2}\right), \tag{8}$$

where $r_{ph}$ is the radius of a circular photon orbit. On the other hand, since $(1-\frac{b}{r})$ vanishes at the throat $r = r_0$, for the unstable circular orbits which are located at the throat (i.e., for unstable orbits for which $r_{ph} = r_0$), it can be seen from Eq. (3) that the conditions in Eq. (6) are satisfied at the throat when[9]

$$R(r_0) = 0, \quad \frac{dR}{dr}\Big|_{r=r_0} \geq 0, \tag{9}$$

which are different from those in Eq. (7). Note that, in Ref. 9, the second condition on the right hand side of Eq. (9) is written as $\frac{d^2R}{dr^2}\Big|_{r=r_0} \geq 0$ instead of $\frac{dR}{dr}\Big|_{r=r_0} \geq 0$. This was a typographic error in that paper. For nonrotating wormholes, a set of conditions similar to those in Eq. (9) have been obtained in Ref. 12. For the circular photon orbits at the throat, $R(r_0) = 0$ gives

$$(1-\omega_0\xi)^2 - \eta\frac{N_0^2}{r_0^2K_0^2} = 0, \tag{10}$$

where the subscript '0' implies that the quantities are evaluated at the throat.

In realistic observation, the apparent shape of a shadow is measured in the observer's sky, a plane which passes through the center of the wormhole geometry

and is normal to the line of sight joining the observer and the center of the wormhole geometry. The coordinates on this plane are denoted by $\alpha$ and $\beta$ and are known as celestial coordinates. The celestial coordinates are related to the impact parameters by[6]

$$\alpha = -\frac{\xi}{\sin\theta_{obs}}, \quad \beta = \left(\eta - \frac{\xi^2}{\sin^2\theta_{obs}}\right)^{1/2}, \tag{11}$$

where $\theta_{obs}$ is the inclination angle of the observer, i.e., the angle between the rotation axis of the wormhole and the line of sight of the observer. In the $(\alpha, \beta)$-plane, Eqs. (8) and (11) define the part of the boundary of the shadow formed by the unstable circular photon orbits which lie outside the throat. However, for the part of the boundary of the shadow which is due to the unstable circular orbits at the throat, we have, from Eqs. (10) and (11)[9],

$$(N_0^2 - \omega_0^2 r_0^2 K_0^2 \sin^2\theta_{obs})\alpha^2 - 2\omega_0 r_0^2 K_0^2 \sin\theta_{obs}\alpha - r_0^2 K_0^2 + N_0^2\beta^2 = 0. \tag{12}$$

The last equation, which incorporates the effect of a wormhole throat and was not considered in Ref. 6, plays very crucial role in determining the shape of the shadow of a wormhole. The complete apparent shape of the shadow is given by the common region enclosed by the curve obtained from Eqs. (8) and (11) and that obtained from Eq. (12) (see Ref. 9 for details).

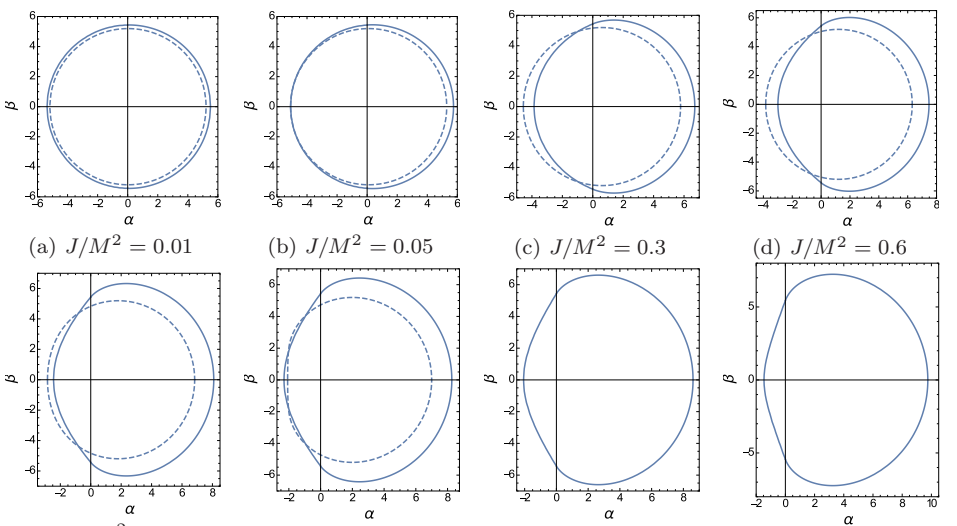

Fig. 1. The shape of the shadow of a rotating wormhole (solid curve) and the Kerr black hole (dashed curve) for different spin values [(a)-(h)]. The metric functions of the wormhole are given by Eq. (2) with $\gamma = 0$ and $\delta = 0$. Here, $\theta_{obs} = 90°$. The axes are in units of the mass $M$. The figures are extracted from Ref. 9.

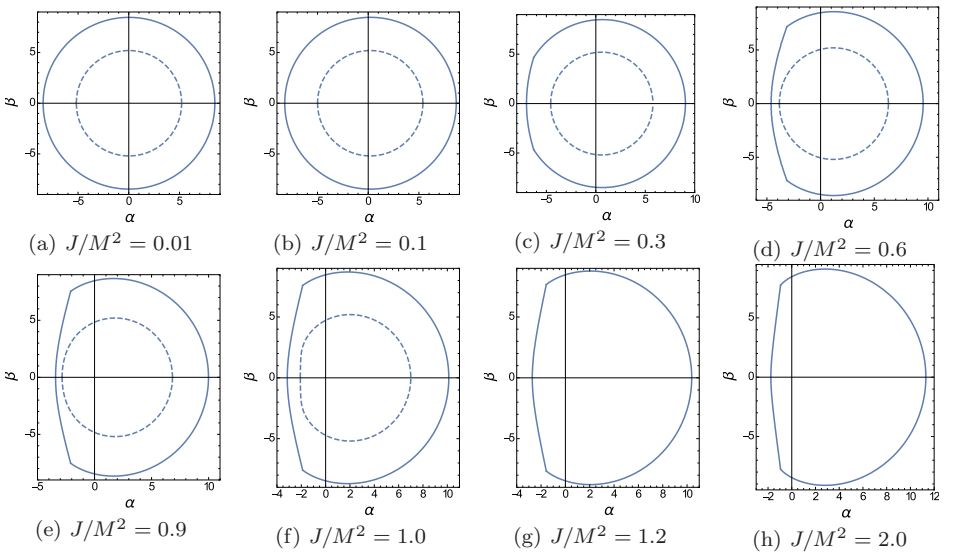

Fig. 2. The shape of the shadow of a rotating wormhole (solid curve) and the Kerr black hole (dashed curve) for different spin values [(a)-(h)]. The metric functions of the wormhole are given by Eq. (2) with $\gamma = 1$ and $\delta = 2$. Here, $\theta_{obs} = 90°$. The axes are in units of the mass $M$. The figures are extracted from Ref. 9.

Figures 1 and 2 show the shadow cast by a rotating wormhole whose metric functions are given by Eq. (2). For comparison, we have also plotted the shadow cast by a Kerr black hole for each set of the parameter values. Note that, for small spin $a$ $(= J/M^2)$, the shape of a wormhole shadow is qualitatively similar to that of the Kerr black hole as they both are almost circular. However, with increasing spin, the characteristic deformation (from the circular shape) in the wormhole shadow is more and more prominent than that in the black hole shadow, resulting in considerable deviation between the two. Such considerable deviation of the wormhole shadow from that of the Kerr black hole may be relevant to discriminate between the two in future observations.

## 4. Conclusion

We have studied shadows cast by a class of rotating Teo wormhole by incorporating the the crucial role that a wormhole throat can play. We have compared our results with those of a Kerr black hole. We find that, for small spin, the shapes of the both black hole and wormhole shadow are qualitatively identical to each other, i.e., both are nearly circular. However, with increasing spin, the characteristic deformation (from the circular shape) in the wormhole shadow is more and more prominent than that in the black hole shadow, resulting in considerable deviation between the two. Such considerable deviation, if detected in future observations, may possibly indicate the presence of a wormhole. In other words, our results indicate that,

through the observations of the shapes of their shadows, a wormhole which have reasonable spin can be distinguished from a black hole.

However, our conclusions are largely based on the specific types of wormholes we have chosen to work with. It will be worthwhile to see whether or to what extent the conclusions drawn here carry over to a broader class of rotating wormholes.

The BRST-BV formalism provides a general and systematic framework to classify consistent deformations of gauge theories. This note is a brief review of the generalization of the method to accommodate the treatment of massive field theories in the Stueckelberg formulation. Applications include the classification of the cubic and quartic interaction vertices for a multiplet of massive spin-1 fields, and of the cubic deformations of the theory of a single massive spin-2 field. The results are shown to correctly reproduce the known vertices of massive Yang–Mills theory and massive gravity, respectively. The formalism also sheds light on the characterization of Stueckelberg gauge theories, by demonstrating in particular that they can be abelianized by means of local field redefinitions.

## 1. Introduction

The problem of *deformations* of field theories concerns the following basic question: given a free theory for a some set of fields, what are the most general interactions that one can add in a *consistent* way?[a] The requirement of consistency is an essential assumption, and is the statement that any deformation must preserve the number and nature of the degrees of freedom. In a gauge theory, in particular, this implies that the number of gauge symmetries must stay the same — since a gauge symmetry is nothing but a constraint on the number of propagating fields — although the form of the symmetries may in general change as one deforms the initial theory.

The solution to the problem of consistent deformations is well known in some relatively simple cases. For instance in the case of the free Maxwell theory, it is easy to prove that the abelian $U(1)$ gauge symmetry admits no deformations, meaning that any interaction vertices must be invariant under this symmetry. In four dimensions one can also show that all such invariants must of the Born–Infeld type, i.e. they can be written solely in terms of a basic set of invariant tensors. In the context of Maxwell theory this implies that any deformation of the action of a massless spin-1 particle must be given by Lorentz-invariant contractions of $F_{\mu\nu}$ and its derivatives. The story is more interesting for a collection of vector fields $A^a_\mu$, with $a = 1, \ldots, n$. The free action may always be diagonalized (assuming no negative-norm states) so as to take the form $S_0 = -\frac{1}{4}\int d^D x\, F^{\mu\nu}_a F^a_{\mu\nu}$, where again

[a] Although in this work we have focused on deformations of free theories, the general formalism is not restricted to this situation. For instance, one could consider higher order deformations of models that are already interacting, or the question of how to couple two sets of degrees of freedom which are independently described by non-trivial theories.

$F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu$ and color indices are raised and lowered with $\delta_{ab}$. As in the single-field case, there is always the possibility of constructing interactions in the form of Born–Infeld terms, which are however less interesting as they correspond to higher-dimension operators. The more compelling direction is instead to allow for deformations of the $U(1)^n$ gauge symmetry, which are no longer trivial if $n \geq 3$. This procedure leads, under some assumptions on the number of derivatives, to Yang–Mills theory as the most general interacting theory for a multiplet of massless spin-1 fields. In other words, the problem of consistent deformations allows one to *derive* Yang–Mills theory purely from the knowledge of the particle content and the global symmetries (in this case Poincaré invariance) that define the model. In particular, the Lie algebraic nature of the deformed gauge transformations is not an added assumption but follows as a consequence of the formalism. More recent application of this method to models of relevance in gravity include the treatment of massless spin-2 fields in [1] and of partially massless spin-2 fields in [2].

These examples were concerned with massless fields for which gauge invariance plays a defining role. Indeed, the BRST-BV method that we will describe below is tailored to the analysis of gauge theories. In this regard, it may seem that deformations of *massive* theories would be much simpler to study given that the consistency of the gauge symmetries is not an issue anymore in this setting. Nevertheless, even in the absence of constraints imposed by gauge invariance, there is still the concern that interactions may introduce extra degrees of freedom. A famous example is the case of a massive spin-2 field, for which generic interactions lead to the presence of an additional scalar mode in the spectrum, the so-called Boulware–Deser ghost.[b] This is our main motivation to generalize the BRST-BV deformation procedure to include the treatment of massive field theories.

Before we proceed with a description of the formalism, it is instructive to comment on the obstacles that one would encounter by following the more direct approach of the Noether procedure. In this set-up, one seeks to construct interactions perturbatively, by expanding the action as $S = S^{(2)} + S^{(3)} + S^{(4)} + \cdots$, while at the same time allowing for field-dependent deformations of the gauge symmetry, i.e. $\delta_\epsilon \varphi^i = \delta^{(0)}_\epsilon \varphi^i + \delta^{(1)}_\epsilon \varphi^i + \delta^{(2)}_\epsilon \varphi^i + \cdots$, where the superscript $(k)$ means $k$ powers of the fields $\varphi^i$, and $\epsilon$ is a gauge parameter. The consistency condition is given by the gauge invariance of the full action, $\delta_\epsilon S = 0$, which is to be solved iteratively for the deformations $S^{(k)}$ and $\delta^{(k)}_\epsilon$. Although straightforward, this method suffers from several drawbacks. First and foremost is the fact that interaction vertices are in general ambiguous due to the existence of trivial deformations, which can arise from total derivatives, from non-linear redefinitions of the fields, and from

[b] From the point of view of effective field theory (EFT), one may argue that additional degrees of freedom arising from the interactions should not be considered an issue, as they will necessarily lie at or above the cutoff of the EFT. Nevertheless, the search for interactions for which such extra fields are absent is still of interest, as it may lead to a higher cutoff compared to what a generic derivative expansion would imply, often making the model more compelling for physical applications. The case of massive gravity is a classic example.

field-dependent redefinitions of the gauge parameters. Next there is the issue of accounting for the existence of gauge symmetries that vanish on-shell, which are likewise trivial and should be discarded. Lastly, although the Noether procedure is in principle perfectly general, in practice it can be quite cumbersome to apply, especially for theories in curved spacetimes where some simplifying techniques cannot be easily applied. We will see that these obstacles can be addressed in a very systematic way within the BRST-BV method.

## 2. BRST-BV formalism

The origin of the BRST-BV method goes back to the antifield formalism of Batalin and Vilkovisky (BV),[3] whose purpose is to provide a fully general approach to the quantization of non-abelian gauge theories, generalizing the Faddeev–Popov procedure as well as the original BRST method.

Consider an action $S[\varphi]$ for a set of fields $\varphi^i$ and with gauge symmetries $\delta_\epsilon \varphi^i = R^i{}_\alpha[\varphi]\epsilon^\alpha$. As in the BRST method, we introduce a ghost $C^\alpha$ for each gauge symmetry, and note that $C^\alpha$ is fermionic if $\epsilon^\alpha$ is bosonic. In addition, we introduce a set of antifields $\varphi^*_i$ and $C^*_\alpha$, respectively for each field and for each ghost. By definition, the antifields have opposite statistics to the fields they match to. The fundamental object that defines the dynamics of the theory is the *BV functional*

$$W = S + \int d^D x \Big[ R^i{}_\alpha[\varphi]\varphi^*_i C^\alpha + f^\gamma{}_{\alpha\beta}[\varphi] C^*_\gamma C^\alpha C^\beta + M^{ij}_{\alpha\beta}[\varphi]\varphi^*_i \varphi^*_j C^\alpha C^\beta + \cdots \Big] . \quad (1)$$

The tensors $R^i{}_\alpha$, $f^\gamma{}_{\alpha\beta}$ and $M^{ij}_{\alpha\beta}$ are in general non-linear functionals of the fields, and the ellipsis stands for an a priori infinite series in antifields, each term multiplied by a "structure functional" of the fields as well as powers of the ghosts. The form of the structure functionals is determined by the *master equation*,

$$(W, W) = 0 , \quad (2)$$

where $(A, B)$ stands for the antibracket of any two functionals $A$ and $B$ (we will not need the explicit definition; see for details). The extension of the action given by the BV functional implies that the original gauge invariance of the theory is removed. However, the information about the gauge symmetry is still encoded in full within the master equation, in the following sense. By expanding (2) in antifields one finds at lowest order the relation $R^i{}_\alpha \frac{\delta S}{\delta \varphi^i} = 0$, which is nothing but the Noether identity associated to the gauge invariance. At the next order one has $R^j{}_\alpha \frac{\delta R^i{}_\beta}{\delta \varphi^j} - R^j{}_\beta \frac{\delta R^i{}_\alpha}{\delta \varphi^j} = f^\gamma{}_{\alpha\beta} R^i{}_\gamma + M^{ij}_{\alpha\beta} \frac{\delta S}{\delta \varphi^j}$, which is the statement that gauge transformations form an algebra. Notice that in general the gauge algebra is not of the Lie type due to the fact that the $f^\gamma{}_{\alpha\beta}$ are not constant. In this way one may continue to higher orders in antifields to derive an infinite tower of consistency relations for the functionals that define the structure of the gauge algebra. For instance at the following order one encounters the Jacobi identity that encodes the consistency of the functionals $f^\gamma{}_{\alpha\beta}$, just like the gauge algebra encodes the consistency of the operators $R^i{}_\alpha$ that define the original gauge transformations.

The main idea of the deformation analysis is to revert this logic.[4] We are now given only a free theory, with some fields and gauge symmetries, and we seek to determine the most general set of interactions by solving the master equation. In practice we do this perturbatively, expanding the BV action as $W = W_0 + gW_1 + g^2W_2 + \cdots$, where $g$ is a formal deformation parameter that will play the role of a coupling constant. At first order in $g$ eq. (2) reads $(W_0, W_1) = 0$, which is to be solved for $W_1$; at second order we have to solve for $W_2$ from the equation $(W_1, W_1) + 2(W_0, W_2) = 0$, and so on. At this stage it may seem that we have not simplified the problem by much in comparison to the Noether procedure — instead of solving for the action and gauge transformations, we now have to solve for the BV functional order by order. The real technical advantage of the BRST-BV formalism may be seen by rephrasing the analysis as a cohomological problem, as we now explain.

We have remarked that the BV action has no gauge invariance, which is precisely the reason for introducing the ghost fields in the first place. But a remnant of the gauge symmetry is still present in $W_0$ in the form of a *BRST symmetry*, $sW_0 = 0$, where $s$ denotes the BRST differential. One can then show that $W_0$ acts as a generator of BRST transformations in the sense that $sA = (W_0, A)$ for any functional $A$. The order-$g$ part of the master equation then states that $W_1$ is BRST-closed, $sW_1 = 0$. Since $s^2 = 0$, given any solution of this equation we can always add a BRST-exact term $W_1' = sB_1$. But it can be proved that such terms are precisely the expressions that encode the possible trivial deformations alluded to above. In other words, the non-trivial solutions of the master equation that we are after are defined by the cohomology of the BRST differential. The method thus provides a very clean mathematical characterization of trivial deformations of field theories.

## 3. Application to massive field theories

It is clear from the construction of the BV functional that gauge symmetries play a crucial role in the formalism. This may seem to preclude the application of the method to treat massive theories, which in their usual parametrization possess no gauge invariance. However, as is well known, gauge symmetries may be straightforwardly introduced simply by adding some extra fields in such a way that the action regains the invariance of the massless theory. This is known as the *Stueckelberg procedure*. In the following we summarize our results of the application of the BRST-BV formalism to analyze interactions for a multiplet of massive spin-1 particles and for a single massive spin-2 particle.[5]

### 3.1. *Multiple massive spin-1 fields*

The starting point is the free action for a collection of massive spin-1 fields $A^a_\mu$ $(a = 1, \ldots, n)$, and is given by a sum of $n$ Proca Lagrangians, and we assume all the fields to have the same mass $m$. To this we add a set of Stueckelberg scalars

$\pi^a$ responsible for restoring the local $U(1)^n$ symmetry of the massless theory, with gauge functions $\epsilon^a$ and corresponding ghosts $C^a$. The antifields are denoted by $A^{*\mu}_a$, $\pi^*_a$ and $C^*_a$.

The solution of the first order deformation of the BV functional may be written as $W_1 = \int d^D x(a_0 + a_1 + a_2)$, where the subscript in $a_k$ denotes the antifield number. From the master equation we obtain $a_2 = \frac{g}{2} f^a{}_{bc} C^*_a C^b C^c$, $a_1 = g f^a{}_{bc} A^{*\mu}_a A^b_\mu C^c + \frac{g}{2} f^a{}_{bc} \pi^*_a \pi^b C^c$, and $a_0 = \frac{g}{2} f^a{}_{bc} \left(-F^{\mu\nu}_a A^b_\mu A^c_\nu + A^\mu_a \partial_\mu \pi^b \pi^c\right)$. Each term has a clear interpretation: $a_2$ encodes the deformation of the gauge algebra, so that the coefficients $f^a{}_{bc}$ play the role of structure constants; $a_1$ encodes the deformation of the gauge transformations at linear order in the fields; and $a_0$ encodes the cubic vertices of the deformed theory. Notice that the existence of a non-trivial $a_0$ enforces the constraint $f_{abc} = f_{[abc]}$ on the structure constants, whereas initially we only had $f^a{}_{bc} = f^a{}_{[bc]}$.

Continuing to the next order, one finds an obstruction when solving for $W_2$ unless one imposes the constraint $f^a{}_{b[c} f^b{}_{de]} = 0$. This is nothing but the Jacobi identity for the structure constants, and therefore the gauge algebra of the theory must be a Lie algebra for the deformations to be consistent. We omit the explicit result for $W_2$, but we remark that it does correctly reproduce, together with $W_1$ as given above, the cubic and quartic non-abelian interactions for a multiplet of massive spin-1 fields, which have been derived previously via other methods.[6]

### 3.2. *Massive spin-2 field*

The free theory of a spin-2 field $h_{\mu\nu}$ of mass $m$ is given by the Fierz–Pauli action. Linear diffeomorphism invariance is restored by the inclusion of a Stueckelberg vector $B_\mu$, and the corresponding ghost is denoted by $C_\mu$. In order to have a well behaved high energy limit, it is useful to further add a Stueckelberg scalar $\varphi$ in order to restore a local $U(1)$ symmetry, whose ghost we denote by $C$.

The calculations in this case are more involved and so we limit ourselves to present only the final result for the cubic vertices (we refer the reader to[5] for details), omitting contributions from the Stuckelberg fields:

$$a_0\Big|_{B_\mu=0=\varphi} = \kappa \mathcal{L}^{(3)}_{\mathrm{EH}}[h] + \frac{\kappa m^2}{2}\left(h^{\mu\nu} h_\mu{}^\rho h_{\rho\nu} - \frac{5}{4} h h^{\mu\nu} h_{\mu\nu} + \frac{1}{4} h^3\right) + \alpha_1 \bar{a}^{(\mathrm{dRGT})}_0 + \alpha_2 \bar{a}^{(\mathrm{PL}_1)}_0 + \alpha_3 \bar{a}^{(\mathrm{PL}_2)}_0 \,. \tag{3}$$

Here $\mathcal{L}^{(3)}_{\mathrm{EH}}$ is the cubic part of the Einstein–Hilbert Lagrangian, so that the deformation parameter $\kappa$ may be identified with $1/M_P^{(D-2)/2}$, with $M_P$ the Planck mass. There are also three arbitrary constants $\alpha_{1,2,3}$ multiplying the homogeneous solutions $\bar{a}_0$ of the master equation. These are all terms of the Born–Infeld type, constructed out of a basic invariant tensor $H_{\mu\nu}$. In particular, $\bar{a}^{(\mathrm{dRGT})}_0$ contains no derivatives of $H_{\mu\nu}$, and when added to the first line in (3) it produces the cubic interactions of dRGT massive gravity.[7] Lastly, the operators $\bar{a}^{(\mathrm{PL})}_0$ involve second

derivatives of $H_{\mu\nu}$ and correspond to the cubic pseudo-linear interaction terms for a massive spin-2 field.[8] Our result in eq. (3) thus provides a full classification of the possible cubic vertices for a single massive graviton.

### 3.3. *Abelianization*

We conclude by commenting on an interesting property of Stueckelberg gauge theories, which has been made manifest thanks to our application of the BRST-BV formalism. This is the property that interacting Stueckelberg theories may always be *abelianized*, that is there always exists a choice of field variables for which the gauge symmetries become abelian, reducing to the symmetries of the free theory. This follows from the fact that the ghost associated to a Stueckelberg symmetry is necessarily BRST-exact, which in turn implies that all deformations of the gauge algebra and the gauge symmetries are trivial. A further interesting consequence of this abelianization property is that the action is of the Born–Infeld type, which makes it a simple matter to construct the most general set of interactions for a given set of fields. That being said, the use of variables that makes the abelian nature of the theory manifest is not always the smartest choice, as this formulation may obscure the correct power counting of operators in the derivative expansion.

We consider a general Einstein–scalar–Gauss-Bonnet theory with a coupling function $f(\phi)$ between the scalar field and the quadratic gravitational Gauss-Bonnet term. We show that the existing no-hair theorems are easily evaded, and therefore black holes may emerge in the context of this theory. Indeed, we demonstrate that, under mild only assumptions for $f(\phi)$, asymptotic solutions describing either a regular black-hole horizon or an asymptotically-flat solution always emerge. We then show, through numerical integration, that the field equations allow for the smooth connection of these asymptotic solutions, and thus for the construction of a complete, regular black-hole solution with non-trivial scalar hair. We present and discuss the physical characteristics of a large number of such solutions for a plethora of coupling functions $f(\phi)$. Finally, we investigate whether pure scalar-Gauss-Bonnet black holes may arise in the context of our theory when the Ricci scalar may be altogether ignored.

*Keywords*: Generalised Gravitational Theories, Gauss-Bonnet term, no-hair theorems, black-hole solutions, scalar hair

## 1. Introduction

The General Theory of Relativity is a beautiful mathematical theory that predicts a variety of gravitational solutions, with the black holes being the most fascinating example. In the context of General Relativity, the black-hole solutions have been uniquely determined and classified according to their properties (mass, charge and angular-momentum). No-Hair theorems, that forbid the association of a black hole with any other "charge" or field, were formulated quite early on. The existence of black-hole solutions associated with a non-trivial scalar field in the region outside the black-hole horizon has also been intensively studied. The *old no-hair theorem*[1] was formulated in the seventies, and excluded static black holes with a scalar field. However, this was outdated by the discovery of black holes with Yang-Mills[2], Skyrme fields[3] or conformally-coupled scalar fields[4]. Twenty years later, the *novel no-hair theorem*[5] was formulated (for more recent analyses, see[6–8]) but this was also

shown to be evaded in the context of the Einstein-Dilaton-Gauss-Bonnet theory[9] and in shift-symmetric Galileon theories[10,11].

In fact, the black-hole solutions[9–11] were derived in the context of the so-called generalised gravitational theories, where additional fields and higher gravitational terms may be present. These theories comprise a popular test-bed for the formulation of the ultimate theory of gravity beyond Einstein's General Theory of Relativity, and are under intense research activity. In this work, we will consider a wide class of gravitational theories where a scalar field $\phi$ has a general coupling function $f(\phi)$ to the quadratic gravitational Gauss-Bonnet (GB) term. Choosing the coupling function to be of an exponential or a linear form, one recovers the two novel black-hole solutions with non-trivial scalar hair[9,11], respectively. In[12] we demonstrated that, in fact, this class of theories with an arbitrary $f(\phi)$ always evades the existing no-hair theorems and allow for the emergence of novel black-hole solutions, with a regular horizon and an asymptotically-flat limit. Here, we review these results and discuss the characteristics of these solutions. We also investigate whether solutions arise in the context of the pure scalar-Gauss-Bonnet theory where the Ricci scalar may be ignored.

## 2. The Einstein-Scalar-Gauss-Bonnet theory

We will therefore consider the following generalised gravitational theory

$$S = \frac{1}{16\pi}\int d^4x\sqrt{-g}\left[R - \frac{1}{2}\,\partial_\mu\phi\,\partial^\mu\phi + f(\phi)R^2_{GB}\right], \tag{1}$$

where the GB term is defined as $R^2_{GB} = R_{\mu\nu\rho\sigma}R^{\mu\nu\rho\sigma} - 4R_{\mu\nu}R^{\mu\nu} + R^2$. By varying the above action with respect to the metric tensor and scalar field, we obtain the following gravitational field equations and the equation for the scalar field:

$$G_{\mu\nu} = T_{\mu\nu}\,, \qquad \nabla^2\phi + \dot{f}(\phi)R^2_{GB} = 0\,, \tag{2}$$

respectively, where a dot denotes the derivative with respect to the scalar field. The energy-momentum tensor has the form

$$T_{\mu\nu} = -\frac{1}{4}g_{\mu\nu}\partial_\rho\phi\partial^\rho\phi + \frac{1}{2}\partial_\mu\phi\partial_\nu\phi - \frac{1}{2}(g_{\rho\mu}g_{\lambda\nu} + g_{\lambda\mu}g_{\rho\nu})\eta^{\kappa\lambda\alpha\beta}\tilde{R}^{\rho\gamma}{}_{\alpha\beta}\nabla_\gamma\partial_\kappa f. \tag{3}$$

In the above, $\tilde{R}^{\rho\gamma}{}_{\alpha\beta} = \eta^{\rho\gamma\sigma\tau}R_{\sigma\tau\alpha\beta} = \epsilon^{\rho\gamma\sigma\tau}R_{\sigma\tau\alpha\beta}/\sqrt{-g}$. In the context of the above theory, we will look for regular, static, spherically-symmetric and asymptotically-flat black-hole solutions described by the line-element

$$ds^2 = -e^{A(r)}dt^2 + e^{B(r)}dr^2 + r^2(d\theta^2 + \sin^2\theta\, d\varphi^2)\,. \tag{4}$$

Using the above expression, the Einstein's equations take the following explicit form

$$4e^B(e^B + rB' - 1) = \phi'^2\left[r^2e^B + 16\ddot{f}(e^B - 1)\right] - 8\dot{f}\left[B'\phi'(e^B - 3) - 2\phi''(e^B - 1)\right], \tag{5}$$

$$4e^B(e^B - rA' - 1) = -\phi'^2r^2e^B + 8\left(e^B - 3\right)\dot{f}A'\phi', \tag{6}$$

$$e^B\left[rA'^2 - 2B' + A'(2 - rB') + 2rA''\right] = -\phi'^2 re^B \\ +8\phi'^2\ddot{f}A' + 4\dot{f}[\phi'(A'^2 + 2A'') + A'(2\phi'' - 3B'\phi')], \qquad (7)$$

while the scalar equation reads

$$2r\phi'' + (4 + rA' - rB')\,\phi' + \frac{4\dot{f}e^{-B}}{r}\left[(e^B - 3)A'B' - (e^B - 1)(2A'' + A'^2)\right] = 0. \qquad (8)$$

In the above, we have assumed that the scalar field depends only on the radial coordinate, and thus the prime denotes differentiation with respect to $r$.

The unknown quantities, that we seek to determine through the solution of the system of Eqs. (5)-(8), are the scalar field $\phi$ and the metric functions $A$ and $B$. Of these, the metric function $B$ may be easily determined in terms of $(\phi, A)$ through Eq. (6). Then, the remaining field equations lead to a system of two independent, ordinary differential equations of second order for the functions $A$ and $\phi$:

$$A'' = \frac{P}{S}\,, \qquad \phi'' = \frac{Q}{S}\,. \qquad (9)$$

The functions $P$, $Q$ and $S$ are rather complicated expressions of $(r, \phi', A', \dot{f}, \ddot{f})$ and may be found in[12].

For a regular horizon to form, we demand that $e^A \to 0$ in Eq. (4), while $\phi$, $\phi'$ and $\phi''$ remain finite, as $r \to r_h$. Then, the 2nd of Eqs. (9) yields the constraint

$$\phi'_h = \frac{r_h}{4\dot{f}_h}\left(-1 \pm \sqrt{1 - \frac{96\dot{f}_h^2}{r_h^4}}\right). \qquad (10)$$

The quantity under the square-root should be positive which results in the additional bound $\dot{f}_h^2 < r_h^4/96$. Using the above in the 1st of Eqs. (9), we may uniquely determine the form of $A'$ near the horizon. Putting everything together, the near-horizon solution reads

$$e^A = a_1(r - r_h) + \dots\,, \qquad e^{-B} = b_1(r - r_h) + \dots\,, \\ \phi = \phi_h + \phi'_h(r - r_h) + \phi''_h(r - r_h)^2 + \dots\,. \qquad (11)$$

On the other hand, at asymptotic infinity, we assume power-law expressions for the metric functions and scalar field as customary. Substituting these expressions into the field equations, we obtain

$$e^A = 1 - \frac{2M}{r} + \frac{MD^2}{12r^3} + \dots\,, \quad e^B = 1 + \frac{2M}{r} + \frac{16M^2 - D^2}{4r^2} + \dots\,, \\ \phi = \phi_\infty + \frac{D}{r} + \frac{MD}{r^2} + \frac{32M^2D - D^3}{24r^3} + \dots\,. \qquad (12)$$

The above asymptotic behaviour is characterised by the ADM mass $M$ and scalar charge $D$ of the black hole. We may therefore conclude that the scalar-tensor theory

(1) with a general coupling function $f(\phi)$ is always compatible with either a regular horizon or an asymptotically-flat limit.

However, no complete black-hole solution may be constructed unless the aforementioned asymptotic solutions are smoothly matched. To investigate whether this is in principle possible, we turn to the novel no-hair theorem[5] and examine its requirements under which it may forbid the existence of such a solution. This theorem assumes first that, at asymptotic infinity, the $T^r{}_r$ component of the energy-momentum tensor is positive and decreasing. Indeed, we find that this has the form

$$T^r{}_r = \frac{e^{-B}\phi'}{4}\left[\phi' - \frac{8e^{-B}\left(e^B-3\right)\dot{f}A'}{r^2}\right] \simeq \frac{\phi'^2}{4} \sim \mathcal{O}(\frac{1}{r^4}). \tag{13}$$

In the near-horizon regime, $T^r{}_r$ should be negative and increasing according to[5]; however, employing the asymptotic solution (11), we find that in our case

$$T^r{}_r = -\frac{2e^{-B}}{r^2}A'\phi'\dot{f} + \mathcal{O}(r-r_h)\,. \tag{14}$$

This expression is always positive-definite since, close to the horizon, $A' > 0$, and $\dot{f}\,\phi' < 0$ according to Eq. (10) for a regular horizon. Also, we find that $T^r{}_r$ is always decreasing close to $r_h$ and as a result, the novel no-hair theorem is non-applicable in our theory.

The above result opens the way for the construction of novel black-hole solutions in the context of the general theory (1). We have therefore numerically solved the system of equations (9), and determined a large number of black-hole solutions with scalar hair for a variety of forms of the coupling function $f(\phi)$: exponential, odd and even power-law, odd and even inverse-power-law. Once the form of $f(\phi)$ was chosen, the input values $(\phi_h, \phi'_h)$, with $\phi'_h$ being given by Eq. (10), always led to a regular black-hole solution with scalar hair. The scalar field and profile of $T^r{}_r$ for those solutions are depicted in Figs. 1(a,b).

Some of the characteristics of the black-hole solutions we found[12] are represented in Figs. 2(a,b), where we depict the indicative case of $f(\phi) = \alpha/\phi$. The scalar charge $D$ is a function of the black-hole mass and thus a dependent quantity; this renders

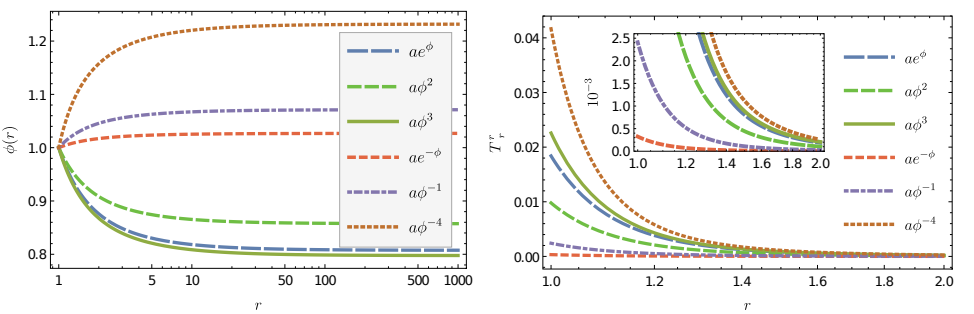

Fig. 1. The scalar field $\phi$ (left plot) and the $T^r{}_r$ component (right plot) for different coupling functions $f(\phi)$, for $a = 0.01$ and $\phi_h = 1$.

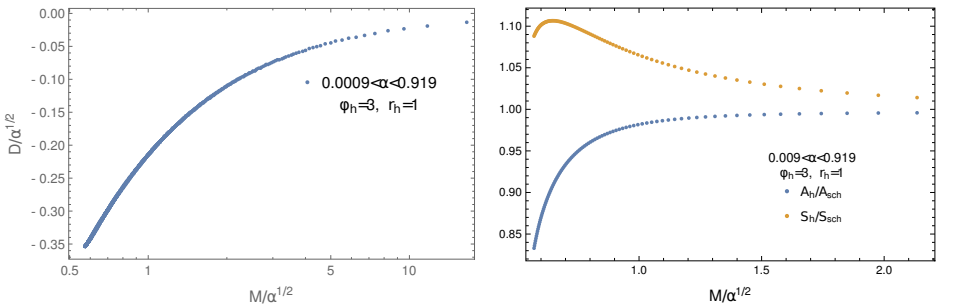

Fig. 2. The scalar charge $D$ (left plot), and the ratios $A_h/A_{Sch}$ and $S_h/S_{Sch}$ (right plot, lower and upper curve respectively) in terms of the mass $M$, for $f(\phi) = \alpha/\phi$.

the scalar hair secondary. For a large mass, the scalar charge vanishes and our black-hole solutions match the Schwarzschild solution. The horizon area is always smaller than the one of the Schwarzschild solution exhibiting also a lower value beyond which the black hole ceases to exist — the latter feature is due to the additional bound emerging from the positivity of the quantity under the square-root in Eq. (10). Its entropy is larger than that of the Schwarzschild case and thus thermodynamically more stable.

## 3. The pure scalar-Gauss-Bonnet theory

We will now investigate whether a regular black-hole solution can arise in the context of a pure scalar-GB theory, i.e. in the absence of the linear Ricci term. By ignoring all terms in the field equations related to the Ricci term, these are simplified — but can we construct again a regular horizon? If we assume as before that, as $r \to r_h$, $\phi'$ remains finite while $A'$ diverges, Eq. (6) now yields: $e^B \simeq 3 + \mathcal{O}(1/A')$; but this does not describe a black hole. We may alternatively demand that $e^B \to \infty$ instead, as $r \to r_h$; then, Eq. (6) gives: $A' \simeq r^2\phi'/8\dot{f} + \mathcal{O}(e^{-B})$. In this case, $A(r)$ is the dependent quantity, and Eqs. (5) and (7) form a system of two differential equations for $B$ and $\phi$. In the limit $r \to r_h$, we find the results[12]

$$B' = -\frac{2}{r}\, e^B + \mathcal{O}\left(e^{-B}\right), \qquad \phi'' = -\frac{e^B}{r}\,\phi' + \mathcal{O}\left(e^{-B}\right). \tag{15}$$

Upon integration, the first equation leads to the solution $e^{-B} = 2\ln(r/r_h)$, which does resemble a horizon, but the second one reveals that this horizon is not regular unless $\phi'(r_h) = 0$, an assumption that trivialises the contribution of the GB term. Alternative ansatzes for the form of the spacetime around the sought-for black hole have also failed to lead to a regular horizon in the absence of the Ricci scalar.

## 4. Conclusions

In the context of a general Einstein-scalar-GB theory, we have demonstrated that the emergence of regular black-hole solutions is a generic feature. For an arbitrary

coupling function $f(\phi)$, we were always able to construct a regular black-hole horizon as well as an asymptotically-flat solution at infinity, and to explicitly show that the novel no-hair theorem is then easily evaded. Our numerical analysis has subsequently led to a large number of regular black-hole solutions for different choices of $f(\phi)$, all characterised by a non-trivial scalar hair (for similar black-hole solutions, see also[13,14]). The study of the pure scalar-GB theory, and the failure to obtain a regular horizon, clearly demonstrates that the presence of the GB term in the theory is a necessary condition for the emergence of novel black holes but not a sufficient one as it must be supplemented by the presence of the linear Ricci term.

We investigate the general approach to finding exact cosmological solutions in $f(R)$ Hořava-Lifshitz gravity, based on Noether's theorem. A feature of this approach is that it uses the behavior of an effective Lagrangian under infinitesimal transformations of the desired symmetry, explicitly determining the form $f(R)$ for which such symmetries exist. It is shown that the dynamics of the scale factor changes according to either a exponential function of time.

*Keywords*: Hořava-Lifshitz gravity; $f(R)$ gravity; Noether symmetry.

## 1. Introduction

At the end of the past millennium, it became clear from the observation of type Ia supernovae and the cosmic microwave background that our universe expands with acceleration [1, 2]. The explanation of this phenomenon within the framework of the general theory of relativity led to the formulation of a large number of models, one of which consists in introducing a mysterious substance, the so-called dark energy (see for example Ref. [3] and references therein for some reviews). The nature of dark energy is still not clear, but mathematically it fits well with the ΛCDM model a wide range of data [4]. Nevertheless, this model has strong theoretical flaws [5], which motivated the search for alternative models [6, 7]. One of the alternatives is the modification of the Einstein-Hilbert term, replacing the Ricci scalar $R$ in the action with some common functions $f(R)$ of the Ricci scalar (see for example Ref. [8]).

In parallel, some models for quantum gravity were developed. In 2009, Hořava [9], based on an idea proposed by Lifshitz [10], formulated a model for a theory of quantum gravity, which takes into account ultraviolet mode renormalizability, due to an anisotropic scaling between space and time, so that Lorentz invariance is violated on ultraviolet scales. However, when choosing the parameter $\lambda = 1$, the infrared limit of the theory reproduces the general theory of relativity. This modification of the general theory of relativity consists in introducing high-order terms into the Einstein-Hilbert action, which lead to different scalings and divide the coordinates into space and time. In theory, there are no ghosts, since there are only second-order

time derivatives in the action, but a clear violation of general covariance introduces a new scalar degree of freedom, due to which pathologies appear [11]. This model developed further and is known as the Hořava-Lifshitz theory (see for example Ref. [12]). From the above considerations, it is clear that the quantum theory of Hořava-Lifshitz, combined with the alternative theory $f(R)$, is a promising candidate for completing the general theory of relativity in the ultraviolet range [13, 14].

In this paper, we consider the Friedman-Lemaître-Robertson-Walker (FLRW) flat spacetime in the framework of the metric formalism $f(R)$ of gravity. We consider a general approach to constructing modified gravity, which is invariant with respect to diffeomorphisms and preserve foliation. The approach was proposed in [14], where special attention was paid to the formulation of modified $f(R)$ Hořava–Lifshitz gravity and its Hamiltonian structure. Following [15], we calculated an effective Lagrangian in which the scale factor $a$ and the Ricci scalar $R$ play the role of independent dynamic variables. This Lagrangian is constructed in such a way that its variation with respect to $a$ and $R$ gives the equations of motion of the Hořava–Lifshitz theory. The form of the function $f(R)$, appearing in the modified action, is then determined by the requirement that the Lagrangian admits the required Noether symmetry [16]. Under Noether symmetry of this cosmological model, we understand that there is a vector field $X$, which is an infinitesimal generator of a symmetry in the tangent space of the configuration space, such that the derivative of the Lagrangian along this vector field vanishes. We will see that, by requiring the Noether symmetry as a feature of the Lagrangian of the model under consideration, we can obtain the explicit form of the function $f(R)$. Since the existence of symmetry leads to constants of motion, we can integrate the field equations, which then lead to a exponential expansion for the universe.

## 2. Modified $f(R)$ Hořava-Lifshitz Gravity

In this work, we consider a more general model of the Hořava-Lifshitz gravity proposed in [14]. The action of such a model has the form

$$S_{f(R_{GHL})} = \int \mathrm{d}^4x\sqrt{g^{(3)}}Nf(R_{GHL}). \tag{1}$$

Here $g^{(3)}$ is determinant of the three-dimensional metric tensor $g_{ij}^{(3)}$ for the ADM metric given in the following form

$$ds^2 = -N^2\mathrm{d}t^2 + g_{ij}^{(3)}\left(\mathrm{d}x^i + N^i\mathrm{d}t\right)\left(\mathrm{d}x^j + N^j\mathrm{d}t\right), \tag{2}$$

where $i, j = 1, 2, 3$, $N$ is the so-called lapse variable and $N^i$ is the shift 3-vector. In the action, we use the function $f(R_{GHL})$, which denotes the generalized curvature of the Hořava-Lifshitz gravity $R_{GHL}$ and is defined as

$$R_{GHL} \equiv K^{ij}K_{ij} - \lambda K^2 + 2\mu\nabla_\mu\left(n^\mu\nabla_\nu n^\nu - n^\nu\nabla_\nu n^\mu\right) - E^{ij}\mathcal{G}_{ijkl}E^{kl}, \tag{3}$$

where $K_{ij}$ is the extrinsic curvature

$$K_{ij} = \frac{1}{2N}\left(\dot{g}^{(3)}_{ij} - \nabla^{(3)}_i N_j - \nabla^{(3)}_j N_i\right), \quad K = K^i{}_i\,, \tag{4}$$

$n^\mu$ is a unit vector perpendicular to the three-dimensional hypersurface $\Sigma_t$ defined by $t =$ constant, and $\nabla^{(3)}_i$ expresses the covariant derivative on the hypersurface $\Sigma_t$. In the last term of Eq. (3), $\mathcal{G}_{ijkl}$ is the inverse of the generalized De Witt metric

$$\mathcal{G}^{ijkl} = \frac{1}{2}(g^{(3)ik}g^{(3)jl} + g^{(3)il}g^{(3)jk}) - \lambda g^{(3)ij}g^{(3)kl}. \tag{5}$$

Here it is important to note that $\mathcal{G}^{ijkl}$ is singular for $\lambda = 1/3$ and $G_{ijkl}$ exist if $\lambda \neq 1/3$. The expression for $E_{ij}$ is constructed to satisfy the "detailed balance principle" [17] and is defined as

$$\sqrt{g^{(3)}}E^{ij} = \frac{\delta W[g^{(3)}_{kl}]}{\delta g^{(3)}_{ij}}, \tag{6}$$

where the form of $W[g^{(3)}_{kl}]$ is given in [18] for $z = 2$ and $z = 3$.

Consider a spatially flat FLRW universe

$$ds^2 = -N^2\mathrm{d}t^2 + a(t)^2 \sum_{i=1,2,3}\left(\mathrm{d}x^i\right)^2, \tag{7}$$

where $N$ can be considered as time-independent and we will fix as $N = 1$. The scalar curvature (3) can be written as

$$R_{GHL} = 3(1 - 3\lambda + 4\mu)\frac{\dot{a}^2}{a^2} + 6\mu\frac{\ddot{a}}{a}. \tag{8}$$

Following [16], in order to investigate Noether's symmetry of the model, it is necessary to determine the effective Lagrangian of the action (1) of the minisuperspace under consideration, in which the scale factor $a$ and the scalar curvature $R_{GHL}$ play the role of independent dynamical variables

$$S = \int dt\mathcal{L}(a, \dot{a}, R_{GHL}, \dot{R}_{GHL}) = \\ \int dt\Big[a^3 f(R_{GHL}) - \nu\Big\{R_{GHL} - \Big(3(1 - 3\lambda + 4\mu)\frac{\dot{a}^2}{a^2} + 6\mu\frac{\ddot{a}}{a}\Big)\Big\}\Big], \tag{9}$$

where $\nu = a^3 df(R_{GHL})/dR_{GHL}$ is a Lagrange multiplier. Then, the effective Lagrangian will have the form

$$\mathcal{L}(a, \dot{a}, R_{GHL}, \dot{R}_{GHL}) = (9\lambda - 3)\dot{a}^2 a f' + 6\mu\dot{a}\dot{R}_{GHL}a^2 f'' + a^3(f'R_{GHL} - f). \tag{10}$$

The equations of motion will have then the following form

$$3H^2 + 2\dot{H} = -\frac{2}{3\lambda - 1}\frac{1}{f'}\Big[\mu f'''\dot{R}^2_{GHL} + \mu f''\ddot{R}_{GHL} + \\ +(3\lambda - 1)f''H\dot{R}_{GHL} + \frac{1}{2}\left(f - R_{GHL}f'\right)\Big]. \tag{11}$$

Also, we have the zero energy condition associated with the above Lagrangian as

$$H^2 = \frac{1}{3(3\lambda-1)}\frac{1}{f'}\left[f'R_{GHL} - f - 6\mu\dot{R}_{GHL}Hf''\right]. \tag{12}$$

Knowing the Lagrangian of the generalized Hořava-Lifshitz gravity, it is possible to determine the Noether symmetry.

## 3. The Noether symmetries in $f(R_{GHL})$ theory of gravity

Here, our aim is to find the function $f(R_{GHL})$ such that the corresponding Lagrangian exhibits the desired symmetry. Following [16], we define the Noether symmetry induced on the model by a vector field $X$ on the tangent space $TQ = \left(a, \dot{a}, R, \dot{R}_{GHL}\right)$ of the configuration space $Q = (a, R_{GHL})$ of the Lagrangian (10) through

$$X = \alpha\frac{\partial}{\partial a} + \beta\frac{\partial}{\partial R_{GHL}} + \frac{d\alpha}{dt}\frac{\partial}{\partial \dot{a}} + \frac{d\beta}{dt}\frac{\partial}{\partial \dot{R}_{GHL}}, \tag{13}$$

such that the Lie derivative of the Lagrangian with respect to this vector field vanishes

$$L_X\mathcal{L} = 0. \tag{14}$$

In Eq.(13), $\alpha$ and $\beta$ are functions of $a$ and $R_{GHL}$ and $\frac{d}{dt}$ represents the Lie derivative along the dynamical vector field, that is,

$$\frac{d}{dt} = \dot{a}\frac{\partial}{\partial a} + \dot{R}_{GHL}\frac{\partial}{\partial R_{GHL}}. \tag{15}$$

Here we substitute the expressions for the effective Lagrangian (10) and combine the coefficients in front of $\dot{a}^2, \dot{R}^2_{GHL}, \dot{a}\dot{R}_{GHL}$. Equating to zero the resulting expression, we obtain the following equations

$$3(3\lambda-1)\left(\alpha + 2a\alpha_a\right)f' + \left[3(3\lambda-1)\beta a + 6\mu a^2\beta_a\right]f'' = 0, \tag{16}$$

$$6\mu a^2\alpha_{R_{GHL}}f'' = 0, \tag{17}$$

$$6\mu\left(2a\alpha + a^2\alpha_a\right)f'' + 6(3\lambda-1)a\alpha_{R_{GHL}}f' + 6\mu a^2\left(\beta f''' + \beta_{R_{GHL}}f''\right) = 0. \tag{18}$$

Then, we collect the remaining free member

$$3\alpha a^2(f'R - f) + \beta a^3 Rf'' = 0. \tag{19}$$

Now, our task is to solve the system of equations (16) - (19) in order to find the cosmological parameters that describe the dynamics of the universe in the framework of the $f(R_{GHL})$ Hořava-Lifshitz gravity. From Eq.(17), it is clear that two cases must be considered: $f'' = 0$ and $\frac{d\alpha}{dR_{GHL}} = 0$, but the solution for $f'' = 0$ has no physical meaning; therefore, we consider only $\frac{d\alpha}{dR_{GHL}} = 0$, then

$$\alpha(a) = \alpha_0 a^{\frac{\beta_0}{\alpha_0}+1}, \beta(a, R) = \beta_0 a^{\frac{\beta_0}{\alpha_0}}R, \tag{20}$$

and

$$f = f_0 R^{-3\frac{\alpha_0}{\beta_0}}, \tag{21}$$

where $\alpha_0 = \frac{2\mu}{3\lambda-6\mu-1}\beta_0$, $f_0, \beta_0$ are integral constants.

## 4. Cosmological solutions

In this section, to describe the dynamics of the universe, we solve analytically the field equations (11) - (12). To this end, we need to find the explicit dependence of the scale factor $a$ in terms of the time $t$. We rewrite Eqs. (11)–(12) as follows

$$3H^2 + 2\dot{H} = -\frac{4\mu(3\lambda-3\mu-1)}{(3\lambda-6\mu-1)^2}\frac{\dot{R}^2_{GHL}}{R^2_{GHL}} + \frac{2\mu}{3\lambda-6\mu-1}\frac{\ddot{R}_{GHL}}{R_{GHL}} + \frac{2(3\lambda-1)}{3\lambda-6\mu-1}\frac{\dot{R}_{GHL}}{R_{GHL}}H + \frac{1}{6\mu}R_{GHL}, \tag{22}$$

$$H^2 = \frac{R_{GHL}}{18\mu} - \frac{2\mu}{1-3\lambda+6\mu}\frac{\dot{R}_{GHL}}{R_{GHL}}H\ . \tag{23}$$

To solve this system we obtain

$$H = \sqrt{\frac{C_1}{C_2}}\tanh(\sqrt{C_1C_2}t), \tag{24}$$

where $C_1 = \frac{Z}{3\mu+3\lambda-1}$, $C_2 = \frac{(3\lambda-1)(3\mu-3\lambda+1)}{2\mu(3\mu+3\lambda-1)}$, or, equivalently,

$$a = a_0\left(e^{\sqrt{C_1C_2}t} + e^{-\sqrt{C_1C_2}t}\right)^{\frac{1}{C_2}}\ . \tag{25}$$

Thus, we have found a general solution to the modified $f(R)$ Hořava-Lifshitz gravity theory. In general, it represents an expanding cosmological model with a scale factor with grows exponentially.

## 5. Conclusion

In this work, we analyzed the $f(R)$ Hořava-Lifhitz gravity model, which is a modification of the original Hořava-Lifhitz model for quantum gravity. We consider the spatially flat FLRW line element to find out what kind of cosmological scenarios are allowed in this modified gravity. Since usually it is very difficult to find analytic solutions to the field equations, we use here the alternative method, which is based on the analysis of the Noether symmetries of a particular effective Lagrangian. In this work, we derive the effective Lagrangian, from the corresponding field equations for the $f(R)$ Hořava-Lifhitz theory in the presence of spatially flat, isotropic and homogeneous line element.

It turns out that the field equations can be represented as a set of two second-order ordinary differential equations, which can be expressed as one differential equation for different variables so that it can be solved by using the standard method

of separation of variables. This simple representation allows us to integrate explicitly the scale factor as well as the Ricci scalar. Both quantities are then explicit functions of time.

The results presented in this work show that the method of Noether symmetries can be applied also in the case of the modified $f(R)$ Hořava-Lifhitz gravity model to derive cosmological solutions. The resulting functions for the scale factor show that the corresponding universe expands either exponentially. This scenario is possible in relativistic cosmology so that, in principle, we could compare our results with observational data from different epochs of the universe evolution. This could be used to set limits on the values of the parameters that enter the Hořava-Lifhitz action.

# Extended mimetic gravity: Hamiltonian analysis and gradient instabilities

Kazufumi Takahashi* and Tsutomu Kobayashi

*Department of Physics, Rikkyo University, Toshima, Tokyo 171-8501, Japan*
**E-mail: takahashik@rikkyo.ac.jp*

We propose a novel class of degenerate higher-order scalar-tensor theories as an extension of mimetic gravity. By performing a noninvertible conformal transformation on "seed" scalar-tensor theories which may be nondegenerate, we can generate a large class of theories with at most three physical degrees of freedom. We identify a general seed theory for which this is possible. Cosmological perturbations in these extended mimetic theories are also studied. It is shown that either of tensor or scalar perturbations is generically plagued with ghost/gradient instabilities. See Ref. 1 for more details.

*Keywords*: Scalar-tensor theories; mimetic gravity; cosmological perturbations.

## 1. Introduction

When one constructs a field theory with higher derivatives, a guiding principle comes from the theorem of Ostrogradsky[2], which states that any theory described by a nondegenerate higher derivative Lagrangian has unstable extra degrees of freedom (DOFs), i.e., Ostrogradsky ghost. Therefore, a theory without Ostrogradsky ghost, often referred to as a *healthy* theory, must have a degenerate Lagrangian.

Within (single-field) scalar-tensor theories in four dimensions, the Horndeski theory[3] (or its equivalent formulation known as generalized Galileons[4,5]) provides a basic ground for studying a wide class of such healthy theories having three DOFs, since it is the most general scalar-tensor theory that yields second-order Euler-Lagrange equations. There are further possibilities of healthy theories beyond the Horndeski class, such as Gleyzes-Langlois-Piazza-Vernizzi (GLPV) theories[6] and quadratic/cubic degenerate higher-order scalar-tensor (DHOST) theories[7–9]. Those quadratic/cubic DHOST theories form the broadest class of healthy scalar-tensor theories known so far. However, these theories are obtained under the assumption that the Lagrangian depends on up to quadratic/cubic order in $\nabla_\mu\nabla_\nu\phi$ (hence the name "quadratic/cubic DHOST"), and thus the very boundary of healthy scalar-tensor theories remains unclear.

In light of this situation, we explore the possibility to construct a new class of DHOST theories by use of conformal/disformal transformation of the metric, which has been employed for investigating the relation between the known scalar-tensor models. To this end, we perform a *noninvertible* conformal transformation on generic scalar-tensor theories that could possess an unwanted extra DOF. Here, the noninvertibility of the transformation is crucial because otherwise the resultant theory could also have an extra DOF[10]. Since the formulation of the new theory

can be regarded as an extension of the mimetic gravity model introduced in Ref. 11, we call the theory *extended mimetic gravity*. We show that these models have at most three DOFs based on Hamiltonian analysis and thus form a broad class of DHOST theories, most of which lie outside the quadratic/cubic DHOST class. We also study the linear stability of cosmological perturbations in our extended mimetic gravity and show that the models obtained in the above explained way generically exhibit the problem of ghost/gradient instabilities.

## 2. Extended Mimetic Gravity

We start from the following general scalar-tensor theory:

$$S_{\rm seed} = \int d^4x\sqrt{-g}\left[f_2(\phi, X)\mathcal{R} + f_3(\phi, X)\mathcal{G}^{\mu\nu}\phi_{\mu\nu} + F(g_{\mu\nu}, \phi, \phi_\mu, \phi_{\mu\nu})\right], \quad (1)$$

with $\mathcal{R}$ and $\mathcal{G}_{\mu\nu}$ being the four-dimensional Ricci scalar and Einstein tensor, $\phi_\mu \equiv \nabla_\mu\phi$, $\phi_{\mu\nu} \equiv \nabla_\mu\nabla_\nu\phi$, and $X \equiv \phi^\mu\phi_\mu$. Note that, for a generic choice of the functions $f_2, f_3$, and $F$, the theory yields Ostrogradsky ghost. Using the action of the form (1) as a seed, we perform the following conformal transformation:

$$g_{\mu\nu} \;\rightarrow\; \tilde{g}_{\mu\nu} = -Xg_{\mu\nu}, \quad (2)$$

Here, $\tilde{g}_{\mu\nu}$ is identified as the metric in the original frame (1), while $g_{\mu\nu}$ is now the metric of the new theory, which we call *extended mimetic gravity*. The transformation (2) is noninvertible as the right-hand side is invariant under conformal transformation of $g_{\mu\nu}$. As a result, the new theory acquires a local conformal symmetry.

To study whether the so-obtained extended mimetic gravity models possess a problematic extra DOF or not, one needs to perform a Hamiltonian analysis. In doing so, we write the action in the ADM language, which becomes of the form

$$S_{\rm EMG} = \int dtd^3x\left[N\sqrt{\gamma}L_{\rm EMG} + \Lambda(NA_* + N^iD_i\phi - \dot{\phi})\right], \quad (3)$$

where $L_{\rm EMG}$ is some function of $(\gamma_{ij}, R_{ij}, \phi, A_*; V_{ij}; D_i)$. Here, we have defined

$$V_{ij} \equiv K_{ij} + \frac{\dot{A}_* - D^i\phi D_iN - N^iD_iA_*}{NA_*}\gamma_{ij}, \quad (4)$$

and introduced an auxiliary variable $A_*$ with a Lagrange multiplier $\Lambda$ so that second-order time derivatives do not appear explicitly in the action. Reflecting the aforementioned local conformal symmetry, $\dot{\gamma}_{ij}$ and $\dot{A}_*$ (namely, $\ddot{\phi}$) appear only in a special combination $V_{ij}$. When one proceeds to a Hamiltonian analysis, this relation leads to an additional primary constraint, which turns out to be first class. Thus, it kills the otherwise existing unwanted DOF, leaving only three DOFs. For a more rigorous and detailed analysis, see Ref. 1.

## 3. Cosmological Perturbations

To see whether the general mimetic theories are phenomenologically viable or not, let us analyze perturbations around the Friedmann-Lemaître-Robertson-Walker (FLRW) background in the mimetic gravity models.

For simplicity, we take the unitary gauge to write $\phi = t$ and impose the constraint $X = -1$ which fixes the conformal gauge DOF. As a consequence, any function of $(\phi, X)$ can be regarded as a function of $t$ only. We also have $N = 1$ since $X$ is written in terms of $N$ as $X = -1/N^2$ in the unitary gauge. Under this setup, the action can be recast in the following form:

$$S_{\rm EMG} = \int dtd^3x\sqrt{\gamma}\left[\left(f_2 - \frac{1}{2}\dot{f}_3\right)R + \mathcal{F}(t, \mathcal{K}_1, \mathcal{K}_2, \mathcal{K}_3, \cdots, \mathcal{K}_\ell)\right], \tag{5}$$

where $\mathcal{F}$ is some function of $t$ and $\mathcal{K}_n \equiv K^{i_1}_{i_2}K^{i_2}_{i_3}\cdots K^{i_n}_{i_1}$ $(n = 1, 2, \cdots, \ell)$. It is useful to define the first and second derivatives of $\mathcal{F}$ respectively as

$$\mathcal{F}_n \equiv \frac{\partial\mathcal{F}}{\partial\mathcal{K}_n}, \quad \mathcal{F}_{mn} \equiv \frac{\partial^2\mathcal{F}}{\partial\mathcal{K}_m\partial\mathcal{K}_n}. \tag{6}$$

Now we substitute the following metric ansatz to the action (5),

$$N = 1, \quad N_i = \partial_i\chi, \quad \gamma_{ij} = a^2e^{2\zeta}\left(\delta_{ij} + h_{ij} + \frac{1}{2}h_{ik}h_{jk} + \cdots\right), \tag{7}$$

where $\chi$ and $\zeta$ are scalar perturbations and $h_{ij}$ denotes a transverse-traceless tensor perturbation. The background EOM is given by

$$\dot{\mathcal{P}} + 3H\mathcal{P} - \mathcal{F} = 0, \quad \mathcal{P} \equiv \sum_{n=1}^{\ell} n\,H^{n-1}\mathcal{F}_n, \tag{8}$$

where $H \equiv \dot{a}/a$ is the Hubble parameter and $\mathcal{F}_n$ are evaluated at the background, $\mathcal{K}_n = 3H^n$. This equation will be used to simplify the expressions of the quadratic actions for the tensor and scalar perturbations below.

The quadratic action for the tensor perturbation $h_{ij}$ is given by

$$S^{(2)}_{\rm T} = \int dtd^3x\frac{a^3}{4}\left[\mathcal{B}\dot{h}^2_{ij} - \mathcal{E}\frac{(\partial_k h_{ij})^2}{a^2}\right], \tag{9}$$

where

$$\mathcal{B} \equiv \sum_{n=2}^{\ell}\frac{n(n-1)}{2}H^{n-2}\mathcal{F}_n, \quad \mathcal{E} = f_2 - \frac{1}{2}\dot{f}_3. \tag{10}$$

The tensor perturbations are stable if $\mathcal{B} > 0$ and $\mathcal{E} > 0$.

The quadratic action for the scalar perturbations $\zeta$ and $\chi$ is

$$S^{(2)}_{\rm S} = \int dtd^3xa^3\left[\frac{3}{2}(3\mathcal{A} + 2\mathcal{B})\dot{\zeta}^2 + 2\mathcal{E}\frac{(\partial_k\zeta)^2}{a^2}\right.$$
$$\left. + \frac{1}{2}(\mathcal{A} + 2\mathcal{B})\left(\frac{\partial^2\chi}{a^2}\right)^2 - (3\mathcal{A} + 2\mathcal{B})\dot{\zeta}\frac{\partial^2\chi}{a^2}\right], \tag{11}$$

where

$$\mathcal{A} \equiv \sum_{m=1}^{\ell} \sum_{n=1}^{\ell} m\, n\, H^{m+n-2} \mathcal{F}_{mn}. \tag{12}$$

Provided that $\mathcal{A} + 2\mathcal{B} \neq 0$, $\chi$ can be eliminated from the action by use of its EOM. Then, we are left with the following quadratic action for curvature perturbation:

$$S_{\rm S}^{(2)} = 2 \int dt d^3x\, a^3 \left[ \frac{\mathcal{B}(3\mathcal{A} + 2\mathcal{B})}{\mathcal{A} + 2\mathcal{B}} \dot{\zeta}^2 + \mathcal{E} \frac{(\partial_k \zeta)^2}{a^2} \right]. \tag{13}$$

Written in this form, one notices that the stability condition for the tensor perturbations, $\mathcal{E} > 0$, is not compatible with the stability for the scalar perturbation, $\mathcal{E} < 0$. This indicates that either of the tensor or scalar perturbations exhibits gradient instabilities, even if one circumvents ghosts by choosing the coefficients in front of the time derivative terms in Eqs. (9) and (13) to be positive.

One would notice that if $\mathcal{B}(\mathcal{A}+2\mathcal{B})(3\mathcal{A}+2\mathcal{B}) = 0$ then the scalar perturbations appear to be nondynamical. This is indeed the case if we choose a Horndeski (or GLPV) theory as seed, where $\mathcal{A} + 2\mathcal{B} = 0$. In this case, it is important to take into account the presence of matter fields other than $\phi$ to discuss the viability of mimetic cosmology. If another scalar field $\psi$ is added to the seed Lagrangian, one can show that the scalar perturbations revive, i.e., there are now two scalar DOFs, and one of them is a ghost.

Thus, we have established that all the mimetic gravity models with three DOFs obtained so far are plagued with ghost/gradient instabilities on a cosmological background (except for the special case of strongly-coupled scalar perturbations). More detailed discussion is found in Ref. 1 (see also Ref. 12).

# Solutions of gravitational field equations for weakly birefringent spacetimes

Nils Alex

*Department of Physics, Friedrich-Alexander University Erlangen-Nuremberg, Staudtstr. 7, 91058 Erlangen, Germany*
*E-mail: nils.alex@fau.de*

The constructive gravity programme applied to electrodynamics with vacuum birefringence yields the — up to unknown gravitational constants — unique compatible gravity theory for the underlying non-metric geometry. Starting from a perturbative variant of this procedure, we solve the resulting gravitational field equations for the geometry perturbation and point out the non-metric refinements to the linear Schwarzschild and the gravitational wave solution.

*Keywords*: Constructive gravity; pre-metric electrodynamics; modified gravity; gravitational waves; massive gravity

## 1. Introduction

Equations of motion for a matter field (e.g. an electromagnetic potential) are always *incomplete* in the sense that the coefficients in these equations, which are functions of the geometric field to which the matter field couples, are not determined. General relativity, in its essence, *closes* Maxwell's equations by providing dynamic equations for the metric tensor. The gravitational closure programme provides a prescription for performing this closure for any kind of matter theory subject to a few conditions.[1] Applying a perturbative variant of this procedure to a certain generalization of Maxwell electrodynamics which does not exclude vacuum birefringence *a priori* has been shown to yield gravitational field equations that predict the dynamics of these birefringent perturbations.[2]

## 2. Birefringent electrodynamics

The most general theory for an electrodynamic potential has been derived by Hehl and Obukhov in Ref. 3 from the principles of conservation of electric charge and magnetic flux and a linear constitutive law. Instead of the usual metric tensor $g$ from Maxwell electrodynamics, the potential couples to a rank 4 tensor field $G$ with symmetries

$$0 = G^{(ab)cd} = G^{ab(cd)} = G^{abcd} - G^{cdab} \tag{1}$$

via the action

$$S[A, G] = \int \mathrm{d}^4x\, \omega_G\, G^{abcd} F_{ab} F_{cd}, \tag{2}$$

where $F = \mathrm{d}A$ denotes the electromagnetic field strength and $\omega_G$ a 1-density built from $G$. This theory is called *General Linear Electrodynamics (GLED)*. Maxwell

electrodynamics is recovered by setting $G^{abcd} = g^{ac}g^{bd} - g^{ad}g^{bc} - \sqrt{-g}\,\epsilon^{abcd}$ and $\omega_G = \frac{1}{24}\epsilon_{abcd}G^{abcd} = \sqrt{-g}$.

A very distinctive property of GLED is the causality of the field equations: While wave covectors in the WKB limit of Maxwell electrodynamics are selected by the causality condition $0 = P(k) = g(k,k)$, which is a homogeneous polynomial of degree two, the causality condition of GLED is of degree four.[3] This allows for more roots of $P$ which introduces the possibility of a polarization-dependent speed of light — birefringence in vacuo.

## 3. Gravitational closure of weakly birefringent electrodynamics

While the gravitational closure procedure is fully laid out, it remains very difficult to follow through because the problem boils down to a set of infinitely many homogeneous first-order PDEs. There is, however, a way around this obstacle: *Perturbative* gravitational closure, which is only concerned with gravitational dynamics of small perturbations of the geometric field. This is also the sector of great phenomenological relevance, because corrections to Einstein gravity and field theories coupling to the geometry should — if present at all — be rather minute.

In Ref. 2, the perturbative gravitational closure procedure has been applied to perturbations $H$ of the GLED geometry $G$,

$$G^{abcd} = \eta^{ac}\eta^{bd} - \eta^{ad}\eta^{bc} - \epsilon^{abcd} + H^{abcd}, \tag{3}$$

which results in a 11-parameter family of field equations for the perturbation $H$, where $H$ has been gauge-fixed and decomposed according to a $3+1$ split into a set of spatial fields (greek indices being spatial indices from 1 to 3, raised and lowered at will with the spatial part $\gamma$ of $\eta$):

**transverse traceless (tt) tensor modes** $U_{\alpha\beta}, V_{\alpha\beta}, W_{\alpha\beta}$ satisfying

$$\begin{aligned} 0 = U_{[\alpha\beta]}, \quad 0 = \partial_\alpha U^{\alpha\beta} \quad \text{and} \quad 0 = \gamma_{\alpha\beta}U^{\alpha\beta}, \\ V_{\alpha\beta}, W_{\alpha\beta} \quad \text{similar}, \end{aligned} \tag{4}$$

**solenoidal vector modes** $U_\alpha, W_\alpha, B_\alpha$ satisfying

$$0 = \partial_\alpha U^\alpha, \quad W_\alpha, B_\alpha \quad \text{similar}, \tag{5}$$

**scalar modes** $V, W, \widetilde{U}, \widetilde{V}, A$.

Einstein gravity corresponds to the sector where only $U_{\alpha\beta}, B_\alpha, \widetilde{U}$, and $A$ are non-zero. In the following sections, we will solve the field equations for two prototypical matter distributions: The inertial point mass, which yields corrections to

the linear Schwarzschild solution of Einstein gravity, and the vacuum, which reveals the causality of the theory.

## 4. Inertial point mass source

An inertial point mass resting at the spatial origin of a coordinate chart is described by the world line

$$\gamma^a(\tau) = \tau\delta^a_0 \tag{6}$$

and produces a contribution of $-M\delta^{(3)}(x)$ in the equation of motion which corresponds to the variation of the action with respect to $A$. Since the matter distribution (6) is stationary, we may restrict our attention to stationary solutions for the gravitational field by setting all time derivatives to zero. In this setup, the field equations for tt and solenoidal vector modes are homogeneous and yield

$$0 = T_{\alpha\beta} \quad \text{for all tt modes,} \tag{7}$$

$$0 = V_\alpha \quad \text{for all solenoidal vector modes.} \tag{8}$$

The field equations for the scalar modes read

$$\begin{aligned}
0 &= \sigma_1\Delta V + \sigma_2\widetilde{U} + \sigma_4\widetilde{V} - 4\sigma_2 A,\\
0 &= \sigma_4\Delta V + \sigma_5 V + \sigma_6\Delta W + \sigma_7 W + (-3\sigma_1+\sigma_2)\widetilde{U} + (-9\sigma_1+3\sigma_2)\widetilde{V}\\
&\quad + (-12\sigma_1+\sigma_2)A,\\
0 &= \sigma_6\Delta V + \sigma_7 V + \sigma_8\Delta W - \sigma_5 W,\\
0 &= (-2\sigma_1 + \frac{2}{3}\sigma_2 - \frac{2}{9}\sigma_3)\Delta\Delta V - \frac{2}{3}\sigma_3\Delta\widetilde{U} + \sigma_9\Delta\widetilde{V} + \sigma_{10}\widetilde{V}\\
&\quad + (4\sigma_2 + \frac{4}{3}\sigma_3)\Delta A,\\
-M &= (-4\sigma_1 + \frac{8}{3}\sigma_2)\Delta\Delta V + 4\sigma_2\Delta\widetilde{U} + (6\sigma_2+2\sigma_3)\Delta\widetilde{V},
\end{aligned} \tag{9}$$

where the constants $\sigma_i$ denote combinations of the 11 independent gravitational constants. The general solution of this system admits the form

$$\begin{aligned}
V(x) &= \frac{M}{4\pi r}[G_1 + G_2 f_\nu(r) + G_3 f_\rho(r)]\\
W(x) &= \frac{M}{4\pi r}[G_4 + G_5 f_\nu(r) + G_6 f_\rho(r)]\\
\widetilde{U}(x) &= \frac{M}{4\pi r}[G_7 + G_8 f_\mu(r) + G_9 f_\nu(r) + G_{10} f_\rho(r)]\\
\widetilde{V}(x) &= \frac{M}{4\pi r}[G_{11} f_\mu(r)]\\
A(x) &= \frac{M}{4\pi r}[G_{12} + G_{13} f_\mu(r) + G_{14} f_\nu(r) + G_{15} f_\rho(r)]
\end{aligned} \tag{10}$$

with functions

$$f_\alpha(r) = \begin{cases} \cos(\sqrt{-\alpha}r) & \alpha < 0 \\ \mathrm{e}^{-\sqrt{\alpha}r} & \alpha \geq 0 \end{cases} \tag{11}$$

and constants $G_i, \mu, \nu, \rho$ depending on the 11 gravitational constants.[a]

The solutions (10) can be regarded as corrections to the linearized Schwarzschild solution of Einstein gravity, which in the context of GLED reads

$$V = 0, \quad W = 0, \quad \widetilde{V} = 0, \quad \widetilde{U}(x) = 4\kappa\frac{M}{4\pi r}, \quad \text{and} \quad A(x) = \kappa\frac{M}{4\pi r}. \tag{12}$$

If (10) shall only introduce *short-ranging* Yukawa corrections — instead of *long-ranging* Coulomb corrections —, the constants $G_1$ and $G_4$ must vanish and the ratio $G_7/G_{12}$ must be equal to 4. These conditions are satisfied by only one condition on the 11 independent gravitational constants and greatly simplify the form of (10) to

$$\begin{aligned} V(x) &= 0, \\ W(x) &= 0, \\ \widetilde{U}(x) &= \frac{M}{4\pi r}[\alpha + \beta\mathrm{e}^{-\sqrt{\mu}r}], \\ \widetilde{V}(x) &= \frac{M}{4\pi r}\gamma\mathrm{e}^{-\sqrt{\mu}r}, \\ A(x) &= \frac{M}{4\pi r}[\frac{1}{4}\alpha - \frac{1}{4}(\beta + 3\gamma)\mathrm{e}^{-\sqrt{\mu}r}]. \end{aligned} \tag{13}$$

Arriving at (13) concludes — perturbatively and only for this special matter distribution — the gravitational closure programme for a theory of electrodynamics with vacuum birefringence. The result is a *prediction* of where and how non-metric refinements are produced by an inertial point mass, depending on 4 unknown gravitational constants. The ramifications of such refinements have been investigated both on the astronomic scale for e.g. galaxy rotation curves[4] as well as on the quantum scale for quantum electrodynamics[5]. Experimental tests based upon these studies could now, in principle, provide approximations or bounds for the unknown parameters in (13).

## 5. Vacuum solutions

In the case of a spacetime with no matter content, the gravitational field equations are a system of coupled homogeneous wave equations with mass and damping terms. A very critical property of the solutions of this system can be examined by calculating the complex eigenvalues of the time evolution: the stability of solutions

[a] This is the result for one of two cases which have to be considered, depending on the exact values of the gravitational constants. The solution in the other case contains products of exponential and trigonometric functions of $r$, but the discussion below and especially the result (13) remain the same.

with respect to small variations of the initial data. Stability in this sense is guaranteed if and only if the real part of each eigenvalue is non-positive. Because we are interested in investigating the sector of the theory which produces only small phenomenological refinements to Einstein gravity, we implement this stability conditions and find that the remaining 10 gravitational constants must satisfy two additional conditions.

Furthermore, for propagating gravitational fields it is desirable that the causality condition in the WKB limit coincides with the Minkowski causality condition $\eta(k,k)=0$. Otherwise, consistent co-evolution of gravitational and electrodynamic fields as proposed by the gravitational closure programme would not be possible. This imposes one further condition on the gravitational constants. With this final condition implemented, we arrive at a 7-parameter family of gravitational field equations wich in vacuo simplify to

**one massless wave equation**

$$0=\Box U_{\alpha\beta}, \tag{14}$$

**massive wave equations**

$$\begin{aligned}
0&=\Box V_{\alpha\beta}+mV_{\alpha\beta}=\Box W_{\alpha\beta}+mW_{\alpha\beta},\\
0&=\Box U_{\alpha}+mU_{\alpha}=\Box W_{\alpha}+mW_{\alpha},\\
0&=\Box V+mV=\Box W+mW,\\
0&=\Box\widetilde{V}+m_{\mathrm{S}}\widetilde{V},
\end{aligned} \tag{15}$$

**constraint equations**

$$\begin{aligned}
B_{\alpha}&=-\frac{1}{2}\dot{U}_{\alpha},\\
\widetilde{U}&=-\frac{1}{3}\Delta V-\frac{\sigma+3}{2}\widetilde{V},\\
A&=\frac{1}{4}\ddot{V}+\frac{1}{4}\frac{\sigma-3}{2}\widetilde{V},
\end{aligned} \tag{16}$$

with three combinations of gravitational constants: a mass $m$, a second mass $m_{\mathrm{S}}$ for the scalar mode $\widetilde{V}$, and $\sigma$. Comparing this result with the vacuum equation for Einstein gravity,

$$0=\Box U_{\alpha\beta}\quad+\text{constraint equations}, \tag{17}$$

we immediately see that the metrically inducible mode $U_{\alpha\beta}$ still obeys a *massless* wave equation, while all non-metric modes evolve according to *massive* wave equations. This fact has a great impact on the phenomenology of the non-metric corrections: In e.g. binary systems, massive modes are only produced above a certain threshold[6] and disperse during their propagation. That is, both the *generation* as well as the *detection* of these modes will be suppressed, depending on the exact values of the gravitational constants.

It is remarkable that, in addition to the one metric and two non-metric tt modes, also *solenoidal vector modes* and *scalar modes* propagate. This introduces new ways a gravitational wave can affect test matter, which is seen by calculating the geodesic deviation of dust spheres: a tt mode propagating in $z$-direction deforms geodesic spheres in $x$- and $y$-direction in a volume preserving way. A trace-free scalar mode propagating in the same direction, on the other hand, would lead to volume-preserving oscillations in $z$- and both lateral directions — exhibiting qualitatively completely new behaviour, which is quantitatively suppressed by the unknown mass. Pure trace modes also introduce a new quality as they make the whole volume of a geodesic sphere oscillate.

*How* these modes can be generated has been studied in Ref. 6 for non-gravitationally bound systems, because emission of gravitational waves from a gravitationally bound system is a second order effect which requires knowledge of the gravitational theory to this order. Currently, two different approaches[7] for obtaining the second order of the gravitational theory consistent with GLED are being pursued. Their results will fill this gap and eventually allow to answer the question: What would the non-metric refinements to emission, propagation and detection of gravitational waves be if the vacuum was birefringent?

# Refinement of Friedmann equations implied by electromagnetic birefringence

Maximilian Düll*

*Zentrum für Astronomie der Universität Heidelberg*
*Philosophenweg 12, 69120 Heidelberg, Germany*
**E-mail: maximilian.duell@uni-heidelberg.de*

The constructive gravity program demands to derive the dynamics for the background geometry of some prescribed matter theory as the solution of a set of partial differential equations – so called gravitational closure equations – whose coefficient functions can be calculated directly from the prescribed matter action. Finding general solutions to the closure equations is hard to achieve in practice. A suitable symmetry reduction of the constructive gravity program will be demonstrated that allows to insert symmetries directly into the closure equations. Using cosmological symmetries – spatial homogeneity and isotropy – enables one to derive the Friedmann equations without Einstein equations for Maxwell electrodynamics as matter input. Studying general linear electrodynamics as a refined matter input, the way towards refined Friedmann equations is laid out.

*Keywords*: constructive gravity, cosmology, pre-metric electrodynamics

## 1. Constructive gravity

Combining the standard model of particle physics with general relativity and comparing them to astrophysical measurements on the energy content of the universe shows a discrepancy; only up to five percent of the universe are actually described by the standard model of particle physics and general relativity in their current form. The remaining 95 percent are attributed to dark matter and dark energy for which no satisfying theoretical model exists until today[1]. This discrepancy strongly indicates that there is something significant that we do not understand about matter, gravity, or their interaction.

In recent years, the constructive gravity program has provided new insights and understanding of the interaction of gravity and matter[2]. Its central tenet is that the gravitational Lagrangian can – and then must – be derived from a prescribed matter action by solving an immutable set of linear partial differential equations, the so called gravitational closure equations, whose coefficient functions depend on the specified matter theory in a simple way. The key physical requirement for the constructive gravity program to work is that the common canonical evolution of data between initial and final data hypersurfaces proceeds in lockstep for both matter and geometry.

A crucial check of the program, namely that using the Lagrangian of the standard model as the matter input yields the Einstein-Hilbert Lagrangian as the unique two-parameter solution of the gravitational closure equations, is passed with flying colours. The scope of the constructive gravity program reaches far beyond the standard model. In fact, for any matter theory that satisfies basic well-posedness and energy conditions, the solution of the associated closure equations yields the

Lagrangian governing the dynamics of whatever (multi-)tensorial background geometry is employed in the formulation of the matter theory. In short, any such matter action, even if a severe modification or extension of the standard model, predicts the suitable gravity theory that must underpin it.

This sheds a new light on the great variety of proposals for modifications and extensions of the standard model. It is useful to spell this out for a physically meaningful modification of the electromagnetic sector of the standard model of particle physics, which replaces Maxwell theory by what is variably called general linear, premetric[3] or area metric electrodynamics. This is the most general theory of electrodynamics with linear field equations that arises from an action. Its action is given by

$$S_{\mathrm{GLED}} = -\frac{1}{8}\int \mathrm{d}^4x\, \omega_G\, F_{ab}F_{cd}\, G^{abcd}\,, \tag{1}$$

where $F$ is the usual electromagnetic field tensor for the gauge potential $A$ and $\omega_G$ a scalar density of weight one built from the background geometry encoded in the fourth rank tensor field $G$. This theory of electrodynamics allows for birefringence in vacuum, an effect that is excluded by construction in Maxwell-Einstein theory. Were one not to provide dynamics for the more general background geometry $G$, the latter would have to be described by hand. This would require to already know whether and how this background geometry would deviate from a metric-induced background of the form

$$G^{abcd} = g^{ac}g^{bd} - g^{ad}g^{bc} - \sqrt{-\det g}\,\epsilon^{abcd}\,. \tag{2}$$

Of course, constructive gravity relieves us from such tinkering, since the gravitational closure equations associated with (1) yield the dynamics for $G$ that allow to predict, rather than stipulate, where the background geometry $G$ takes which values. Closing the matter action by addition of the thus obtained gravitational action then provides the suitable refinement of the Einstein-Maxwell action as it is demanded by dropping the par-force exclusion of vacuum birefringence. This is of course just exactly what constructive gravity is about: learning about the gravitational implications of modifications of the matter theory, which sometimes are nil and more often not (even in cases where intuitive reasoning would suggest no implication for gravity).

## 2. Symmetry-reduced constructive gravity

While it is clear from a theoretical point of view that solving the closure equations yields the desired gravitational Lagrangian, it is at best difficult to do so in practice. Even if one were able to find a general solution to the closure equations, one would not find general solutions to the resulting gravitational field equations, just as in case of the Einstein equations. The way around this, for the purpose of cosmology, is to implement the assumed cosmological symmetries already at the level of the

closure equations rather than later at the level of the gravitational field equations. One can visualize the situation as in figure 1.

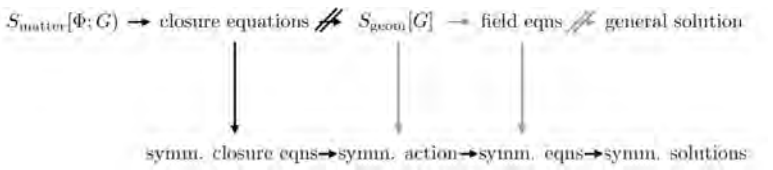

Fig. 1. Key idea of the symmetry reduction in the constructive gravity program. Diagram commutes if symmetric criticality is satisfied [5].

This diagram only commutes if implementing a symmetry at the level of an action or even before – in the closure equations – produces the correct symmetric field equations[a]. Fels and Torre investigated this question of symmetric criticality [5] and derived sufficient conditions for when one may impose a symmetry already at the level of an action (only the simplest of which is if the symmetry group is compact).

With this being a sufficient criterion, also symmetries stemming from non-compact group can be inserted properly into the closure equations. In the case of spatial homogeneity and isotropy, one is left with three different topologies for the symmetric spatial hypersurfaces. Only the case of 3-spheres (closed cosmology) originates from a compact symmetry group. In this work, we will stick with flat cosmology and choose flat planes as the spatially homogeneous and isotropic hypersurfaces. Still, as shown in 3, checking the viability of the symmetry reduction with Maxwell electrodynamics as matter input, produces the correct Friedmann equations with a non-compact underlying symmetry group. Once this is established, attention will turn towards finding the refined Friedmann equations for a universe with general linear electrodynamics in section 4.

## 3. Cosmological closure of Maxwell electrodynamics

Because it is clear that the Friedmann equations are the symmetry-reduced version of the Einstein equations which, in the philosophy of constructive gravity, arise from Maxwell electrodynamics as matter input into the associated closure equations, we employ precisely this standard case as a proof of principle. Apart from providing this proof of concept, the interesting insight is that constructive gravity allows to obtain the two Friedmann equations without using the Einstein equations.

[a]This is not guaranteed a priori. Imagine the situation in classical mechanics. Variation of the action is comparing possible curves with respect to each other and choosing the one making the action stationary. By inserting a symmetry into the action, one compares curves obeying the symmetry – in general fewer than before. By comparing fewer candidate curves, one can produce fake solutions compared to the full setting with symmetry applied in the equations of motion.

In order to identify the form of a Lorentzian metric with spatial homogeneity and isotropy, one solves the Killing condition

$$(\mathcal{L}_{K_i} g)^{ab} = 0 \tag{3}$$

with six Killing vector fields generating this symmetry [4,6,7]. As already mentioned above, we choose flat planes as the spatial hypersurfaces. This allows to write the resulting metric in a simple form

$$g^{ab} = \mathrm{diag}\left(\frac{1}{N^2(t)}, -\frac{1}{a^2(t)}, -\frac{1}{a^2(t)}, -\frac{1}{a^2(t)}\right)^{ab} \tag{4}$$

with the usual scale factor $a(t)$ and a time-dependent lapse function $N$ in an ADM split. Now, an important technical step in the constructive gravity enters the symmetry reduction – namely the introduction of the actual geometric degrees of freedom $\varphi^A$ [b]. The spatial metric $g$ can be expressed in terms of the actual degrees of freedom by virtue of a linear map $\hat{g}^{\alpha\beta}(\varphi^A) = I^{\alpha\beta}{}_A\, \varphi^A$ with a constant matrix $I$ [2]. The resulting gravitational action and its Lagrangian are then built from the actual d. o. f. $\varphi^A$. Another crucial step is the expansion of the gravitational Lagrangian

$$\mathcal{L}^{\mathrm{grav}} = \sum_{N=0}^{\infty} C_{A_1 \ldots A_N}[\varphi^A]\, k^{A_1} \ldots k^{A_N} \tag{5}$$

in terms of generalized velocities $k^A$ and expansion coefficients $C_{A_1 \ldots A_N}$ which are functionals of the actual geometric d. o. f.s and which the closure equations are solved for.

After symmetry reduction, the symmetry-reduced expansion coefficients $C^{\mathrm{symm}}_{A_1 \ldots A_N}$ only depend on the scale factor $a(t)$ which is the only freedom left in flat cosmology. The derivative of a symmetric expansion coefficient can be expressed via a chain rule,

$$C'_{A_1 \ldots A_N}(a) = \frac{\partial C_{A_1 \ldots A_N}}{\partial \varphi^A}\left(\varphi^B(a)\right)\, \frac{\partial \varphi^A}{\partial a}\,. \tag{6}$$

The derivatives $\frac{\partial C_{A_1 \ldots A_N}}{\partial \varphi^A}$ also appear in the gravitational closure equations. The task is now to evaluate the closure equations on symmetric configurations, that is evaluate all equations by setting $\varphi^A = \varphi^A(a)$ and then compute expressions for the derivatives $\frac{\partial C_{A_1 \ldots A_N}}{\partial \varphi^A}$. For each expansion coefficient, this can be calculated in several pages and the procedure will not be presented in this brief article. One ends up at ordinary differential equations for every coefficient. Solving them and

[b] The motivation for introducing actual degrees of freedom stems from the necessity to encode all symmetry conditions and constraints arising from the ADM split into a set of independent variables. For the refined geometry $G$ appearing in (1), performing an ADM split gives rise to non-linear constraints on the spatial geometry [2]. Introducing a suitable parametrization in terms of the actual geometric d. o. f. takes care of these constraints.

plugging all results together, one ends up at an action of the form

$$S_{\text{cosmo}} = \int \mathrm{d}t \left( \frac{\Lambda}{8\pi G} N a^3 + \frac{3}{8\pi G} \frac{a\dot{a}^2}{N} \right) . \tag{7}$$

with two integration constants – the cosmological and the gravitational constant.

In order to complete the symmetry reduction, a suitable matter source has to be determined by applying the Killing condition to the energy momentum tensor

$$T_{ab} := -2 \sqrt{-\det g^{\cdot\cdot}} \, \frac{\delta \mathcal{S}_{\text{matter}}}{\delta g^{ab}} . \tag{8}$$

This tensor then has diagonal form with only two functions of time remaining which can be identified as energy density $\rho$ and pressure $p$ of a perfect fluid in analogy to standard theory. By variation of the total action

$$S_{\text{total}} = S_{\text{cosmo}} + S_{\text{matter}} \tag{9}$$

with respect to lapse and the scale factor, the two Friedmann equations known from standard cosmology are recovered – without using the Einstein equations at any point. This successful proof of principle serves as the starting point for a symmetry reduction of the closure equations associated to general linear electrodynamics.

## 4. Cosmological closure of general linear electrodynamics

The background geometry of general linear electrodynamics is the fourth rank tensor field $G$ for which the Killing condition reads

$$\left(\mathcal{L}_{K_i} G\right)^{abcd} = 0 . \tag{10}$$

Using the six Killing vector fields that describe spatial homogeneity and isotropy, one now finds two scale factors $a(t)$ and $c(t)$ besides the lapse $N(t)$.

Proceeding with the symmetry reduction of the constructive gravity program as in the previous case, one now obtains two partial differential equations

$$\begin{aligned} \frac{\partial C_{A_1 \ldots A_N}}{\partial a} &= \frac{\partial C_{A_1 \ldots A_N}}{\partial \varphi^A} \left(\varphi^B(a,c)\right) \frac{\partial \varphi^A}{\partial a} , \\ \frac{\partial C_{A_1 \ldots A_N}}{\partial c} &= \frac{\partial C_{A_1 \ldots A_N}}{\partial \varphi^A} \left(\varphi^B(a,c)\right) \frac{\partial \varphi^A}{\partial c} \quad \forall N \geq 0 \end{aligned}$$

The procedure is exactly the same as in the previous case. Evaluate the closure equations by setting $\varphi^A = \varphi^A(a,c)$ everywhere to obtain expressions for the derivatives $\frac{\partial C_{A_1 \ldots A_N}}{\partial \varphi^A}$ and solve the two PDEs for every expansion coefficient. The general setting of the coefficient functions of the closure equations is more involved here[2]. For instance, one coefficient function vanishes when setting $\varphi^A = \varphi^A(a,c)$; first taking derivatives of this coefficient and setting $\varphi^A = \varphi^A(a,c)$ after that, produces non-vanishing components. This fact requires to also consider derivatives of the closure equations which are evaluated on $\varphi^A = \varphi^A(a,c)$ after having taken the derivative of the full equation. These calculations are very extensive and currently,

we are working on an automation using computer algebra. The first coefficient $C$ of the expansion (5) of the gravitational Lagrangian is already determined; it is necessary to evaluate the closure equations ($C1$) and the derivative with respect to the geometric degrees of freedom $\varphi^A$ of ($C1$) and ($C5$) in the current numbering[2]. One then finds that $C$ takes the form

$$C = K_0\, a^3\, c^{-9} \tag{11}$$

with $K_0$ a constant of integration[4].

Once all expansion coefficients are calculated, the cosmological action can be constructed from them. It is straightforward to generalize the concept of the energy momentum tensor to refined spacetime geometries[8] and especially the tensor field $G$[4,6]. As there are now two scale factors, we will obtain three refined Friedmann equations by variation with respect to the lapse function and the two scale factors – but only once the cosmological action is calculated.

## 5. Conclusions and Outlook

In this article, it was demonstrated that a suitable symmetry reduction of the constructive gravity program allows to derive Friedmann equations directly from Maxwell electrodynamics. Refined Friedmann equations follow from general linear electrodynamics as matter input once the involved evaluation of the symmetry-reduced gravitational closure equations is completed. Besides, studying the three independent components of the gravitational source tensor have to be studied more closely and a physical interpretation of a perfect fluid in a spacetime with general linear electrodynamics is needed. Once the refined Friedmann equations have been obtained, one can complement them with an equation of state and derive solutions. With these solutions, comparisons and predictions such as the age of the universe can be made. This is work in progress.

In this manuscript, we will discuss the construction of covariant derivative operator in quantum gravity. We will find it is more perceptive to use affine connections more general than metric compatible connections in quantum gravity. We will demonstrate this using the canonical quantization procedure. This is valid irrespective of the presence and nature of sources. General affine connections can introduce new scalar fields in gravity.

*Keywords*: quantization, connections, non-metricity, scalar fields

## 1. Introduction

In this manuscript, we will discuss a few aspects of spacetime geometry relevant to quantum gravity. In Sec.2, we will discuss the construction of covariant derivative operator in quantum gravity. In this article, we will deal with only affine connections and denote general affine connections by affine connections or connection coefficients.[1,2] We will find it is more perceptive to use affine connections more general than metric compatible connections in quantum gravity. We will use the canonical quantization procedure and the Arnowitt-Deser-Misner (ADM) formalism to show this.[3] This is valid irrespective of the presence and nature of sources. This is a general mathematical issue which will be there, in a theory of quantum gravity which is not a quantum field theory in a fixed background, provided some components of metric can be taken as independent variables in a neighborhood of the spacetime manifold. This can be done around any regular point of the spacetime manifold.[4] We will also use the general metric-metric commutators to illustrate this issue.[2]

## 2. Quantum Gravity and Covariant Derivatives

We now consider quantization of gravity by using the canonical quantization procedure. Canonical quantization is important to find the particle spectrum when we quantize a classical theory. In the canonical quantization of gravity, metric becomes operator on a Hilbert space. We represent such operators by carets. Affine connections present in the covariant derivatives act on the tensor operators and we represent them also by the symbols: $\hat{\Theta}^{\alpha}_{\ \mu\nu}$. Affine connections will contain components of metric and their spacetime derivatives and also other fields as evident from the previous discussions.

In a Hamiltonian formulation, induced metric on a set of constant time surfaces is used as dynamical variable. The induced metric on a set of constant time surfaces is given by:

$$h_{\mu\nu} = g_{\mu\nu} + n_\mu n_\nu \tag{1}$$

where $n_\mu$ is the unit normal to the constant time surfaces. An expression for conjugate momenta is given by Eq.(4). We presently use the symbols $\hat{h}, \hat{\pi}$ to denote the corresponding collection of canonical operators. In general, the Levi-Civita connections contain metric and time derivative of metric components and hence, will depend on the canonical conjugate variables $(\hat{h}, \hat{\pi})$. We now express covariant derivative operator in the following form:

$$\hat{\nabla}'_\mu \hat{A}_\nu = [\partial_\mu - \hat{\Gamma}^\alpha{}_{\mu\nu}(\partial\hat{g}, \hat{g})]\hat{A}_\alpha = [\partial_\mu - \hat{\Gamma}^\alpha{}_{\mu\nu}(\hat{\pi}, \hat{h})]\hat{A}_\alpha$$

Here, $\hat{\Gamma}^\alpha{}_{\mu\nu}$ are operator version of the Levi-Civita connections. We adopt the following operator ordering in connection coefficients. Whenever there appears a product between partial derivatives of metric and metric itself, the partial derivative is kept as the first term and metric is kept as the second term. The ordering of the operators $(\hat{h}, \hat{\pi})$ in $\hat{\Gamma}^\alpha{}_{\mu\nu}$ is given to be the same as that written in the above equation, *i.e*, $\hat{h}$ is kept as the successor of $\hat{\pi}$.

We next consider the operator: $q^\mu \hat{\nabla}'_\mu q^\nu$, where $q^\mu$ is a vector field acting as $q^\mu \hat{I}$ on the Hilbert space. This operator contains canonical conjugate pairs of variables when we choose affine connections to be given by the Levi-Civita connections. In this case, we will have the following expression:

$$[q^\mu \hat{\nabla}'_\mu q^\nu]\,|\Psi\rangle \neq 0 \tag{2}$$

remaining valid in a given state $|\Psi\rangle$ with an arbitrary well-behaved vector field $q^\mu$. We will not have a complete set of states for which the expectation value of the operator in the *l.h.s* is zero with negligible fluctuations for all well-behaved vector fields. This will be valid only in the classical limit, and is a subject similar to the familiar Ehrenfest's theorems in non-relativistic quantum mechanics. Similar discussions will remain valid even if we choose affine connections to be given by more general expressions.[5] In general, affine connections will contain canonical pairs of variables from metric sector to have proper classical limit of the Levi-Civita connections, and the concept of geodesics will not remain exact for all vector fields in a quantum state. This will also remain valid for parallel transport and the notion of parallel transport is not exact in a quantum theory of gravity. This is expected and indicates that we can use affine connections more general than the metric compatible connections even in free quantum gravity.

We now consider the metric compatibility conditions. The metric compatibility conditions are to be replaced by the operator identity: $\hat{\nabla}'_\mu[\hat{g}_{\alpha\beta}] \equiv 0$. The action of $\hat{\nabla}'_\mu[\hat{g}_{\alpha\beta}]$ on any state is zero if connection operators are given by the Levi-Civita connection operators and we choose the operator ordering same as that mentioned

in.[5] Here, we always keep metric operators as the successors of the partial derivatives of themselves. The same will also remain valid for $\hat{\nabla}'_{\mu}[\hat{g}_{\alpha\beta}]$. Here, $\hat{g}_{\alpha\beta}$ will be kept at the right of the Levi-Civita connections. We also define the contravariant components of metric as: $\hat{g}^{\alpha\kappa}\hat{g}_{\kappa\beta} = \delta^{\alpha}_{\beta}$. This ordering leads to the operator identity: $\hat{\nabla}'_{\mu}[\hat{g}_{\alpha\beta}] \equiv 0$ irrespective of the ordering of $(\hat{h}, \hat{\pi})$ chosen in the partial derivatives of metric components. However, the operator version of metric compatibility conditions need not be consistent with a canonical quantization condition. We will demonstrate this in the following.

As mentioned above, in a Hamiltonian formulation we use induced metric on a set of constant time surfaces as dynamical variable. Thus, $g_{\mu\nu}$ is replaced by: $h_{\mu\nu} = g_{\mu\nu} + n_{\mu}n_{\nu}$. Here, $n_{\mu}$ is given by $(-N, 0, 0, 0)$, $N$ being the lapse function. The contravariant $n^{\mu}$ is given by: $\frac{1}{N}(1, -N^1, -N^2, -N^3)$; where $N^i$ are the shift functions. We have: $g_{00} = N_k N^k - N^2$, $g_{0i} = N_i$ and $N_i = g_{ij}N^j$.[4] The induced metric on the constant time surfaces coincide with the spatial part of $g_{\mu\nu}$ which are expressed as $g_{ij}$. These fields are taken to dynamical variables in general relativity and we have the following Poisson brackets:

$$\left\{g_{ij}(t, \vec{x}), \pi^{kl}(t, \vec{y})\right\} = \delta^{k}_{(i}\delta^{l}_{j)}[\delta(\vec{x}, \vec{y})] \tag{3}$$

Where, $\vec{x}$ refers to the spatial coordinates and the Poisson bracket is evaluated at equal time. The delta function is defined without recourse to metric. The conjugate momentum is a spatial tensor density and is given by:

$$\pi^{pl} = -\sqrt{|g_{ij}|}(K^{pl} - Kg^{pl}) \tag{4}$$

Where $|g_{ij}|$ is the determinant of the spatial metric, $K_{pl} = -\nabla'_{p}n_l$ is the extrinsic curvature of the spatial sections, $g^{pl}$ is the inverse of $g_{pl}$ and $K$ is the trace of the extrinsic curvature taken *w.r.t* $g_{ij}$.[4] We can also define the Poisson brackets for the lapse and shift functions although their conjugate momenta vanish giving primary constraints.[4] Thus, in a Hamiltonian formulation with the Einstein-Hilbert action, we have constraints and we can not naively replace the Poisson brackets by commutators when we try to quantize the theory.[4] There are two principal approaches to quantize the theory.[4] In the first approach, gauge fixing conditions are introduced to render the complete set of constraints second class.[4] These conditions also determine the lapse and shift functions. We then pick two components of $g_{ij}$ as independent variables and quantize these components using standard commutation relations. We can solve the constraints to evaluate other commutators. The second approach is similar to the Gupta-Bleuler method used to quantize electrodynamics and was initiated by Dirac.[4] In this approach the classical variables are treated as independent variables and the constraints are imposed on the quantum states. In this case, we can replace the classical Poisson brackets by commutators when we quantize the theory.

We now demonstrate that it is appropriate to extend the Levi-Civita connections and metric compatibility conditions as long as we can regard components of spatial

metric on the constant time surfaces as independent physical variables subjected to usual canonical quantization conditions. We will also find that we can not have a Hilbert space on which we can impose the metric compatibility conditions when such quantization conditions remain valid. In the following, we will restrict our attention to a neighborhood around a regular point $'x'$. We can extend the neighborhood to the complete spacetime manifold leaving away singularities and other possible irregular points associated with the constraints.[4] We pick a component of spatial metric, say $g_{pl}$, as an independent physical variable. We then have the following equal time commutator:

$$[\hat{g}_{pl}(t,\vec{x}),\hat{\pi}^{pl}(t,\vec{y})] = i\delta^{p}_{(p}\delta^{l}_{l)}[\delta(\vec{x},\vec{y})] \tag{5}$$

Where, the point $'y'$ belongs to the above mentioned neighborhood of $'x'$. There will be another such commutator for the other independent variable. The *r.h.s* of the commutator is taken to be a distribution that is a spatial tensor density in the spatial coordinates of $\hat{\pi}^{pl}(t,\vec{y})$. The *r.h.s* will be replaced by different expressions when we replace $\hat{g}_{pl}(t,\vec{x})$ by any dependent component of metric including $g_{0\mu}$. These terms are determined by the secondary constraints, gauge fixing conditions, definitions of the lapse and shift functions given before and the fundamental commutators given by the above equation. Covariant derivatives give changes in a tensor when we move from one point to a neighbouring point. If the Levi-Civita connections are consistent with the commutators obtained above, corresponding spatial covariant derivatives of both sides of any of the commutators *w.r.t* the arguments of metric will agree since both sides are equal for all components of metric. We now consider Eq.(5). The action of $\hat{\nabla}'_{xk}$ on the *r.h.s* is same as that on a second rank covariant tensor and will contain spatial partial derivatives of the delta function. It will also contain additional terms dependent on connections and metric that can explicitly depend on time due to explicit time dependence of the gauge fixing conditions.[4] This covariant derivative is not vanishing in general for all values of $\vec{x}$. The left hand side vanishes as can be found from the following expression:

$$\hat{\nabla}'_{xk}\left\{\hat{g}_{pl}(t,\vec{x})\right\}\hat{\pi}^{pl}(t,\vec{y}) - \hat{\pi}^{pl}(t,\vec{y})\hat{\nabla}'_{xk}\left\{\hat{g}_{pl}(t,\vec{x})\right\} = 0 \tag{6}$$

This follows since we are imposing the operator versions of the metric compatibility conditions. This can also be seen by applying the *l.h.s* of the above equation to any state, introducing a sum over a complete set of states between the products of the operators and using the fact that the action of $\hat{\nabla}'_{\mu}[\hat{g}_{\alpha\beta}]$ on any state is zero if connection operators are given by the Levi-Civita connection operators with operator ordering chosen below Eq.(2). Thus, the Levi-Civita connections are not consistent with the canonical commutators given by Eq.(5). We will consider other operator ordering in the Levi-Civita symbols in Appendix:A and we will find that similar inconsistency arise in these cases also. Similar situation will remain valid for any point in the manifold where we can introduce constant time surfaces and assume the existence of a metric component as an independent field in a neighborhood

around that point. The above inconsistency will also arise with a different choice of constant time surfaces. Thus, there will be a multitude of coordinate systems where we can not use the Levi-Civita connections as connection coefficients if we impose the quantization condition given by Eq.(5). This also indicates that we can not use the Levi-Civita connections as connection coefficients in all coordinate systems that are diffeomorphic to these coordinate systems due to the tensorial character of $C^{\alpha}_{\mu\nu}$.

In Dirac's approach to quantize gravity, all the classical variables are independent and we quantize them accordingly. We can find out $[\hat{g}_{0\beta}(t,\vec{x}), \hat{\pi}^{pl}(t,\vec{y})]$ from the definitions of the lapse and shift functions and $[\hat{N}^{\lambda}(t,\vec{x}), \hat{\pi}^{pl}(t,\vec{y})] = 0$, where $N^0 = N$.[4] All spatial components $g_{ij}$ satisfy canonical commutation relations given by Eq.(5). We will again have the inconsistency mentioned above when we use the Levi-Civita connections. In this case, the action of $\hat{\nabla}'_{xk}$ on the *r.h.s* of Eq.(5) is given by expressions like: $i[\partial_{xk}\delta(\vec{x},\vec{y}) - 2\hat{\Gamma}^{0}{}_{kp}(t,\vec{x})\hat{N}^{p}(t,\vec{x})\delta(\vec{x},\vec{y}) - 2\hat{\Gamma}^{p}{}_{kp}(t,\vec{x})\delta(\vec{x},\vec{y})]$, where we have taken $p = l$ and there is no sum over the repeated indices. Also, we can not make the Levi-Civita connections consistent with the commutation relation given by Eq.(5) by introducing additional constraints on the physical Hilbert space. If we demand that the action of $\hat{\nabla}'_{xk}$ to the *r.h.s* of Eq.(5) vanishes on the physical Hilbert space, we will have the constraint:

$$[\partial_{xk}\delta(\vec{x},\vec{y}) - 2\hat{\Gamma}^{0}{}_{kp}(t,\vec{x})\hat{N}^{p}(t,\vec{x})\delta(\vec{x},\vec{y}) - 2\hat{\Gamma}^{p}{}_{kp}(t,\vec{x})\delta(\vec{x},\vec{y})]|\Psi\rangle = 0 \qquad (7)$$

Where, we have again taken $p = l$ and there is no sum over the repeated indices. There will be other similar constraints associated with other commutators. These states also satisfy the secondary constraints. We have used the operator identities $\hat{\nabla}'_{\mu}\hat{g}_{\alpha\beta} = 0$, and the Levi-Civita connections. All the above conditions will lead to singular expressions involving $\delta(\mathbf{0})$ and the partial derivatives $\delta'(\mathbf{0})$ for expectation values of some of the variables: $\hat{g}_{0\mu}, \hat{g}_{ij}, \hat{N}^{p}$ and $\hat{\Gamma}^{\alpha}_{\mu\nu}$. This is valid for all physical states and is physically undesirable. Lastly, the above problems will arise if we use any set of metric compatible connections.

In the first approach to quantize the theory, it is unlikely that there will exist a set of gauges that is time dependent, render the complete set of constraints second class and also remove the inconsistency mentioned above. It is not possible to remove the inconsistency in the second approach to quantize the theory. Also, it is expected that $[\hat{g}_{\alpha\beta}(x^{\mu}), \hat{g}_{\alpha\beta}(y^{\nu})]$ will depend on $(x^{\mu}, y^{\nu})$ non-trivially with non-vanishing covariant derivatives.[2] We can consider semiclassical theories like quantum fields in curved spaces to assume so. Thus, it is more appropriate to use connections more general than metric compatible connections in quantum gravity. The above discussions are valid irrespective of the presence and nature of sources. We can analyze this issue further in the following way. The Levi-Civita connections and metric compatibility conditions are taken as basic assumptions to calculate the scalar curvature when we use the Einstein-Hilbert action to describe classical and quantum gravity. It is better to discuss quantization and non-metricity using the metric-affine action or Palatini action where metric and affine connections are

independent variables. We have found that nen-metricity can give scalar fields in the theory. One of the scalar fields can give negative stress-tensor.[5]

In this paper, we present a brief account of a generic premetric gravity model based an the energy-momentum conservation law. Our main goal is to discuss the generic properties of the gravitational constitutive pseudotensor. We present irreducible decomposition of this object under the permutation group, or, equivalently, under the general linear group $GL(4,\mathbb{R})$. Even when the consideration is restricted to the metric ansatz, the nontrivial skewon and axion parts emerge. A special choice of the free dimensionless parameters recovers the standard GR in its premetric version.

*Keywords*: Premetric gravitational model, teleparallel gravity, gravitational constitutive tensor

## 1. Introduction

Gauge field theories such as electromagnetism and Yang-Mills models can be presented in premetric formalism[1–3] that separates the structure into the system of metric-free field equations based on conservation laws and the constitutive law between the basis field variables. In the simplest vacuum case, the constitutive law is expressed in terms of the metric tensor.

At first glance, the standard GR does not allow for such premetric description since it is based essentially on the metric variable. In this paper, we demonstrate how GR can be recast into a form suitable for premetric reformulation. This extension is based on two field variables, the gravitational excitation $H_\alpha$ and the field strength $F^\alpha$, that satisfy the system of field equations that is completely similar to the Maxwell system of electromagnetism. A linear constitutive relation between the vector-valued 2 forms $H_\alpha$ and $F^\alpha$ is established with a sixth order constitutive pseudo-tensor. This new gravitational quantity is a central subject of our consideration. In order to find the physical meaning of the constitutive tensor, we provide its irreducible decomposition under the general linear group $GL(4,\mathbb{R})$. We demonstrate the contributions of different irreducible parts to the coframe Lagrangian, energy-momentum current and dispersion relation. In metric case, we present a most general even and odd metric-dependent ansatz for the constitutive tensor. We find the physical meaning of different irreducible pieces of metric constitutive tensor and recover the standard GR for a special values of parameters.

## 2. Premetric gravitational model

In this section, we present a brief description of the premetric formulation of the gravity model, see Refs. 3, 4, 5, 6. The construction is very similar to the premetric representation of electromagnetism.[1,2]

### 2.1. *Field equation*

We assume the following basic postulate:

*Every viable model of gravity must be based on conservation law of the energy-momentum current of matter and field.*

In the canonical approach, the energy-momentum current is described as a mixed-type tensor or, equivalently, as a covector-valued twisted 3-form $\Sigma_\alpha$. For a system including matter and gravitational field, $\Sigma_\alpha$ consists of two independent pieces – for matter and for field,

$$\Sigma_\alpha = {}^{(m)}\Sigma_\alpha + {}^{(f)}\Sigma_\alpha \,. \tag{1}$$

The inhomogeneous field equation is considered as a consequence of the energy-momentum conservation law. For topologically trivial regions, it is realized as an equation for the excitation variable

$$d\Sigma_\alpha = 0 \qquad \Longrightarrow \qquad \Sigma_\alpha = dH_\alpha \,. \tag{2}$$

The latter equation is a vector-valued analog of the electromagnetic field equation $J = dF$. Thus, we define a twisted covector-valued 2-form of *gravitational excitation* $H_\alpha$ that is expressed in the basis of odd (twisted) 2-forms $\epsilon_{\beta\gamma}$ as

$$H_\alpha = \frac{1}{2} H^{\beta\gamma}{}_\alpha \, \epsilon_{\beta\gamma}. \tag{3}$$

*Gravitational field strength* is defined as an even (untwisted) vector-valued 2-form $F^\alpha$ that is expressed in the basis $\vartheta^{\beta\gamma}$ of even (untwisted) 2-forms as

$$F^\alpha = \frac{1}{2} F_{\beta\gamma}{}^\alpha \vartheta^{\beta\gamma}. \tag{4}$$

In an analogy to the electromagnetic field equation $dF = 0$, the gravitational field strength is assumed to satisfy the closeness field equation

$$dF^\alpha = 0 \qquad \Longrightarrow \qquad F^\alpha = d\vartheta^\alpha \,. \tag{5}$$

For topologically trivial regions, the field equations yields the existence of the *gravitational potential* $\vartheta^\alpha$. It is a vector-valued analog of the potential 1-form $A$ of electromagnetism.

Using the form of the electromagnetic Lorentz force $f_\alpha = (e_\alpha \rfloor F) \wedge J$, we define the *gravitational Lorentz force* as a 4-form relating the field strength to the energy-momentum current of matter

$$f_\alpha = \left(e_\alpha \rfloor F^\beta\right) \wedge {}^{(\mathrm{m})}\Sigma_\beta \,. \tag{6}$$

Also the twisted 3-form of *energy-momentum current of the coframe field*

$$ {}^{(\vartheta)}\Sigma_\alpha = \frac{1}{2}\left[F^\beta \wedge (e_\alpha \rfloor H_\beta) - H_\beta \wedge (e_\alpha \rfloor F^\beta)\right] , \tag{7} $$

and the *gravitational Lagrangian*

$$ {}^{(\vartheta)}\Lambda = -\frac{1}{2} F^\alpha \wedge H_\alpha \tag{8} $$

are defined as full vector-valued analogs of the corresponding quantities of the standard Maxwell electromagnetism.

### 2.2. *Gravitational constitutive pseudo-tensor*

In order to complete the undetermined system of field equations (2) and (5), a constitutive relation between two basic field variables $H_\alpha$ and $F^\alpha$ must be introduced. Such type of a relation depends on physical model of medium. A wide class of electromagnetic models is described by a linear local constitutive relation. In order to describe a most general linear constitutive relation, we use the expansions of the twisted form $H$ and untwisted form $F$ relative to the basis coframe of 1-forms $\vartheta^\alpha$ and the dual basis of vectors $e_\alpha$. Recall a most general linear relation between the components of the electromagnetic fields $H$ and $F$ reads

$$ H^{\alpha\beta} = \frac{1}{2}\chi^{\alpha\beta\gamma\delta} F_{\gamma\delta} , \tag{9} $$

where $\chi^{\alpha\beta\gamma\delta}$ is the *electromagnetic constitutive pseudo-tensor.* It has 36 independent components and irreducibly decomposed into principal part, skewon, and axion parts as $36 = 20 \oplus 15 \oplus 1$.

With this electromagnetic constitutive relation in mind, we postulate a similar local linear constitutive relation between the components of the fields $H_\alpha$ and $F^\alpha$

$$ H^{\beta\gamma}{}_\alpha = \frac{1}{2}\chi^{\beta\gamma}{}_\alpha{}^{\nu\rho}{}_\mu F_{\nu\rho}{}^\mu . \tag{10} $$

The *gravitational constitutive pseudotensor* obeys the symmetries

$$ \chi^{\beta\gamma}{}_\alpha{}^{\nu\rho}{}_\mu = -\chi^{\gamma\beta}{}_\alpha{}^{\nu\rho}{}_\mu = -\chi^{\beta\gamma}{}_\alpha{}^{\rho\nu}{}_\mu \tag{11} $$

so it has 576 independent components.

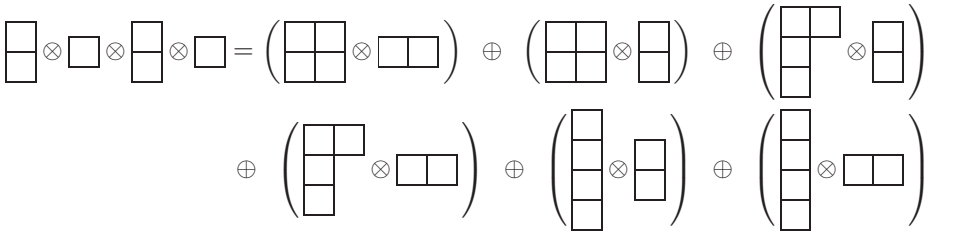
If we additionally assume that the model is completely specified by the Lagrangian (8), we have to restrict our consideration to reversible processes. In this case, we can specialize to a constitutive pseudo-tensor with an additional reciprocity condition

$$ \chi^{\beta\gamma}{}_\alpha{}^{\nu\rho}{}_\mu = \chi^{\nu\rho}{}_\mu{}^{\beta\gamma}{}_\alpha . \tag{12} $$

In this case, the set of the 576 independent components of $\chi^{\beta\gamma}{}_\alpha{}^{\nu\rho}{}_\mu$ is reduced to only 300 ones.

Treating the covariant and contravariant indices as belonging to two separate tensor spaces, the irreducible decomposition of a full (non-restricted) tensor $\chi^{\alpha\beta}{}_\mu{}^{\gamma\delta}{}_\nu$

is defined as a product of two irreducible decompositions. The corresponding Young diagrams are expanded into 6 independent pieces



(13)

Explicitly, the irreducible pieces of the constitutive tensor are expressed as

$$ {}^{[1]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := \chi^{\alpha\beta}{}_{(\mu}{}^{\gamma\delta}{}_{\nu)} - {}^{[3]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} - {}^{[5]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}, \tag{14} $$

$$ {}^{[2]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := \chi^{\alpha\beta}{}_{[\mu}{}^{\gamma\delta}{}_{\nu]} - {}^{[4]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} - {}^{[6]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}, \tag{15} $$

$$ {}^{[3]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := (1/2)\left(\chi^{\alpha\beta}{}_{(\mu}{}^{\gamma\delta}{}_{\nu)} - \chi^{\gamma\delta}{}_{(\mu}{}^{\alpha\beta}{}_{\nu)}\right), \tag{16} $$

$$ {}^{[4]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := (1/2)\left(\chi^{\alpha\beta}{}_{[\mu}{}^{\gamma\delta}{}_{\nu]} - \chi^{\gamma\delta}{}_{[\mu}{}^{\alpha\beta}{}_{\nu]}\right), \tag{17} $$

$$ {}^{[5]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := \chi^{[\alpha\beta}{}_{(\mu}{}^{\gamma\delta]}{}_{\nu)}, \tag{18} $$

$$ {}^{[6]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := \chi^{[\alpha\beta}{}_{[\mu}{}^{\gamma\delta]}{}_{\nu]}. \tag{19} $$

These pieces produce the decomposition of the tensor space into direct sum of invariant subspaces with the dimensions, respectively,

$$ 576 = 200 \ \oplus \ 120 \ \oplus \ 150 \ \oplus \ 90 \ \oplus \ 10 \ \oplus \ 6. \tag{20} $$

Additionally to the described above $S_2 \times S_4$ irreducible decomposition of the constitutive tensor, we study in Ref. 5 an alternative $S_6$ irreducible decomposition based on the pure covariant representation of this tensor.

Let us turn to a possible physical identification of the irreducible parts. We calculate the contributions of the irreducible parts to the coframe Lagrangian, the energy-momentum current and into the dispersion relation. The results are summarized in the following table:

| Irreducible Parts | Nomenclature | Lagrangian | Energy-momentum | Dispersion |
|---|---|---|---|---|
| ${}^{[1]}\chi^{\alpha\beta}{}_{\gamma}{}^{\mu\nu}{}_{\rho}$ | Principal-1 | yes | yes | yes |
| ${}^{[2]}\chi^{\alpha\beta}{}_{\gamma}{}^{\mu\nu}{}_{\rho}$ | Skewon-1 | no | yes | yes |
| ${}^{[3]}\chi^{\alpha\beta}{}_{\gamma}{}^{\mu\nu}{}_{\rho}$ | Skewon-2 | no | yes | yes |
| ${}^{[4]}\chi^{\alpha\beta}{}_{\gamma}{}^{\mu\nu}{}_{\rho}$ | Principal-2 | yes | yes | yes |

## 3. A metric-dependent ansatz

In this section we study the gravitational constitutive tensor constructed from the familiar building blocks – metric tensor $g_{\alpha\beta}$ and the permutation pseudotensor $\epsilon^{\alpha\beta\gamma\delta}$.

### 3.1. *Even and odd parts of the constitutive tensor*

We start with the most general expression that can be constructed from the metric tensor $g^{\alpha\beta}$ alone and apply the symmetry relation constrains. We obtain a *parity conserving ansatz* for the constitutive pseudo-tensor

$$^{\text{even}}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = \frac{\sqrt{-g}}{\varkappa}\left(\beta_1\, g^{\gamma[\alpha}g^{\beta]\delta}g_{\mu\nu} + \beta_2\,\delta^{[\alpha}_{\mu}g^{\beta][\gamma}\delta^{\delta]}_{\nu} + \beta_3\,\delta^{[\alpha}_{\nu}g^{\beta][\gamma}\delta^{\delta]}_{\mu}\right). \tag{21}$$

Here, $\varkappa$ is the gravitational constant, $g := \det g_{\mu\nu}$, the parameters $\beta_1, \beta_2, \beta_3$ are arbitrary dimensionless constants.

A most general construction that involves permutation pseudo-tensor $\epsilon^{\alpha\beta\gamma\delta}$ together with metric tensor $g_{\alpha\beta}$ yields a *parity violating ansatz*. Applying the symmetry relation constraints we obtain an expression with three independent terms

$$^{\text{odd}}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = \frac{1}{\varkappa}\left[\beta_4\,\varepsilon^{\alpha\beta\gamma\delta}\,g_{\mu\nu} + \beta_5\,\varepsilon^{\alpha\beta[\gamma}{}_{[\mu}\,\delta^{\delta]}_{\nu]} + \beta_6\left(\delta^{[\alpha}_{(\mu}\varepsilon^{\beta]\gamma\delta}{}_{\nu)} - \delta^{[\gamma}_{(\mu}\varepsilon^{\delta]\alpha\beta}{}_{\nu)}\right)\right]. \tag{22}$$

The general metrical constitutive tensor encompasses the parity-even and parity-odd pieces,

$$\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = {}^{\text{even}}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) + {}^{\text{odd}}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g). \tag{23}$$

Computing the irreducible parts, we find two zero terms

$$^{[2]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = {}^{[6]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = 0 \tag{24}$$

and four nontrivial terms:

• Principal-1 part is build up from the even part of the constitutive tensor. It contributes to the Lagrangian, energy-momentum current and dispersion relation

$$^{[1]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = \frac{\sqrt{-g}}{\varkappa}\left[\beta_1\, g^{\gamma[\alpha}g^{\beta]\delta}g_{\mu\nu} + (\beta_2+\beta_3)\,\delta^{[\alpha}_{(\mu}g^{\beta][\gamma}\delta^{\delta]}_{\nu)}\right], \tag{25}$$

• Skewon-2 part is constructed from the pure odd part of the constitutive tensor. It is not involved in the Lagrangian but contributes to the energy-momentum current and dispersion relation

$$^{[3]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = \frac{\beta_6}{\varkappa}\left(\delta^{[\alpha}_{(\mu}\varepsilon^{\beta]\gamma\delta}{}_{\nu)} - \delta^{[\gamma}_{(\mu}\varepsilon^{\delta]\alpha\beta}{}_{\nu)}\right), \tag{26}$$

• Principal-2 part is similar to the Principal-1 but includes even and odd pieces

$$^{[4]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = \frac{1}{\varkappa}\left[(\beta_2-\beta_3)\,\sqrt{-g}\delta^{[\alpha}_{[\mu}g^{\beta][\gamma}\delta^{\delta]}_{\nu]} + \beta_5\,\varepsilon^{\alpha\beta[\gamma}{}_{[\mu}\,\delta^{\delta]}_{\nu]}\right], \tag{27}$$

• Axion-1 part is of the odd origin. It is included into the Lagrangian but does not contribute to the energy-momentum current and to the dispersion relation

$$ {}^{[5]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = \frac{\beta_4}{\varkappa}\,\varepsilon^{\alpha\beta\gamma\delta}\,g_{\mu\nu}. \tag{28} $$

Summarizing, a general metric-dependent constitutive tensor encompasses two principal ${}^{[1]}\chi$ and ${}^{[4]}\chi$ parts, one axion ${}^{[5]}\chi$ part, and one skewon ${}^{[3]}\chi$ part.

### 3.2. *GR recovered*

In the framework of the teleparallel equivalent $\mathrm{GR}_{||}$ of general relativity (GR) we have found (see Eq. (88) in Ref. 5) for the parameters $\beta$:

$$ \left.\begin{array}{lll} \beta_1 = 4\,, & \beta_2 = 16\,, & \beta_3 = -8 \\ \beta_4 = 0\,, & \beta_5 = 0\,, & \beta_6 = 0 \end{array}\right\} \quad \mathrm{GR}_{||}\,. \tag{29} $$

The $\mathrm{GR}_{||}$ Lagrangian is distinguished from the other teleparallelism Lagrangians as being *locally Lorentz invariant*,

$$ \Lambda = \chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) F_{\alpha\beta}{}^{\mu} F_{\gamma\delta}{}^{\nu} = R\sqrt{-g} + \text{total derivative}\,. \tag{30} $$

Any other additional term in the gravitational Lagrangian breaks this local invariance. The irreducible parts of this constitutive tensor are Principal-1 and Principal-2 pieces, respectively

$$ {}^{[1]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = 4\frac{\sqrt{-g}}{\varkappa}\Big[\, g^{\gamma[\alpha} g^{\beta]\delta} g_{\mu\nu} + 2\,\delta^{[\alpha}_{(\mu} g^{\beta][\gamma} \delta^{\delta]}_{\nu)} \Big] \tag{31} $$

$$ {}^{[4]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = 24\frac{\sqrt{-g}}{\varkappa}\Big[\, \delta^{[\alpha}_{[\mu} g^{\beta][\gamma} \delta^{\delta]}_{\nu]} \Big], \tag{32} $$

## 4. Conclusion

- We presented a general premetric formalism for gravity based on the energy-conservation law.
- The linear local constitutive equation involves 6-th order constitutive tensor.
- The tensor is decomposed irreducibly and some physical meaning of its independent terms is established. In the linear approximation, it is reminiscent of the treating recently presented in Ref. 7.
- We outlined the embedding of the metric-dependent constitutive tensor in the general scheme.
- The telepallel version of GR is found as a unique Lorentz-invariant model.

The basics of the premetric approach are discussed, including the essential details of the formalism and some of its beautiful consequences. We demonstrate how the classical electrodynamics can be developed without a metric in a quite straightforward way: Maxwell's equations, together with the general response law for material media, admit a consistent premetric formulation. Furthermore, we show that in relativistic theories of gravity, the premetric program leads to a better understanding of the interdependence between topological, affine, and metric concepts.

*Keywords*: Premetric theory, electrodynamics, teleparallelism, wave propagation.

## 1. Development of premetric ideas

The study of the metric-free, or premetric, models has a rich and long history. The corresponding timeline of works which developed the premetric approach in physics is as follows. As a starting point, we mention H. Minkowski (1908) who established the special-relativistic (Poincaré-covariant) formalism for Maxwell's theory. F. Kottler (1912) subsequently provided the generally covariant formulation of electromagnetism which was eventually taken by A. Einstein (1916) as a basis for a quasi-premetric formulation of Maxwell's theory. F. Kottler (1922) then actually pioneered the premetric approach by constructing, based on integral conservation laws, metric-free theory for Newton's gravity and Maxwell's electrodynamics. Similar line was followed by É. Cartan (1923) in electrodynamics and by D. van Dantzig (1934) who proposed a general premetric program in physics. Important technical contributions came from I. Tamm (1925) who studied a general linear constitutive law and from A. Sommerfeld (1948) who coined, following Mie, the notions of extensive and intensive quantities. The formal structure of electrodynamics was thoroughly investigated by E.J. Post (1962) and by C. Truesdell and R. Toupin (1960) in the framework of the formal field theory. An important issue of recovering the metric (deriving light-cone) was then clarified in the works of R. Toupin (1965), M. Schönberg (1971), and A. Jadzcyk (1979). W.-T. Ni (1973) was the first to propose an axion-dilaton extension of Maxwell's theory, and subsequently F. Wilczek (1987) looked into experimental issues of axion electrodynamics. See[1–4] for exact references.

Why going metric-free? Quoting Edmund Whittaker (1953): *Since the notion of metric is a complicated one, which requires measurements with clocks and scales, generally with rigid bodies, which themselves are systems of great complexity, it seems undesirable to take metric as fundamental, particularly for phenomena which are simpler and actually independent of it.* Furthermore, as we know (in Einstein's approach), metric is identified with the gravitational field. Thereby, one can say that

a metric formulation of a physical theory is "contaminated" by gravity. Hence, by revealing the metric-free relations one actually finds the most fundamental physical structures. In this sense, premetric approach helps to understand the essential interdependence between topological, affine, and metric concepts. Moreover, from the experimental standpoint, counting is obviously the simplest measurement!

### 1.1. *Principles of premetric approach*

Premetric axiomatics is straightforward. Construction of a metric-free physical model is inherently based on conservation laws. The latter should be phenomenologically verified by means of a certain counting process without use of the metric. Next, all physical objects are divided into two sets: extensive variables (*how much?*) are distinguished from intensive variables (*how strong?*). Based on the conservation laws, the two sets of *fundamental equations* then naturally arise for excitations (extensities) and for strengths (intensities). Final step: to convert the model into a predictive theory, one adds the *linking equations*, or constitutive relations, between excitations and field strengths.

The essence of the premetric art is formulated as follows: Fundamental equations are metric-free; the metric only enters via linking equations (constitutive relations).

## 2. Premetric electrodynamics

Classical electrodynamics admits a consistent premetric formulation[1]. Based on the conservation of electric charge $dJ = 0$, one arrives at $dH = J$, and the magnetic flux conservation results in $dF = 0$. Conservation laws require just *counting procedures* – of electric charges and magnetic flux lines. No distance concept is needed, therefore the premetric framework arises naturally.

Excitations $H = (\mathcal{D}, \mathcal{H})$ are measurable via the *charge*. These are extensive variables (how much?). Field strengths $F = (E, B)$ are measurable via the *force*. They are intensive variables (how strong?).

*Fundamental equations* of electrodynamics are metric-free:

$$dH = J, \qquad dF = 0. \tag{1}$$

*Linking equations* (constitutive relations) yield a predictive theory

$$H = \kappa\,[F]\,, \qquad H_{\alpha\beta} = \kappa_{\alpha\beta}{}^{\mu\nu} F_{\mu\nu}. \tag{2}$$

The metric is hidden/encoded in the constitutive tensor $\kappa_{\alpha\beta}{}^{\mu\nu}$. Constitutive relation can be more general – nonlinear and even nonlocal.

Using the local coordinates $x^i = (t, x^a)$, we have the $(1+3)$-decompositions

$$H = \mathcal{H}_a dx^a \wedge dt + \mathcal{D}^a \epsilon_a, \qquad F = E_a dx^a \wedge dt + B^a \epsilon_a, \tag{3}$$

(with $dx^a$ and $\epsilon_a$ bases of spatial 1- and 2-forms) and the local and linear constitutive law (2) is recast into

$$\mathcal{H}_a = -\,\mathfrak{C}^b{}_a\, E_b + \mathfrak{B}_{ba}\, B^b\,, \qquad \mathcal{D}^a = -\,\mathfrak{A}^{ba}\, E_b + \mathfrak{D}_b{}^a\, B^b\,. \tag{4}$$

With $\varepsilon^{ab} = \varepsilon^{ba}$, $\mu^{-1}_{ab} = \mu^{-1}_{ba}$, $\gamma^c{}_c = 0$, a convenient parametrization reads as[1]:

$$\mathfrak{A}^{ba} = -\,\varepsilon^{ab} + \epsilon^{abc} n_c, \qquad \mathfrak{B}_{ba} = \mu^{-1}_{ab} - \epsilon_{abc} m^c, \tag{5}$$

$$\mathfrak{C}^b{}_a = \gamma^b{}_a - s_a{}^b + \delta^b_a\, s_c{}^c + \alpha\, \delta^b_a, \qquad \mathfrak{D}_b{}^a = \gamma^a{}_b + s_b{}^a - \delta^a_b\, s_c{}^c + \alpha\, \delta^a_b. \tag{6}$$

Thereby the fine structure of the constitutive tensor is eventually revealed:

$$\kappa = \underbrace{\begin{pmatrix} \gamma^b{}_a & \mu^{-1}_{ab} \\ -\varepsilon^{ab} & \gamma^a{}_b \end{pmatrix}}_{\textit{principal}\text{ part 20 comp.}} + \underbrace{\begin{pmatrix} -s_a{}^b + \delta^b_a s_c{}^c & -\epsilon_{abc} m^c \\ \epsilon^{abc} n_c & s_b{}^a - \delta^a_b s_c{}^c \end{pmatrix}}_{\textit{skewon}\text{ part 15 comp.}} + \underbrace{\alpha \begin{pmatrix} \delta^b_a & 0 \\ 0 & \delta^a_b \end{pmatrix}}_{\textit{axion}\text{ part 1 comp.}} \tag{7}$$

## 3. Premetric formulation of gravity

Kottler in 1922 formulated a premetric nonrelativistic (Newton's) gravity. However, the spacetime metric = gravity in general relativity (GR) theory, and one may ask whether a premetric *relativistic* gravity makes any sense? In GR, the answer is negative. However, a *teleparallel* framework offers a viable opportunity[2–4]. Qualitatively, one proceeds by replacing the electric charge with the "gravitational charge" = mass (energy-momentum). The conservation of the gravitational charge $d\Sigma_\alpha = 0$ yields $dH_\alpha = \Sigma_\alpha$, thereby introducing the gravitational excitation 2-form $H_\alpha = \frac{1}{2} H_{ij\alpha} dx^i \wedge dx^j = \frac{1}{2} \check{H}^{\rho\sigma}{}_\alpha \epsilon_{\rho\sigma}$. Furthermore, the gravitational flux conservation results in $dF^\alpha = 0$, introducing the gravitational field strength 2-form $F^\alpha = \frac{1}{2} F_{ij}{}^\alpha dx^i \wedge dx^j = d\vartheta^\alpha$, so that the coframe $\vartheta^\alpha$ plays a role of the gravitational potential. The premetric formulation of gravity can be then consistently constructed along the lines of premetric electromagnetism. The corresponding gravitational-electromagnetic analogy is summarized in Table 1.

Table 1. Premetric electromagnetism-gravity analogy

| Objects and Laws | Electromagnetism | Gravity |
|---|---|---|
| Source current 3-form | $J$ | $\Sigma_\alpha$ |
| Conservation law | $dJ = 0$ | $d\Sigma_\alpha = 0$ |
| Excitation 2-form | $H$ | $H_\alpha$ |
| Inhomogeneous field equation | $dH = J$ | $dH_\alpha = \Sigma_\alpha = {}^{(\vartheta)}\Sigma_\alpha + {}^{(\mathrm{m})}\Sigma_\alpha$ |
| Field strength 2-form | $F$ | $F^\alpha$ |
| Homogeneous field equation | $dF = 0$ | $dF^\alpha = 0$ |
| Potential 1-form | $A$ | $\vartheta^\alpha$ |
| Potential equation | $dA = F$ | $d\vartheta^\alpha = F^\alpha$ |
| Lorentz force | $f_\alpha = (e_\alpha \rfloor F) \wedge J$ | $f_\alpha = \left(e_\alpha \rfloor F^\beta\right) \wedge {}^{(\mathrm{m})}\Sigma_\beta$ |
| Energy-momentum 3-form | $\frac{1}{2}(F \wedge e_\alpha \rfloor H - H \wedge e_\alpha \rfloor F)$ | $\frac{1}{2}(F^\beta \wedge e_\alpha \rfloor H_\beta - H_\beta \wedge e_\alpha \rfloor F^\beta)$ |
| Lagrangian 4-form | $\Lambda = -\frac{1}{2} F \wedge H$ | $\Lambda = -\frac{1}{2} F^\alpha \wedge H_\alpha$ |
| Constitutive tensor | $\chi^{\alpha\beta\gamma\delta}$ | $\chi^{\beta\gamma}{}_\alpha{}^{\nu\rho}{}_\mu$ |

### 3.1. *Gravitational constitutive tensor*

The local and linear constitutive law

$$\check{H}^{\alpha\beta}{}_{\mu} = \frac{1}{2}\chi^{\alpha\beta}{}_{\mu}{}^{\rho\sigma}{}_{\nu}\, F_{\rho\sigma}{}^{\nu} \tag{8}$$

describes a rich class of gravity models. The symmetry properties $\chi^{\beta\gamma}{}_{\alpha}{}^{\nu\rho}{}_{\mu} = -\chi^{\gamma\beta}{}_{\alpha}{}^{\nu\rho}{}_{\mu} = -\chi^{\beta\gamma}{}_{\alpha}{}^{\rho\nu}{}_{\mu}$ yield a simple number count $(6\times 4)\times(6\times 4) = 576$ of components of the constitutive tensor. The constitutive relation is *reversible* when $\chi^{\beta\gamma}{}_{\alpha}{}^{\nu\rho}{}_{\mu} = \chi^{\nu\rho}{}_{\mu}{}^{\beta\gamma}{}_{\alpha}$, with a reduced number of components: $24(24+1)/2 = 300$.

Splitting $\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \overset{+}{\chi}{}^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} + \overset{-}{\chi}{}^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}$ into reversible and irreversible parts,

$$\overset{+}{\chi}{}^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := \frac{1}{2}(\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} + \chi^{\gamma\delta}{}_{\nu}{}^{\alpha\beta}{}_{\mu}), \quad \overset{-}{\chi}{}^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} := \frac{1}{2}(\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} - \chi^{\gamma\delta}{}_{\nu}{}^{\alpha\beta}{}_{\mu}), \tag{9}$$

one derives a decomposition $\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \sum_{I=1}^{8} {}^{[I]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}$ of the constitutive tensor into six irreducible parts:

$${}^{[1]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \overset{+}{\chi}{}^{\alpha\beta}{}_{(\mu}{}^{\gamma\delta}{}_{\nu)} - \overset{+}{\chi}{}^{[\alpha\beta}{}_{(\mu}{}^{\gamma\delta]}{}_{\nu)}, \quad {}^{[2]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \overset{-}{\chi}{}^{\alpha\beta}{}_{[\mu}{}^{\gamma\delta}{}_{\nu]} - \overset{-}{\chi}{}^{[\alpha\beta}{}_{[\mu}{}^{\gamma\delta]}{}_{\nu]}, \tag{10}$$

$${}^{[3]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \overset{-}{\chi}{}^{\alpha\beta}{}_{(\mu}{}^{\gamma\delta}{}_{\nu)}, \qquad {}^{[4]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \overset{+}{\chi}{}^{\alpha\beta}{}_{[\mu}{}^{\gamma\delta}{}_{\nu]}, \tag{11}$$

$${}^{[5]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \overset{+}{\chi}{}^{[\alpha\beta}{}_{(\mu}{}^{\gamma\delta]}{}_{\nu)}, \qquad {}^{[6]}\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu} = \overset{-}{\chi}{}^{[\alpha\beta}{}_{[\mu}{}^{\gamma\delta]}{}_{\nu]}. \tag{12}$$

We call ${}^{[1]}\chi$ a reversible symmetric principal part (principal-1), ${}^{[4]}\chi$ a reversible antisymmetric principal part (principal-2), ${}^{[5]}\chi$ a reversible axion (axion-1), ${}^{[2]}\chi$ a skewon antisymmetric principal part (skewon-1), ${}^{[3]}\chi$ a skewon symmetric principal part (skewon-2), and ${}^{[6]}\chi$ a skewon axion (axion-2).

Comparing to electromagnetism, we have three parts in Maxwell's theory (7): $\chi^{\mu\nu\alpha\beta} = \frac{1}{2}\epsilon^{\mu\nu\rho\sigma}\kappa_{\rho\sigma}{}^{\alpha\beta} = {}^{(1)}\chi^{\mu\nu\alpha\beta} + {}^{(2)}\chi^{\mu\nu\alpha\beta} + {}^{(3)}\chi^{\mu\nu\alpha\beta}$: the principal ${}^{(1)}\chi$ piece and the axion ${}^{(3)}\chi$ (both reversible); and the skewon ${}^{(2)}\chi$ (irreversible).

When the metric exists on spacetime, the most general linear constitutive tensor

$$\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}(g) = \frac{1}{\varkappa}\Big[\beta_1\, g^{\gamma[\alpha}g^{\beta]\delta}g_{\mu\nu} + \beta_2\,\delta^{[\alpha}_{\mu}g^{\beta][\gamma}\delta^{\delta]}_{\nu} + \beta_3\,\delta^{[\alpha}_{\nu}g^{\beta][\gamma}\delta^{\delta]}_{\mu} \tag{13}$$

$$+\beta_4\,\varepsilon^{\alpha\beta\gamma\delta}\,g_{\mu\nu} + \beta_5\,\varepsilon^{\alpha\beta[\gamma}{}_{[\mu}\,\delta^{\delta]}_{\nu]} + \beta_6\left(\delta^{[\alpha}_{(\mu}\varepsilon^{\beta]\gamma\delta}{}_{\nu)} - \delta^{[\gamma}_{(\mu}\varepsilon^{\delta]\alpha\beta}{}_{\nu)}\right)\Big] \tag{14}$$

encompasses four irreducible parts: principal-1 proportional to $\beta_1$ and $(\beta_2+\beta_3)$, principal-2 proportional to $\beta_5$ and $(\beta_2-\beta_3)$, skewon-2 $\sim\beta_6$, and axion-1 $\sim\beta_4$.

### 3.2. *Propagation of gravitational waves*

In a geometric optics approximation, $F^{\alpha} = \mathcal{F}^{\alpha}e^{i\Phi}$ with rapidly varying phase $\Phi$ and slowly changing amplitude $\mathcal{F}^{\alpha}$ (eikonal ansatz). Alternatively, in Hadamard's theory, wave is described as a discontinuity across characteristic hypersurface (wave front). In any case, vacuum field equations reduce to algebraic system for amplitudes

$$dH_{\alpha} = 0,\ dF^{\alpha} = 0 \qquad \Longrightarrow \qquad \chi^{\mu\nu}{}_{\alpha}{}^{\rho\sigma}{}_{\beta}\,\mathcal{F}_{\rho\sigma}{}^{\beta}\,q_{\nu} = 0,\ \epsilon^{\mu\nu\rho\sigma}\,\mathcal{F}_{\rho\sigma}{}^{\alpha}\,q_{\nu} = 0, \tag{15}$$

with the wave covector $q = d\Phi = q_\mu \vartheta^\mu$. As a result, $\mathcal{F}_{\rho\sigma}{}^\alpha = A_\rho{}^\alpha q_\sigma - A_\sigma{}^\alpha q_\rho$, and from (15) for the amplitude $A_\mu{}^\nu$ we find a *characteristic equation*

$$M^\mu{}_\alpha{}^\nu{}_\beta \, A_\nu{}^\beta = 0\,, \qquad M^\mu{}_\alpha{}^\nu{}_\beta := \chi^{\mu\rho}{}_\alpha{}^{\nu\sigma}{}_\beta \, q_\rho \, q_\sigma. \tag{16}$$

The dispersion relation (Fresnel equation) arises as a solvability condition of (16). Decomposing $A_\alpha{}^\beta = \mathring{A}_\alpha{}^\beta + A\delta_\alpha^\beta$ into traceless part ($\mathring{A}_\alpha{}^\alpha = 0$) and trace $A = \frac{1}{4} A_\gamma{}^\gamma$:

$$N^\mu{}_\alpha{}^\nu{}_\beta \, \mathring{A}_\nu{}^\beta = 0, \qquad N^\mu{}_\alpha{}^\nu{}_\beta = M^\mu{}_\alpha{}^\nu{}_\beta M^\rho{}_\rho{}^\sigma{}_\sigma - M^\mu{}_\alpha{}^\rho{}_\rho M^\sigma{}_\sigma{}^\nu{}_\beta. \tag{17}$$

Notice the gauge freedom: $A_\nu{}^\beta \to A_\nu{}^\beta + q_\nu C^\beta$ leaves (16) invariant for any $C^\beta$.

In the metric-dependent case (14), for generic class of models with $2\beta_1 - \beta_2 - \beta_3 \neq 0$ and $2\beta_1 + \beta_3 \neq 0$ the characteristic equation splits into decoupled equations

$$(2\beta_1 - \beta_3) \left\{ 3 \left(q^2 \delta^\mu_\alpha - q^\mu q_\alpha\right) \left(q^2 \delta^\nu_\beta - q^\nu q_\beta\right) - (q^2 g_{\alpha\beta} - q_\alpha q_\beta) q^\mu q^\nu \right\} \mathring{A}_{(\mu\nu)} = 0, \tag{18}$$

$$(2\beta_1 + \beta_3) \left(q^2 \delta^\mu_\alpha - q^\mu q_\alpha\right) \left(q^2 \delta^\nu_\beta - q^\nu q_\beta\right) \mathring{A}_{[\mu\nu]} = 0, \tag{19}$$

and the scalar mode is recovered from $3q^2 A = \mathring{A}_\nu{}^\mu q_\mu q^\nu$. Therefore, only symmetric $\mathring{A}_{(\mu\nu)}$ mode is dynamical if $2\beta_1 = -\beta_3$, whereas only antisymmetric $\mathring{A}_{[\mu\nu]}$ mode remains dynamical when $2\beta_1 = \beta_3$.

The teleparallel equivalent general relativity model $\mathrm{GR}_{||}$ is a special case when both $2\beta_1 - \beta_2 - \beta_3 = 0$ and $2\beta_1 + \beta_3 = 0$. Explicitly: $\beta_4 = \beta_5 = \beta_6 = 0$ and

$$\beta_1 = -1\,, \qquad \beta_2 = -4\,, \qquad \beta_3 = 2. \tag{20}$$

For $\mathrm{GR}_{||}$ coupling constants (20), the characteristic equation (16) reduces to

$$q^2 h_{\alpha\beta} - q_\alpha q^\gamma h_{\gamma\beta} - q_\beta q^\gamma h_{\alpha\gamma} = 0, \tag{21}$$

which describes the usual spin 2 graviton mode $h_{\alpha\beta} = A_{(\alpha\beta)} - \frac{1}{2} g_{\alpha\beta} A_\gamma{}^\gamma$.

### 3.3. *Recovering General Relativity*

The teleparallel equivalent $\mathrm{GR}_{||}$ theory (20) is distinguished among other coframe models by the following remarkable properties:

- Field equations are invariant under local Lorentz group [5,6]
  $\vartheta^\alpha \longrightarrow L^\alpha{}_\beta(x)\vartheta^\beta, \quad L^\alpha{}_\beta \in SO(1,3)$.
- Black hole solutions exist [7].

The gravitational Lagrangian of $\mathrm{GR}_{||}$ actually reduces to Hilbert's Lagrangian $\Lambda = -\frac{1}{8}\chi^{\beta\gamma}{}_\alpha{}^{\rho\sigma}{}_\mu F_{\beta\gamma}{}^\alpha F_{\rho\sigma}{}^\mu = -\frac{1}{2\varkappa} R +$ total derivative. The constitutive tensor has only two nontrivial irreducible parts – principal-1 and principal-2.

*Premetric gravity summarized.* Fundamental equations are metric-free:

$$dH_\alpha = \Sigma_\alpha, \qquad dF^\alpha = 0. \tag{22}$$

Metric enters only in linking (constitutive law) equations (8), where [8] for $\mathrm{GR}_{||}$:

$$\chi^{\alpha\beta}{}_\mu{}^{\gamma\delta}{}_\nu = \frac{1}{\varkappa} \left( -g^{\gamma[\alpha} g^{\beta]\delta} g_{\mu\nu} - 4\delta^{[\alpha}_\mu g^{\beta][\gamma} \delta^{\delta]}_\nu + 2\delta^{[\alpha}_\nu g^{\beta][\gamma} \delta^{\delta]}_\mu \right). \tag{23}$$

## 4. Conclusions and outlook: On Kottler's path

Following the pioneering contributions by Kottler, Cartan and van Dantzig, the premetric program works universally in physics, embracing classical particle mechanics, kinetic theory, and (most importantly) electromagnetism and gravity. A feasible premetric gravity theory can be constructed on the basis of the energy-momentum conservation law as a teleparallel coframe model. The corresponding general local and linear constitutive relation encompasses *six* irreducible parts (2 principal, 2 skewon, and 2 axion).

In premetric approach, one can view constitutive tensor $\chi^{\alpha\beta}{}_{\mu}{}^{\gamma\delta}{}_{\nu}$ as an independent variable. This opens new perspectives in electromagnetism and gravity theory such as:

- Natural extensions with *axion, skewon, and dilaton* fields[9]
- Natural extension to *parity odd* contributions[5,10]
- Convenient framework to discuss *Lorentz violating* models[11]
- Nonlinear gravity models, $f(R)$ and $f(T)$, in particular[12,13]
- Nonlocal constitutive laws[14,15]

### Acknowledgments

This talk is essentially based on the papers[2–4] written in collaboration with Friedrich Hehl, Yakov Itin and Jens Boos. I am grateful to Marcus Werner for the kind invitation and support which made it possible for me to attend MG15.

# Observers' measurements of time and length in premetric electrodynamics

Christian Pfeifer

*Laboratory of Theoretical Physics, Institute of Physics, University of Tartu, W. Ostwaldi 1 50411 Tartu, Estonia*
*E-mail: christian.pfeifer@ut.ee*

The notion of observers' and their measurements is closely tied to the Lorentzian metric geometry of spacetime, which in turn has its roots in the symmetries of Maxwell's theory of electrodynamics. Modifying either the one, the other or both ingredients to our modern understanding of physics, requires also a reformulation of the observer model used. In this presentation we will consider a generalized theory of electrodynamics, so called local and linear premetric, or area metric, electrodynamics and its corresponding spacetime structure. On this basis we will describe an observer's measurement of time and spatial length. A general algorithm how to determine observer measurements will be outlined and explicitly applied to a first order premetric perturbation of Maxwell electrodynamics. The latter contains for example the photon sector of the minimal standard model extension. Having understood an observer's measurement of time and length we will derive the relativistic observables time dilation and length contraction. In the future a modern relativistic description of the classical test of special relativity shall be performed, including a consistent observer model.

*Keywords*: premetric electrodynamics, relativity, observers, radar experiment, time dilation, length contraction

## 1. From electrodynamics to relativity

The origins of special and general relativity and, in particular, of the relation between observers by Lorentz transformations, lies in Maxwell's theory of electrodynamics. It predicts the propagation of light on the integral curves of the directions forming the null cones cones of a Lorentzian metric, and the Lorentz transformations are those transformations which leave this structure invariant, globally for the flat Minkowski metric, locally for any non-flat Lorentzian metric g encoding gravity. Thus historically, first there was a viable relativistic matter field theory which described the behaviour of the electromagnetic field correctly, and then, a theory of gravity consistent with the relativity principles of the matter field theory was constructed[1].

Modifications and extensions of general relativity, and of the field theories forming the standard model of particle physics, are numerous and disperse in various directions. However, it is rarely discussed what happens to the description of observers and their measurements, when one changes the theoretical models of gravity or matter. In approaches where gravity is still encoded into a spacetime metric and matter fields are minimally coupled to this metric, such as f(R)-gravity or other modifications of the Einstein-Hilbert action only involving the metric[2], the observer description from general relativity is still applicable. But, when one changes the field which encodes gravity away from the metric, or introduces couplings of this

field to matter fields, like in the standard model extension (SME) framework[3,4], the Robertson-Mansouri-Sexl (RMS) framework[5,6], Finsler geometries[7] or premetric electrodynamics[8,9], the influence of the added concepts on observers, their measurements and their relation between each other has to be investigated and a consistent observer model has to be constructed.

Here we summarize how one obtains an observer's measurement of time and spatial lengths starting from a theory of electrodynamics in the following algorithm, using the techniques developed in the articles[10,11]:

I. Derive the geometric optics limit of the theory of electrodynamics.
II. Derive the Lagrange functions $L^{\#}$ and $L^{*}$, which define the motion of massless and massive particles on the manifold, from the geometric optic limit.
III. Use $L^{*}$ to realize the clock postulate, i.e. to identify the proper time normalization of observer worldlines $x$ by choosing $L^{*}(\dot{x}) = 1$.
IV. Model the radar experiment by demanding that for a spatial direction $X$ the vectors $N^{+} = \ell_{\dot{x}}(X)\dot{x} + X$ and $N^{-} = \tilde{\ell}_{\dot{x}}(X)\dot{x} + X$ are the tangents of the light rays of the radar signal, i.e. are null-vectors of $L^{\#}$.
V. A solution of $L^{\#}(N^{\pm}) = 0$ defines the radar length $\mathcal{L}_U(X) = \ell_{\dot{x}}(X) + \tilde{\ell}_{\dot{x}}(X)$ an observer on worldline $x$ associates to an object represented by the vector $X$.

To demonstrate how the general algorithm works in practice we apply it to first order modification of Maxwell electrodynamics caledl weak premetric electrodynamics.

Throughout this article we use the convention that $\eta = \mathrm{diag}(1, -1, -1, -1)$.

## 2. Weak premetric electrodynamics

The field equations of weak premetric electrodynamics are[12]

$$(\eta^{ac}\eta^{bd} + \mathcal{K}^{abcd})\partial_b F_{cd} = 0, \quad F_{cd} = \partial_{[c}A_{d]}\,, \tag{1}$$

the tensor $\mathcal{K}^{abcd}$ parametrizes the deviations from metric electrodynamics and has the following properties $\mathcal{K}^{abcd} = \mathcal{K}^{[ab][cd]} = \mathcal{K}^{[cd][ab]}$ and $\mathcal{K}^{a[bcd]} = 0$.

**Step I. Plane waves: The geometric optic limit.** Wave covectors $k$ of the plane waves solving the field equations are the roots of the Fresnel polynomial $\mathcal{G}(k)$[13]

$$\mathcal{G}(k) = \eta^{-1}(k,k)^2 - \eta^{-1}(k,k)\mathcal{K}(k,k) + \frac{1}{2}\big(\mathcal{K}(k,k)^2 - \mathcal{J}(k,k,k,k)\big)\,. \tag{2}$$

The tensor fields appearing are derived from the perturbation tensor defining the field equations

$$\mathcal{K}(k,k) = \mathcal{K}^{ac}k_a k_c = \mathcal{K}^{abc}{}_b k_a k_c, \tag{3}$$

$$\mathcal{J}(k,k,k,k) = \mathcal{J}^{acef}k_a k_c k_e k_f = \mathcal{K}^{abcd}\mathcal{K}^{e}{}_{b}{}^{f}{}_{d}k_a k_c k_e k_f\,. \tag{4}$$

Observe that, in order to study the correction in the propagation of light predicted by the perturbation of the field equations to first order, it is necessary to consider the

Fresnel polynomial to second order. For the following, in particular the condition $\det(\partial_{k_a}\partial_{k_b}\mathcal{G}(k)) \neq 0$ must hold[10].

**Step II.: The determination of the Lagrange functions $L^{\#}$ and $L^{*}$.** The Lagrangian which determines the propagation of light is given by the dual polynomial of $\mathcal{G}(k)$, i.e. by the unique polynomial satisfying $L(\dot{x}(k)) = Q(k)\mathcal{G}(k)$, where $\dot{x}^a(k) = \partial_{k_a}\mathcal{G}(k)$. Employing $\dot{x}^\flat = \eta(x,\cdot)$ we find

$$\begin{aligned} L^{\#}(\dot{x}) &= \eta(\dot{x},\dot{x})^2 + 3\mathcal{K}(\dot{x}^\flat,\dot{x}^\flat)\eta(\dot{x},\dot{x}) \\ &\quad + \frac{1}{2}(3\mathcal{J}(\dot{x}^\flat,\dot{x}^\flat,\dot{x}^\flat,\dot{x}^\flat) + 4\mathcal{K}(\dot{x}^\flat,\dot{x}^\flat)^2 + 5\mathcal{K}_{ac}\mathcal{K}^c{}_b\dot{x}^a\dot{x}^b\eta(\dot{x},\dot{x})) \qquad (5) \\ &= \eta(\dot{x},\dot{x})^2 + h_1(\dot{x},\dot{x})\eta(\dot{x},\dot{x}) + h_2(\dot{x},\dot{x},\dot{x},\dot{x})\,. \qquad (6) \end{aligned}$$

The abbreviations $h_1$ and $h_2$ were introduced to display the radar length formula later in a compact form. The motion of observers and their geometric clock is given by a second Lagrangian $L^*$ which can be obtained from the Helmholtz action

$$S[x,k,\lambda] = \int \mathrm{d}\tau\, \Big(k_a\dot{x}^a - \lambda \ln\big(\mathcal{G}(\tfrac{k}{m})\big)\Big), \qquad (7)$$

by eliminating $k$ and the Lagrange multiplier $\lambda$ with help of the corresponding equations of motion. Doing so we find the length functional

$$S[x] = \int \mathrm{d}\tau\; L^*(\dot{x}) = \int \mathrm{d}\tau\; \sqrt{\eta(\dot{x},\dot{x})}\left(1 + \frac{1}{4}\frac{\mathcal{K}(\dot{x}^\flat,\dot{x}^\flat)}{\eta(\dot{x},\dot{x})}\right). \qquad (8)$$

Physically this parametrization invariant action integral measures the observer's proper time, and mathematically speaking $L^*$ is a Finsler function.

**Step III.: The clock postulate.** An observer worldline is a cuvre $x(\tau)$ whose tangent satisfies $L^*(\dot{x}) = 1$, or explicitly $\eta(\dot{x},\dot{x}) = 1 - \frac{1}{2}\mathcal{K}(\dot{x}^\flat,\dot{x}^\flat)$. The directions $X$ which are spatial w.r.t. $x$ satisfy $X^a\partial_{\dot{x}^a}L^* = \eta(\dot{x},X) + \frac{1}{2}\mathcal{K}(\dot{x}^\flat,X^\flat) = 0$.

## 3. The radar length

**Step IV.: Setup the radar experiment.** An observer on a wordline $x(\tau)$ with tangent $\dot{x}$ emits light along the curve with tangent $N^+$ towards the end of an object, which is modelled by a vector $X$ spatial w.r.t. $\dot{x}$. There the light gets reflected and propagates back to the observer along the curve with tangent $N^-$. The observer measures the time of flight of the light between its emission and return. This time is the radar length the observer associates to the object. The tangents of the light curves $N^+ = \ell_{\dot{x}}(X)\dot{x} + X$ and $N^- = \tilde{\ell}_{\dot{x}}(X)\dot{x} - X$ must satisfy $L^{\#}(N^+) = 0 = L^{\#}(N^+)$, which can be solved for $\ell_{\dot{x}}(X)$ and $\tilde{\ell}_{\dot{x}}(X)$.

**Step V.: Solve for the radar length.** The radar length then is given by $\mathcal{L}_{\dot{x}}(X) = \ell_{\dot{x}}(X) + \tilde{\ell}_{\dot{x}}(X)$.

The influence of $L^{\#}$ on the radar experiment is obvious, however it is important to stress that also $L^*$ enters the calculation by the demands that $\dot{x}$ satisfies $L^*(\dot{x}) = 1$ and the fact that $X$ shall be spatial w.r.t. $\dot{x}$, see the comments below (8).

Using the explicit form of $L^{\#}$ and $L^{*}$ in (5) and (8), the desired radar length is given by, see[12] for the derivation,

$$\mathcal{L}_{\dot{x}}(X)_{\sigma\tilde{\sigma}} = 2\sqrt{-\eta(X,X)} \tag{9}$$
$$+\frac{\epsilon}{4}\frac{\left(\sigma\sqrt{B(X,\dot{x})}+\tilde{\sigma}\sqrt{\tilde{B}(X,\dot{x})}\right)}{\sqrt{-\eta(X,X)}}-\frac{\epsilon}{2}\frac{h_1(X,X)-2h_1(\dot{x},\dot{x})\eta(X,X)}{\sqrt{-\eta(X,X)}}.$$

The abbreviations $B$ and $\tilde{B}$ are lengthy functions of the perturbation tensors $h_1$ and $h_2$ defined in (6), they are displayed in[12]. The labels $\sigma$ and $\tilde{\sigma}$ can each take the values $+1$ or $-1$ and label which polarization of light has been used for $N^{+}$ resp. $N^{-}$. For example $\sigma=\tilde{\sigma}$ yields the radar length deermined by the same polarization used for $N^{+}$ and $N^{+}$, while $\sigma=-\tilde{\sigma}$ represents the case when the reflection at the end of the object changes the polarization of the light.

## 4. Relativistic Observables

Having clarified an observers measurement of time and spatial lengths we can derive the classical relativistic observables time dilation and length contraction. To do so, consider two observers on inertial wordlines $x_1$ and $x_2$, which have met at some point in spacetime. There they synchronized their clocks. After a proper time $t_1$ the first observer may decompose the tangent of the worldline of the second observer in terms of an equal time displacement vector $X=t_1V$ as $t_2\dot{x}_2=t_1(\dot{x}_1+V)$, where $V$ is the relative velocity between the observers.

The relation between the proper time $t_2$ of the second observer and the proper time $t_1$ then is

$$t_2L^{*}(\dot{x}_2)=t_2=t_1L^{*}(\dot{x}_1+V)=t_1\sqrt{1+\eta(V,V)}\left(1+\epsilon\frac{1}{12}\frac{h_1(V,V)}{(1+\eta(V,V))}\right). \tag{10}$$

Most interestingly, for weak premetric theories of electrodynamics for which $h_1^{ab}=\mathcal{K}^{acb}{}_{d}=0$, no change in the time dilation between observers compared to special relativity appears.

The calculation of the length contraction is more involved. Let observer $x_1$ carry a spatial object $Y$ to which it associates the radar length $\mathcal{L}_{\dot{x}_1}(Y)$. With respect to the observer $x_2$ the object $Y$ is not spatial, so first one needs to determine the projection $\bar{Y}$ of $Y$ onto the spatial directions of $x_2$. Then, $x_2$ can associate the radar length $\mathcal{L}_{\dot{x}_2}(\bar{Y})$ to $\bar{Y}$. The length contraction factor is given by the fraction $\frac{\mathcal{L}_{\dot{x}_1}(Y)}{\mathcal{L}_{\dot{x}_2}(\bar{Y})}$. The result is a complicated function of the perturbations $h_1$ and $h_2$ which can be found in[12]. The interesting observation is that, in contracts to the time dilation, even for $h_1^{ab}=\mathcal{K}^{acb}{}_{d}=0$ the effect does acquire a first order modification compared to the special relativistic result.

## 5. Conclusion

A modification of the geometry away from metric spacetime geometry requires a careful revision of the observer model used to compare observations with theoretical predictions. The example of the radar length demonstrates nicely that, in particular for Finslerian spacetime geometries it is not viable to simply exchange the Lorentzian metric employed in general relativity with the Finslerian metric evaluated at the observer curve on the tangent bundle for a description of observables.

The future task for spacetime geometries based on a Finsler function or a general dispersion relation is to find a description of observers from these quantities and to clarify the transformations mapping them onto each other.

# Covariant constructive gravity

Tobias Reinhart* and Nils Alex

*Department Physik, Friedrich-Alexander Universität Erlangen-Nürnberg, 91058 Erlangen, Germany*
**E-mail: tobi.reinhart@fau.de*

We present a method of constructing perturbative equations of motion for the geometric background of any given tensorial field theory. Requiring invariance of the gravitational dynamics under spacetime diffeomorphisms leads to a PDE system for the gravitational Lagrangian that can be solved by means of a power series ansatz. Furthermore, in each order we pose conditions on the causality of the gravitational equations, that ensure coevolution of the matter fields and the gravitational background is possible, i.e. gravitational equations and matter equations share the same initial data hypersurfaces.

*Keywords*: Constructive gravity; diffeomorphism invariance; causality

## 1. Introduction

Given a matter field theory in terms of an action functional $S_{mat}[\Phi; G)$ for a tensorial matter field $\Phi$ whose geometric background is provided by an additional tensorfield $G$, the problem of constructive gravity consists of completing the matter field equations with EOM for $G$ that make the coupled system of matter dynamics and supplemented gravitational dynamics a predictive theory. In contrast to the existing canonical framework described in Ref. 1 , we outline in the following how this problem can be tackled perturbatively from the spacetime covariant point of view.

## 2. Perturbative diffeomorphism invariance

Let $M$ be a smooth 4-dimensional manifold that represents spacetime. The gravitational field is described as a tensorfield $G$ on $M$, i.e. as a section of a bundle $\pi_F : F \to M$, with adapted coordinate functions $(x^m, v_A)$, where $F \subset T^m_n M$ for some $m$ and $n$. The equations we want to construct for $G$ shall be given as Euler-Lagrange-Equations of an up to now unknown Lagrangian $L : J^1F \to \Lambda^4 M$, which is a bundle map from the first order jet bundle over $F$ with coordinates $(x^m, v_A, v_{Ap})$ to the bundle of volume forms on $M$. One of the key requirements we pose on the to-be-constructed gravitational EOM is the invariance under spacetime diffeomorphisms. The action of $\mathrm{Diff}(M)$ on M extends naturally to $F$ by pullback and can then be lifted to the first jet bundle in standard ways.[3] Doing so, given $f \in \mathrm{Diff}(M)$ that acts on $M$, we can construct bundle automorphisms $f_*$ and $j^1 f_*$ that act on $F$ and $J^1F$, respectively. Diffeomorphism invariance of the theory is given if the Lagrangian is equivariant w.r.t. the lifted action on $J^1F$ and the action by pullback on $\Lambda^4 M$, i.e. for all $f \in \mathrm{Diff}(M)$ it holds that:

$$L \circ j^1 f_* = f_* \circ L. \tag{1}$$

On the Lie algebra level, (1) can be shown to be equivalent to the following set of first order partial differential equations for $L$:[3]

$$\begin{aligned} 0 &= L_{:m} \\ 0 &= L^{:A} C^{Bm}_{An} v_B + L^{:Ap} C^{Bm}_{An} v_{Bp} - L^{:Am} v_{An} + L\delta^m_n \\ 0 &= L^{:A(p|} C^{B|m)}_{An} v_B, \end{aligned} \tag{2}$$

where the constant tensor $C^{Bm}_{An}$ is obtained from the lie-algebra action of vector fields $\xi$ on $F$, $\xi_F = \xi^m \partial_m + C^{Bm}_{An} V_B \partial_m \xi^n \partial^A$ and hence depends on the specific nature of $G$. Here and in the following we use the notation $L_{:m} := \partial_m L$, $L^{:A} := \partial^A L$, etc. Later on we are going to use the equivariance condition of the Lagrangian to explicitly construct gravitational EOM. It is then often advantageous to work directly on the level of the EOM. Given a Lagrangian $L(x^m, v_A, v_{Ap})$ we obtain the corresponding EOM by applying the variational derivative to $L$ and equating to zero:

$$\begin{aligned} 0 =& E^A(x^m, v_A, v_{Ap}, v_{Apq}) := \frac{\delta L}{\delta v_A} = L^{:A} - D_m(L^{:Am}) \\ & D_m := \partial_m + v_{Am} \cdot \partial^A + v_{Apm} \cdot \partial^{Ap}. \end{aligned} \tag{3}$$

The EOM are now described by a function $E^A$ on $J^2F$. As consequence of (1) the EOM satisfy the following first order partial differential equation system:

$$\begin{aligned} 0 =& E^A_{:m} \\ 0 =& E^{A:B} C^{Cm}_{Bn} v_C + E^{A:Bp} C^{Cm}_{Bn} v_{Cp} - E^{A:Bm} v_{Bn} \\ & + E^{A:Bpq} C^{Cm}_{Bn} v_{Cpq} - 2E^{A:Bpm} v_{Bpn} + E^A \delta^m_n + E^B C^{Am}_{Bn} \\ 0 =& E^{A:B(p|} C^{C|m)}_{Bn} v_C + E^{A:B(p|q} C^{C|m)}_{Bn} v_{Cq} - E^{A:Bpm} v_{Bn} \\ 0 =& E^{A:B(pq|} C^{C|m)}_{Bn} v_C. \end{aligned} \tag{4}$$

The problem of constructing diffeomorphism invariant theories for a given tensor field $G$ is thereby translated into the equivalent problem of finding solutions to the equivariance equations (2) on the Level of the Lagrangian or the equations (4) on the level of the EOM. Details concerning the derivation of these equations can be found in Ref. 2. In most cases of physical interest, obtaining general solutions to either one of the two systems of equations is strikingly difficult. Therefore we are going to construct perturbative solutions, more precisely we are seeking power series expansions of the Lagrangian (or the EOM) that solve the equations (2) (or the equations (4)) up to the desired order.[4] We choose an expansion point $x_0$ that is induced by the flat Minkowski metric $\eta_{ab}$, i.e. $x_0 = (x^m, N_A, 0, ..)$, where the coordinates $N_A = N_A(\eta_{ab})$ are functions of the flat Minkowski metric and the derivative coordinates are zero. This allows the perturbatively constructed theory of gravity to be interpreted as an expansion around flat Minkowski spacetime. Discharging any explicit $x^m$ dependency that is prohibited due to the first equation in (2) from the very beginning, the most general expansion of the Lagrangian is

given as:

$$\begin{aligned} L = {} & L^{:A:B}\big|_{x_0}(v_A - N_A)(v_B - N_B) + L^{:Ap:Bq}\big|_{x_0} v_{Ap} v_{Bq} \\ & + L^{:A:B:C}\big|_{x_0}(v_A - N_A)(v_B - N_B)(v_C - N_C) \\ & + L^{:Ap:Bq:C}\big|_{x_0} v_{Ap} v_{Bq}(v_C - N_C) + \mathcal{O}(4). \end{aligned} \tag{5}$$

Here any linear terms are neglected as they do not contribute to the EOM. Terms with an odd number of indices are neglected as these can otherwise be eliminated using a result that can be derived from the equivariance equations:[2] If the chosen expansion point is eta-induced, the expansion coefficients in (5), i.e. $L^{:A:B}|_{x_0}$, etc. are linear combinations of sums of products of $\eta^{ab}$ and $\epsilon^{abcd}$. Inserting the induced expansion of the EOM into (4) and evaluating at $x_0$ yields a set of linear equations for the expansion coefficients that contribute to the EOM in linear order. Prolonging (4), i.e. deriving with respect to the coordinates of $J^2F$, inserting the expansion of the $E^A$ and again evaluating at $x_0$, we obtain a system of linear equations for the second order expansion coefficients. In total, by doing so we end up with the following set of linear equations for the linear order expansion coefficients:

$$\begin{aligned} 0 &= L^{:A:B}\big|_{x_0} C^{Cm}_{Bn} N_C \\ 0 &= \big|_{(pqm)} L^{:Ap:Bq}\big|_{x_0} C^{Cm}_{Bn} N_C, \end{aligned} \tag{6}$$

where $... = \big|_{(pqm)}$ denotes the total symmetrization in $pqm$ for the whole equation. In quadratic order we obtain:

$$\begin{aligned} 0 = {} & -2L^{:A:B}\big|_{x_0} C^{Cm}_{Bn} + 6L^{:A:B:C}\big|_{x_0} C^{Dm}_{Bn} N_D + 2L^{:B:C}\big|_{x_0} C^{Am}_{Bn} - 2L^{:A:C}\big|_{x_0} \delta^m_n \\ 0 = {} & \big|_{(pq)} 2L^{:Ap:Cm}\big|_{x_0} \delta^q_n + L^{:Ap:Bq}\big|_{x_0} C^{Cm}_{Bn} + L^{:Ap:Cq:B}\big|_{x_0} C^{Dm}_{Bn} N_D \\ & + L^{:Bp:Cq}\big|_{x_0} C^{Am}_{Bn} + L^{:Ap:Cq}\big|_{x_0} \delta^m_n \\ 0 = {} & \big|_{(pm)} L^{:Ap:Cm}\big|_{x_0} \delta^q_n - 2L^{:Ap:Bq}\big|_{x_0} C^{Cm}_{Bn} \\ & + \big[L^{:Bp:Cq:A}\big|_{x_0} - L^{:Ap:Cq:B}\big|_{x_0} - L^{:Bp:Aq:C}\big|_{x_0}\big] C^{Dm}_{Bn} N_D \\ 0 = {} & \big|_{(pqm)} L^{:Ap:Bq}\big|_{x_0} C^{Cm}_{Bn} + L^{:Ap:Bq:C}\big|_{x_0} C^{Dm}_{Bn} N_D. \end{aligned} \tag{7}$$

Note that the complex quest of solving the PDE system (4) which guarantees diffeomorphism invariance is now translated, at least perturbatively, into the much simpler task of solving a system of linear equations. Furthermore the presented equations take this form irrespective of the specific gravitational field $G$. The only quantity that depends on $G$ is the constant tensor $C^{Am}_{Bn}$ that can easily be computed once $G$ is specified. Solving this linear system can be simplified even further by again exploiting the fact that the expansion coefficients are built from $\eta^{ab}$ and $\epsilon^{abcd}$. We construct the most general such expression for each coefficient. These expressions obviously involve undetermined constants. Inserting into (7) yields a system of linear equations for these constants.

## 3. Examples of the construction procedure

In the following we present two examples of the previously described construction procedure.

### 3.1. *Metric gravity*

Given the action functional of a Klein-Gordon matter field on a fixed metric background

$$S_{\mathrm{KG}}[\Phi; g_{ab}) = \int \mathrm{d}^4x\sqrt{-g}g^{ab}\partial_a\Phi\partial_b\Phi, \tag{8}$$

we want to construct a second order expansion of diffeomorphism invariant EOM for $g_{ab}$ around $\eta_{ab}$. Starting with the linear order equations (6), the first step is computing the most general expressions built from $\eta^{ab}$ and $\epsilon^{abcd}$ for the two linear expansion coefficients. Using the induced symmetries of these one readily finds that:

$$L^{:ab:cd}\big|_{x_0} = \mu_1 \cdot \eta^{ab}\eta^{cd} + \mu_2 \cdot \eta^{c(a}\eta^{b)d}. \tag{9}$$

In similar ways we compute the expression for $L^{:abp:cdq}$ with constants $\nu_1, .., \nu_4$. Inserting in (6) and solving for the unknown constants we get:

$$\begin{aligned} &\mu_1 = 0,\ \mu_2 = 0 \\ &\nu_2 = -\nu_1,\ \nu_3 = 2\nu_1\ \nu_4 = -2\nu_1. \end{aligned} \tag{10}$$

Performing the same computation for the quadratic order expansion coefficients and the corresponding equations (7), we are left with one overall constant $\nu_1$ which is irrelevant once the EOM are equated to zero. Furthermore the two terms in the expansion of $E^A$ that have no contributions of derivatives of $g_{ab}$ are identically zero.[a] Comparing the obtained quadratic order expansion of the EOM with the Einstein field equations we conclude that the two systems coincide.

### 3.2. *Area metric gravity*

As a second example we consider the action functional of general linear electrodynamics, in short GLED. The action is given as

$$S_{\mathrm{GLED}}[A_m; G_{abcd}) = \int \mathrm{d}^4x\omega_G G^{abcd}F_{ab}F_{cd}, \tag{11}$$

where $A$ is the electromagnetic potential, $F = dA$ is the field strength, $G$ is the so called area metric, a (0,4) tensor field with the symmetries $G_{abcd} = G_{cdab} = -G_{bacd}$ and $\omega_G$ is a density of weight 1 constructed from $G$. The components of the inverse

[a] In the following such terms are referred to as mass terms and the corresponding constants are called masses, whereas the remaining terms and constants are called kinetic terms and gravitational constants respectively.

area metric $G^{abcd}$ are defined by $G^{abcd}G_{cdef} = 4\delta^{[a}_{e}\delta^{b]}_{f}$. We choose $N_{abcd} = \eta_{ac}\eta_{bd} - \eta_{ad}\eta_{bc} - \epsilon_{abcd}$ as expansion point. With this choice, we recover—to zeroth order in the gravitational field—Maxwell electrodynamics on a Minkowski background. As before we construct ansätze for the expansion coefficients from $\eta^{ab}$ and $\epsilon^{abcd}$. Solving the equations (6) and (7) we obtain 3 masses and 7 gravitational constants in linear order, 5 additional masses and 36 additional gravitational constants in quadratic order. Details regarding this particular example can be found in Ref. 2.

## 4. Causal compatibility of gravitational and matter field equations

Apart from diffeomorphism invariance, the second crucial requirement that constructive gravity poses on the gravitational dynamics is their causal compatibility with the given matter theory.[1] Physically meaningful matter theories have hyperbolic EOM, i.e. given initial data on an initial data hypersurface in $M$, the EOM can be used to evolve this initial data and thereby uniquely predict the values of the matter field away from the hypersurface. Assuming this for the given matter theory, one can construct a certain polynomial function on the symmetric product $S^k(T^*M)$, the so called principal polynomial of the matter equations $P$. From the vanishing set of $P$ a convex cone in each $T^*_xM$ is constructed. It can be shown that precisely those hypersurfaces that have at each point a co-normal vector lying inside this cone are admissible initial data hypersurfaces.[1,4] If the gravitational EOM shall complete the given matter dynamics to a predictive theory, we must require that there exist initial data hypersurfaces that are common to both EOMs. This is certainly the case if the principal polynomial of the gravitational EOM has the same vanishing set as the principal polynomial of the matter theory. In the following we are going to explore how this additional requirement might or might not restrict the gravitational constants and masses that were obtained in the previous two examples. We start with metric gravity. The principal polynomial of the Klein-Gordon theory is, up to an overall factor, simply given by

$$P_{\mathrm{KG}}(k) = g^{ab}k_ak_b = \eta^{ab}k_ak_b - \eta^{ac}\eta^{bd}h_{cd}k_ak_b + \mathcal{O}(2), \tag{12}$$

where we introduced $h_{ab} := g_{ab} - \eta_{ab}$ and expanded the polynomial in powers of $h_{ab}$. Computing the principal polynomial of the perturbative expansion of metric gravity obtained before, we find that

$$P_{\mathrm{metric}}(k) = \left\{(\eta^{ab}k_ak_b - \eta^{ac}\eta^{bd}h_{cd}k_ak_b)\right\}^2 + \mathcal{O}(2). \tag{13}$$

Obviously this polynomial describes the same vanishing set as $P_{\mathrm{KG}}$. Hence we get no additional condition from the causality requirement. This is not too surprising as except from an overall gravitational constant there is no freedom left in the perturbative metric EOM in the first place.

The principal polynomial of GLED was first computed by Rubilar[5] and is given by

$$\begin{aligned} P_{\mathrm{GLED}}(k) &= -\frac{1}{24}\omega_G^2 \epsilon_{mnpq}\epsilon_{rstu} G^{mnra} G^{bpsc} G^{dqtu} k_a k_b k_c k_d \\ &= \big[1 - A\eta(H) - \frac{1}{2}A\epsilon(H) + \frac{1}{12}\epsilon(H)\big]\eta(k)^2 - H(k)\eta(k) + \mathcal{O}(2) \\ &= \big\{\big[1 - \frac{1}{2}A\eta(A) - \frac{1}{4}A\epsilon(H) + \frac{1}{24}\epsilon(H)\big]\eta(k) - \frac{1}{2}H(k)\big\}^2 + \mathcal{O}(2), \end{aligned} \tag{14}$$

where $H_{abcd} := G_{abcd} - N_{abcd}$, $\eta(H) := \eta^{ac}\eta^{bd}H_{abcd}$, $\epsilon(H) := \epsilon^{abcd}H_{abcd}$, $H(k) := \eta^{ac}\eta^{bp}\eta^{cq}H_{abcd}k_p k_q$, $\eta(k) := \eta^{pq}k_p k_q$ and $A$ is a constant that depends on the specific choice for the density $\omega_G$. Note that, as we are only interested in the vanishing set of the principal polynomial, we can multiply a given polynomial with a non vanishing density of arbitrary weight. Such a density admits the general form

$$X = 1 + b_1 \cdot (\eta(H) + \frac{1}{2}\epsilon(H)) + \frac{b_2}{12}\epsilon(H) + \mathcal{O}(2), \tag{15}$$

for arbitrary constants $b_1$ and $b_2$. Multiplying (14) with such a density we see that perturbatively the GLED polynomial describes the same vanishing set as

$$\begin{aligned} \widetilde{P}_{\mathrm{GLED}}(k) = X \cdot P_{\mathrm{GLED}} = \big\{\big[1 - \frac{1}{2}(A - b_1)\eta(H) - \frac{1}{4}(A - b_1)\epsilon(H)) + \\ \frac{1 + b_2}{24}\epsilon(H)\big]\eta(k) - \frac{1}{2}H(k)\big\}^2 + \mathcal{O}(2). \end{aligned} \tag{16}$$

The principal polynomial of the constructed, diffeomorphism invariant expansion of area metric gravity to second order is calculated as

$$P_{\mathrm{area}} = \big\{\big[1 - \frac{1}{2}C\eta(H) - \frac{1}{4}C\epsilon(H) + \frac{7}{12 \cdot 13}\epsilon(H)\big]\eta(k) - \frac{1}{2}H(k)\big\}^{13} + \mathcal{O}(2), \tag{17}$$

where $C$ is an expression that depends on the gravitational constants of the theory, but not on $H_{abcd}$.[2] Comparing (16) and (17) shows that, multiplying the GLED polynomial with a density with constants $b_1 = A - C$ and $b_2 = \frac{1}{13}$, the two polynomials are products of the same factor and therefore describe the same vanishing set in $\mathcal{O}(2)$. Hence already the required diffeomorphism invariance fixes the principal polynomial of area metric gravity to the point where, perturbatively, the EOM have the same initial data hypersurfaces as those of GLED.

In the young field of constructive gravity, the gravity theory constructed from general linear electrdynamics has been frequently used as a physically meaningful text case for the entire approach. Based on a Newtonian approximation of area metric gravity, we use the rotation curves of low surface brightness galaxies to determine ranges for the gravitational constants in this weak field limit. Thus we are able to show that even by using very simple models for the distribution of visible matter in the galaxies, Newtonian area metric gravity yields reasonable rotation curves and consistent estimates for the gravitational constants. Area-metric gravity turns out to not be an alternative to dark matter, but to reduce the dark matter fraction and to remove the need for a distribution subtantially different from visible matter.

*Keywords*: constructive gravity, rotation curves, dark matter, area metric

## 1. Introduction

The rotation properties of spiral galaxies have puzzeled astronomers for about 100 years now.[1] Without the introduction of dark matter, Newtonian physics is not able to explain the flattened behaviour of the velocity curve for large distances from the centre. Until today, neither have dark matter particles been detected, nor has a modified theory been found which all by itself could explain all phenomena connected to dark matter.

In this work, we will assess whether a modified theory using the constructive gravity algorithm yields flat rotation curves in a universe with area metric matter. We will also look for estimates on the gravitational constants under the assumption that gravity is not governed by general relativity but its area metric refinement instead.

## 2. Newtonian Area Metric Gravity

The constructive gravity programme offers a fundamental connection between the matter content of a universe and the dynamics of its spacetime structure. Indeed using the toolset given by the construction equations,[2] one may take a matter theory and construct the corresponding theory of gravity.

Area metric gravity is constructed – in this fashion – as the gravity theory that underlies a refinement of Maxwellian electrodynamics, namely the general linearized

electrodynamics defied by the Lagrangian

$$\mathcal{L}_{\mathrm{GLED}} = \omega_G G^{\alpha\beta\gamma\delta} F_{\alpha\beta} F_{\gamma\delta}, \tag{1}$$

with the tensor $G^{\alpha\beta\gamma\delta} = G^{([\alpha\beta][\gamma\delta])}$ being antisymmetric in the first and the second index pair and symmetric to an exchange of both pairs. To date, no general solution is known for the construction equations that one needs to set up for this matter theory in order to find the dynamics of the fourth-rank tensor geometry encoded in $G$. However, the equations have been solved for a linear perturbation around the standard metric geometry.[2] Ref. 2 also finds the 3D screen manifold action

$$\begin{aligned} S_{\mathrm{grav,GLED}}(\lambda) = -\int \mathrm{d}^4x \frac{m}{2}\gamma_{\alpha\beta}\dot{\lambda}^\alpha\dot{\lambda}^\beta + mA(\lambda(t)) + m\Omega_{\alpha\beta}(\lambda(t))\dot{\lambda}^\alpha\dot{\lambda}^\beta \\ + \frac{m}{2}A(\lambda(t))\gamma_{\alpha\beta}\dot{\lambda}^\alpha\dot{\lambda}^\beta \end{aligned} \tag{2}$$

for the motion of a point particle with trajectory $\lambda(t)$ and mass $m$ on a weak area metric spacetime, where the fields $A(\lambda)$ and $\Omega(\lambda)$ are found from the construction equations. Starting from this solution, many known phenomena can be reassessed to check for a possible realization of area metric gravity. Many astrophysical objects even do not require a full relativistic form as in eq. 2, but can be evaluated using a small velocity and weak field limit[3]

$$\mathcal{L}_{\mathrm{grav,GLED}} \approx -\frac{m}{2}\gamma_{\alpha\beta}\dot{\lambda}^\alpha\dot{\lambda}^\beta + mA(\lambda(t)) \tag{3}$$

with a point particle potential

$$A(r) = -\frac{G}{|r-r'|}\left(1 + \nu e^{-\mu|r-r'|}\right),$$

that will be referred to as the "Newtonian limit" further on. This Yukawa correction term introduces a gravitational length scale with the constant $\mu$.

## 3. Galaxy Rotation Curves

### 3.1. *Symmetric potentials*

To determine galaxy rotation curves, one needs to find the orbital velocities of test bodies within a galactic potential $\Phi$. For simplicity, the potential is assumed to be cylindrically symmetric around the axis of rotation. For a spiral galaxy, two basic types of models can be distinguished: Core-centered models use a spherical mass distribution with a disk of negligible mass, while disk models only contain a flat disk without a central bulge.

The rotation curves for spherical distributions can be calculated analytically, or at least symbolically, for a wide range of density distributions. As the shell theorem does not hold for the area metric correction, contributions from outside the test

mass orbit arise. We get the general expression

$$\Phi[\rho](r) = \tilde{\Phi}(M|_r) - \frac{4\pi\nu G}{\mu r}\left(e^{-\mu r}\int_0^r \mathrm{d}r'\ r'\rho(r')\sinh(\mu r') + \sinh(\mu r)\int_r^\infty \mathrm{d}r'\ r'\rho(r')e^{-\mu r'}\right) \tag{4}$$

for the sphere's gravitational potential[3] with $\bar{\Phi}$ being the standard Newtonian potential. Potentials of disklike distributions can be assessed by using a multipole expansion. Now the rotation curves may be calculated via the relation

$$v^2 = r\frac{\partial\Phi}{\partial r}. \tag{5}$$

### 3.2. *Models and methods*

In this study three common spherical models were used. While the isothermal model is a simple model for a dark matter halo, the Hernquist and Plummer models are more realistic for visible matter distrbutions. The disklike approach was done with a Kuzmin disk. The following table shows the mass density distributions for the four models:

Table 1. Models used for the galactic fits

| | |
|---|---|
| Isothermal | $\rho_I(r) = \frac{\rho_0 a^2}{r^2}$ |
| Hernquist | $\rho_H(r) = \frac{Ma}{2\pi r(a+r)^3}$ |
| Plummer | $\rho_P(r) = \frac{3Ma^2}{4\pi(a^2+r^2)^{\frac{5}{2}}}$ |
| Kuzmin disk | $\rho_K(z,R) = \delta(z)\frac{aM}{2\pi(a^2+R^2)^{\frac{3}{2}}}$ |

Using the emcee Monte Carlo Markov Chain package,[4] galaxy rotation curves were fit to the velocity distributions of 22 low surface brightness galaxies from Ref. 5.

Three such fits were performed. The first fit, with the weak field standard metric theory, was used for comparison and for generating starting values for the gravitational constants. The second fit, with the area metric corrections, yielded individual best fits for the 22 galaxies. The third fit, using the weighted mean of the best-fit values for the gravitational constants from step two, was done to check whether this mean generates consistent rotation curves.

### 3.3. *Individual galactic fits*

While only the isothermal sphere – and for some galaxies the Kuzmin disk – yielded adequate rotation curves, in the area metric regime all four models provide reasonable fits for the galaxies with a sufficient sample size (21 of 22).

For the fits using the weighted mean gravitational constants $\mu$ and $\nu$, we find that most galaxies have a good fit in this parameter range (see Fig. 1). However, Hernquist and Plummer spheres show a bump in their rotation curves for small radii. In seven datasets this small bump is also present in the data, the other galaxies do not show this behaviour. There are two possible explanations. On the one hand, there might be no data available for such small radii where the galaxy shows this bump, on the other hand, this might be a sign for a misfit in the density model. This could mean that the core behaviour cannot be described with these simple models or that some galaxies are more disklike and others are bulge dominated.

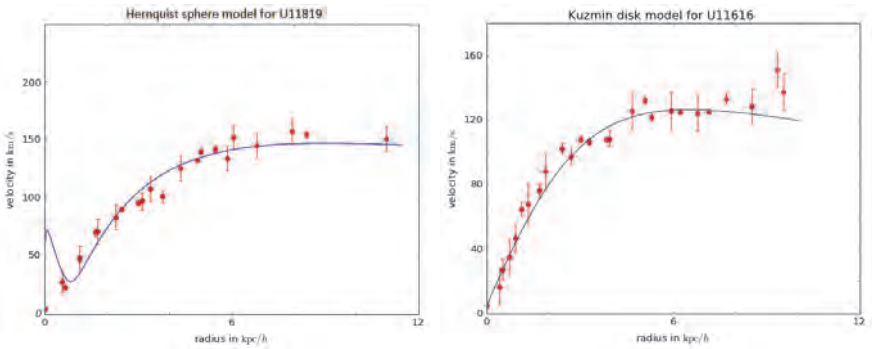

Fig. 1. Sample fits for a Hernquist and a Kuzmin model with area metric correction.

### 3.4. *Implications for area metric gravity*

The four models provide reasonable fits for most of the low surface brightness galaxy data used. The isothermal sphere model reproduces the metric result with vanishing area metric correction. This was expected as the isothermal model already provided a good fit in the first run using Newton's theory.

However, in area metric gravity both density distributions that are close to a typical distribution of visible matter also yield reasonable results for rotation curves over the observable distance range without the need for some particular dark matter distribution. Furthermore, the total galactic mass within area metric gravity is up to 30% lower in comparison to the metric results, reducing the amount of dark matter needed for explaining the observations.

The weighted mean gravitational constants using the spread of the MCMC-samples gives results that differ by about two standard deviations from zero (see Fig. 2), except for the isothermal sphere result. The remaining three models yield comparable constants:

Combining the results we find the guesses $\mu \approx 0.023 \pm 0.010\ kpc^{-1}$ and $\nu \approx 0.011 \pm 0.05$ for area metric gravity. This is not yet a significant difference from zero, but shows a trend that is worth to be investigated further.

Table 2. Area metric gravitational constants for different galaxy model fits

| | $\mu \pm \sigma_\mu$ [h/kpc] | $\nu \pm \sigma_\nu$ |
|---|---|---|
| Isothermal | n/a | $0.000002 \pm 0.00010$ |
| Plummer | $0.025 \pm 0.014$ | $0.017 \pm 0.009$ |
| Hernquist | $0.021 \pm 0.011$ | $0.0021 \pm 0.0028$ |
| Kuzmin | $0.008 \pm 0.002$ | $0.0044 \pm 0.0013$ |

Due to the exponential behaviour of the correction term, effects of area metric gravity are restricted to phenomena near the intrinsic length scale $1/\mu$ of the theory. Compared to the current uncertainty in Newton's constant, the correction does not play a role for phenomena four orders of magnitude off the intrinsic scale. This makes the Newtonian effects of area metric gravity basically unmeasurable in a laboratory. On cosmological scales, however, one would observe a slightly altered gravitational constant by a factor $1 + \nu$, which makes the Newtonian limit of area metric gravity a MOND-like theory.

The theory's scaling behaviour leads to another insight: If the intrinsic length scale is not within the range of galaxy diameters, the galactic dynamics would not be affected and area metric rotation curves would be the same as for standard Newtonian gravity.

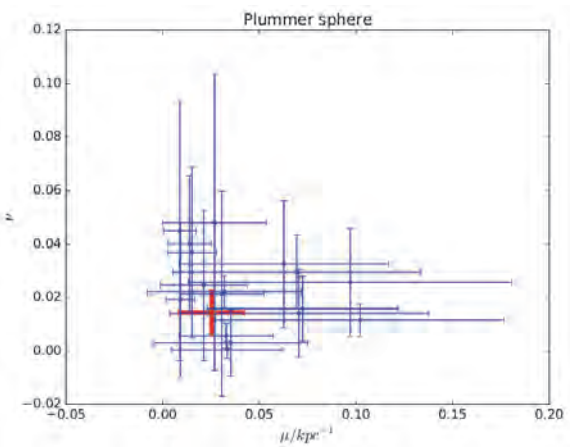

Fig. 2. Weighted mean area metric gravitational constants for a Plummer sphere model.

## 4. Outlook

Several topics connected to the rotation curve issue should be inspected more closely in the future. On the one hand, the density distributions used are mostly based on random motion in a metric universe. These may not be stable anymore for an area

metric geometry which may introduce additional corrections. On the other hand, further phenomena should be used to determine better range estimates for the new gravitational constants.

There are three areas of interest for a determination of the constants. The first is astrophysical phenomena based on linearized area metric gravity like the one presented here, including relativistic phenomena. The second area is effects based on symmetry reduced solutions. In particular, area metric cosmology has gained some attention so far, but has not been resolved yet completely. The third area is the inspection of the matter side. As matter and gravitational dynamics are linked, non-metric quantum effects may be used to restrict the complimentary gravitational constants.[6]

*E-mail: f.p.schuller@utwente.nl*

Constructive gravity allows to calculate the Lagrangian for gravity, provided one previously prescribes the Lagrangian for all matter fields on a spacetime geometry of choice. We explain the physical and mathematical foundation of this result and point out how to answer questions about gravity that previously could not be meaningfully asked.

*Keywords*: canonical gravity; standard model extension; hyperbolic equations; causal structure; generalized geometry; dispersion relation; modified gravity; quantum field theory, hydrogen hyperfine structure, gravitational waves.

## 1. Introduction

Constructive gravity reveals a connection between matter dynamics and gravitational dynamics, which is deeper than previously appreciated. The key result[1] is this: Three physically mild conditions on a given action

$$S_{\text{matter}}[A,G) \tag{1}$$

for a matter field $A$ (on which the action depends locally) on a geometric background described by one or several tensor fields $G$ (on which the action depends only ultralocally), suffice to derive a universal system of linear homogeneous partial differential equations whose coefficient functions depend on the given matter action and whose solutions provide diffeomorphism-invariant actions

$$S_{\text{geometry}}[G] \tag{2}$$

for the geometry that are causally consistent with the initially prescribed matter dynamics and must be be added to the latter in order to provide a closed system of equations for both the matter and the geometry.

The mechanism behind this causally consistent closure of given matter field dynamics is simple. First, the matter dynamics unequivocally determine[2] — no matter how complicated the background geometry on which they are formulated and as long as elementary well-posedness and energy conditions hold — all ways in which the spacetime may be foliated into initial data hypersurfaces for the matter degrees of freedom. The only further step then consists in a straightforward technical exploitation[3] of the requirement[4] that the geometric background be furnished with canonical dynamics that evolve the pertinent *geometric* degrees of freedom between any two of the initial data hypersurfaces for the stipulated *matter* dynamics, thus making these the common initial data hypersurfaces for both the geometry and the matter fields. Without this requirement, no sustained prediction for the total matter-geometry dynamics could possibly be made. With this requirement, one has a condition so strong as to typically determine the action for the geometry

up to only a few constants of integration. After adding the thus obtained action for the geometry to the matter action, the resulting coupled field equations describe how the geometry is influenced by the presence of dynamical matter fields (which amounts to the generation of a gravitational field) and, conversely, how the motion of matter is influenced by the geometry (which amounts to the influence exerted by gravity on matter).

The thus constituted constructive gravity program hence simply takes a matter action as an input and provides a canonically compatible gravitational action as its output. Starting the program with standard model matter[5], one obtains the Einstein-Hilbert action with two undetermined constants in place of the gravitational and the cosmological constant. Starting the program, instead, with modifications of standard model matter, a correspondingly modified action for the underlying geometry can be obtained and provides the gravity theory for all geometric degrees of freedom that is selected by causal consistency. In any case, gravitational field dynamics are revealed to be a mere consistency condition, imposed by the entirety of matter field dynamics one postulates and tailor-made for the geometric background fields employed by the matter field equations. In programmatic brevity, the philosophy underlying constructive gravity is: Matter first, gravity second.

### 1.1. *A previously not solvable problem*

In order to appreciate the far-reaching implications of what is said above, consider the following phenomenologically interesting observational scenario. Assume that future advances in radioastronomy reveal that electromagnetic waves propagating through vacuum regions of space suffer birefringence effects of various strengths, however small, while there is no indication at all that there would be any violation of the linear superposition principle in the observed energy range. This scenario presents one small step for the matter phenomenologist, but one giant leap for the gravitational theorist. It is easy for the matter phenomenologist, since the most general electrodynamics action that generates linear field equations on a tensorial background geometry takes the form[6]

$$S_{\text{matter}}[A, G) = \int d^4x\, \omega_G\, G^{abcd} F_{ab} F_{cd}\,, \tag{3}$$

where $A$ is the familiar electromagnetic gauge potential with the associated field strength $F = dA$, while $G$ is an, at first arbitrary, fourth-rank tensor field and $\omega_G = (\epsilon_{ijkl} G^{ijkl})^{-1}$ is a weight-one scalar density constructed from it. The quadratic appearance of the field strength $F$ and its two-form character render only those components of $G$ relevant that conform to the algebraic symmetry conditions

$$G^{abcd} = G^{cdab} \quad \text{and} \quad G^{abcd} = -G^{bacd}\,, \tag{4}$$

while finiteness of the density factor imposes the open condition $\epsilon_{ijkl} G^{ijkl} \neq 0$. Any observed birefringence effect can now be modelled in one way or another by suitably

adapting the 21 independent components of the tensor field $G$ at each point within the spacetime region of the electromagnetic wave such as to fit the obervational data. Given the described hypothetical observations, this is certainly the correct classical matter model[7]. But in this form, it is yet of little predictive power, since both the location and strength of vacuum birefringence and further effects beyond Maxwellian electrodynamics entirely depend on the values taken by the fourth-rank tensor field $G$. Without a way to predict the values taken by the tensor field $G$, one is thus not able to predict the electromagnetic field either.

The only way to predict the values of the geometric field $G$ (up to equivalence under diffeomorphisms) with the least possible prejudice is to furnish $G$ with dynamics of its own, by extending the action (3) to the total action

$$S[A,G] = S_{\text{matter}}[A,G) + S_{\text{geometry}}[G] \tag{5}$$

such that the stationarity conditions

$$\frac{\delta S_{\text{matter}}}{\delta A_a}[A,G) = 0 \qquad \text{and} \qquad \frac{\delta S_{\text{geometry}}}{\delta G^{abcd}}[G] = -\frac{S_{\text{matter}}}{\delta G^{abcd}}[A,G) \tag{6}$$

recover both the phenomenologically enforced general linear electromagnetic field equations and the gravitational field equations. The central problem to solve in order to make this work, of course, is the identification of all physically consistent choices of the action $S_{\text{geometry}}[G]$ for the geometry. But finding the gravitational actions that can underpin given matter dynamics is the very problem solved by constructive gravity.

### 1.2. *A familiar problem solved a century ago*

It will be enlightening to see how standard general relativity arises, in the philosophy of constructive gravity, from standard model matter. Other than for the previous example, the reader will not need to have mastered the general machinery described in this article in order to follow the steps of the constructive gravity program in some more detail for the present case, because one simply recovers known concepts from general relativity – even if from a slightly different conceptual perspective: all mathematical objects of the general theory reduce here to their familiar form. Simplifying as much as possible for the purpose of clarity, we consider the matter field action

$$S_{\text{matter}}[\varphi, g) = \int d^4x \sqrt{\det g}\, \left(g^{ab}\partial_a\varphi\partial_b\varphi - m^2\varphi^2\right) \tag{7}$$

for a scalar field $\varphi$ and a second rank tensor field $g$, about which we do not need to assume anything a priori beyond the symmetry and non-degeneracy conditions

$$g^{ab} = g^{ba} \qquad \text{and} \qquad \det g \neq 0\,. \tag{8}$$

In order to find the elementary well-posedness and energy conditions on the matter theory that need to be satisfied for the constructive gravity program to apply, one first calculates the principal polynomial of the postulated matter field equations in

each spacetime cotangent space (see section 2 for an outline of the general theory), which information is equivalent to the one held in an even-rank totally symmetric contravariant tensor field $P$. For the dynamics defined by (7), this principal tensor field happens to be of second rank and turns out to be given by

$$P^{ab} = g^{ab} \,. \tag{9}$$

From the point of view of the general theory, it is a pure coincidence that this principal tensor field $P$ has the same rank as the fundamental geometry $g$ and additionally that it is in fact identical to it. (That this truly is a coincidence is impressively illustrated by the fact that for the previously considered general linear electrodynamics, the principal tensor field $P^{abcd} = \omega_G^2 \epsilon_{mnpq} \epsilon_{rstu} G^{mnr(a} G^{b|ps|c} G^{d)qtu}$ is found to be cubic in the fundamental geometry $G$ underlying that matter theory and as a totally symmetric tensor certainly does not share its index symmetries, although it coincidentally has the same rank.) Indeed, some occurrences of the inverse metric in general relativity are in fact occurrences of the principal tensor field, while others are occurrences of the fundamental geometry. Failure to recognize this degeneracy as coincidental goes with impunity only in general relativity proper, but in fact lies at the heart of causality problems of various generalized theories of gravity and matter[8]. The general well-posedness and energy conditions[1,2] that a matter theory must satisfy in order to be a viable starting point for the constructive gravity program boil down, in the present special example, to the condition that the principal polynomial $P$ be of Lorentzian signature. That also the *fundamental geometry* $g$ must have Lorentzian signature is only due to the very particular coincidence (9).

It is obvious that for the previous subsection's general linear electrodynamics with its pertinent fourth-rank principal tensor $P$, a more general algebraic classification than the signature classification of symmetric bilinear forms needs to kick in and that the implications for the underlying fundamental geometry $G$ are even more intricate to extract, but ultimately obtainable[9]. From a practical point of view, here and in general, one may perfectly ignore the rather extensive theoretical machinery running in the background and write down the the so-called gravitational closure equations (in either functional differential or partial differential form) — which determine the desired gravitational Lagrangian within the constructive gravity program and are informed by the assumed matter theory — by ultimately employing only the pertinent fundamental geometry and the calculated principal polynomial in the coefficient functions of the closure equations. Their solution[1,3] for the present case of Klein-Gordon dynamics on a Lorentzian background yields – without any a priori knowledge of metric geometry whatsoever – the two-parameter family

$$S^{\kappa,\Lambda}_{\text{geometry}}[g] = \kappa \int d^4x \sqrt{\det g}\,(R - 2\Lambda) \tag{10}$$

of gravitational actions, which one recognizes as the Einstein-Hilbert action with both the gravitational and cosmological constant left to be determined by

experiment. The Ricci scalar, or rather its definition in terms of the metric, arises automatically in the solution of the closure equations, which are just informed about the matter dynamics though the principal polynomial of the latter and indeed the underlying fundamental geometry. In the parlance of the constructive gravity program, Einstein-Hilbert gravity arises as the gravitational closure of Klein-Gordon theory. The same result is obtained by starting from Maxwell theory or indeed the entire standard model[5].

## 2. Principal polynomials of matter field equations

We now turn to an exposition of the general theory, for which the previously mentioned examples present just special cases.

Starting point of the gravitational closure mechanism is a matter action of the form

$$S_{\text{matter}}[A, G] = \int_M d^4x\, \mathcal{L}(A(x), \partial A(x), \ldots, \partial^N A(x), G(x))\,, \tag{11}$$

where $\mathcal{L}$ is a scalar density, $A$ is a smooth $GL(4,\mathbb{R})$-irreducible tensor field (or, more generally, a finite collection of various such) representing the matter whose dynamics is determined by $S_{\text{matter}}$ and $G$ is a smooth tensor field (or, again, a finite collection of various such), to which we will refer as the geometry on the smooth four-dimensional manifold $M$. Note that we assume that our matter actions depend locally on the matter fields and ultralocally on the geometry.

Variation with respect to the matter field $A$ yields the tensor-density equations of motion

$$0 = \frac{\delta S_{\text{matter}}}{\delta A^{\mathcal{M}}(x)} \equiv \sum_{n=0}^{N} Q^{a_1\ldots a_n}_{\mathcal{M}\mathcal{N}}[A(x), G(x)]\partial_{a_1}\cdots\partial_{a_n} A^{\mathcal{N}}(x)\,, \tag{12}$$

where $A^{\mathcal{M}}(x)$ indicates components with respect to the $GL(4,\mathbb{R})$ representation space in which $A(x)$ takes its values at any point $x \in M$ and the $Q$ are $N+1$ coefficient functionals with local dependence of $A$ and $G$. For field equations that are linear in their highest order derivative term, the corresponding coefficient functions

$$Q^{a_1\ldots a_N}_{\mathcal{M}\mathcal{N}}(G(x)) \tag{13}$$

do not depend on the field $A$ at all, and only ultralocally on the geometry $G$. In order to avoid inessential technical complications, we restrict attention here to such matter models.

We first discuss the case in which the field equations (12) do not feature any hidden integrability conditions, which could otherwise alter the highest derivative coefficient functions. In this straightforward case, the causal structure of the matter field dynamics is encoded entirely in the functions (13). In particular, well-posedness for the matter field dynamics described by $S_{\text{matter}}$ on a fixed geometry $(M, G)$ — in other words, the question of whether one can find a suitable foliation of spacetime into hypersurfaces such that prescription of initial field data on one

such hypersurface suffices for the dynamics to predict the data on another, neighbouring, such hypersurface such that the resulting spacetime matter field solves the field equations — requires that the $a$-solution space of the infinite frequency limit Wentzel-Kramers-Brillouin condition

$$Q^{a_1\dots a_N}_{\mathcal{M}\mathcal{N}}(G(x))k_{a_1}\dots k_{a_N}a^{\mathcal{N}} = 0 \tag{14}$$

is at least $(S+1)$-dimensional, where $S$ is the dimension of the gauge orbits featured by the matter theory[1]. It can be shown[10,11] that this condition can always be written as a polynomial condition

$$\widetilde{P}^{i_1\dots i_{\deg \tilde{P}}}(x)k_{i_1}\cdots k_{i_{\deg \tilde{P}}} = 0 \qquad \text{for } k \in T^*_xM\,, \tag{15}$$

where $\widetilde{P}^{i_1\dots i_{\deg P}}(x)$ are the coefficient functions for some totally symmetric tensor density $P$ of weight one. Since this is a homogeneous condition we may and will regularly de-densitize this condition by use of some meaningful scalar density that can be constructed ultralocally in terms of the geometry $G$ and then denote the resulting totally symmetric tensor field by $P$. Since, in the language of the theory of partial differential equations, $P(x)$ is the principal polynomial (in the cotangent fibre variable $k$) of the field equations (12), we refer to $P$ as the principal tensor field.

In the presence of hidden integrability conditions – which are only revealed by systematically repeated differentiation and elimination of the equations that were originally obtained by variation – the highest order coefficient functions may be altered once the integrability conditions have been made explicit. The simplest example illustrating this is the system

$$A_x + A_{yy} = 0 \qquad \text{and} \qquad A_y + A_{yx} = 0\,, \tag{16}$$

for which only differentiation and elimination reveals the contained implication $A_{xx} - A_{yy} = 0$, which crucially alters the highest order coefficient functions of the equations of motion (even making them into a non-square matrix) and hence the calculation and final form of the principal tensor.

Extending a given system of partial differential equation, such that all hidden integrability conditions are made explicit, is achieved by the Cartan-Kuranishi algorithm[12]. From the highest order coefficient functions of a so obtained system, which is then termed involutive, one may then calculate the principal tensor, by a slight generalization of the prescription given before for systems without hidden integrability conditions. The algorithm for taking equations of motion $\Phi_B[A] = 0$ for fields $u^{\mathcal{M}}$ into involutive form revolves around repeated calculation of the so-called geometric symbols

$$(M_q)_{B\mathcal{N}}{}^{\nu} := \frac{\partial \Phi_B}{\partial A^{\mathcal{N}}{}_{,\nu}}[A] \qquad \text{for } q = \nu_1 + \cdots + \nu_{\dim M}\,, \tag{17}$$

where the derivative $A^{\mathcal{N}}{}_{,\nu}$ with respect to the multi-index $\nu = (\nu_1, \dots, \nu_{\dim M})$ denotes the $q$-th partial derivative $\partial_1^{\nu_1}\partial_2^{\nu_2}\dots\partial_{\dim M}^{\nu_{\dim M}}A^{\mathcal{N}}$ of the field component $A^{\mathcal{N}}$,

for $q$ being the currently highest derivative order of the intermediate system of equations generated in each step of the now easily performed Cartan-Kuranishi algorithm:

(1) Having calculated the components of the the geometric symbol for the current set of equations (starting with the initially given set of equations if no other set has been generated yet by the algorithm), they are arranged into a matrix $M_q$ whose rows are labeled by the index $B$ and whose columns are labelled by the combination of the indices $\mathcal{N}$ and $\nu$. The only rule for how this labelling is done is that the resulting column indices (non-strictly) decrease in the class $1 \leq c(\nu) \leq \dim M$ of the multiindex $\nu$, which is defined as the smallest $i$ for which $\nu_i$ is non-zero. The actual calculational step then consists in taking the thus constructed matrix to row echelon form by judicious linear combinations of row vectors only. For any $i = 1, \ldots, M$ one then reads off the set of coefficients

$$\beta_q^{(i)} := \text{number of pivot elements in all columns of class } i\,. \tag{18}$$

(2) Prolongate the current system, i.e., combine it with all $\dim M$ possible first order partial derivatives of each of its current equations and calculate the matrix $M_{q+1}$ for this prolongated system. This allows to determine whether the system, as it was before this last prolongation, is pre-involutive. This is the case if the beta coefficients satisfy the pre-involutivity condition

$$\sum_{i=1}^{\dim M} i\beta_q^{(i)} = \operatorname{rank}(M_{q+1})\,. \tag{19}$$

If this is not the case, consider the just calculated prolongated system the new current system and return to the first step with the thus updated system of equations. It is guaranteed that the above equality will be satisfied after a finite number of iterations on steps 1 and 2, in which case one then proceeds to step 3.

(3) Consider the prolongated system that has just been calculated to confirm that the pre-involutivity condition of step 2 has been satisfied, but still consider the unprolongated system as the current system. If no integrability condition (an equation of equal or lower derivative order than the current system that is linearly independent of the latter) can be derived from the prolongated systems, the current system is called involutive and the algorithm terminates. If, however, integrability conditions are found, they are appended to the current system and the such extended system is handed as the new current system to step 1 of the algorithm. It is guaranteed that after a finite number of iterations of steps 1, 2 and 3, the algorithm terminates.

Application of the algorithm to the system (16) yields beta-coefficients $\beta_2^{(1)} = 2$ and $\beta_2^{(2)} = 1$ and rank 3 for the prolongated system, which identifies the initially given system as already pre-involutive in step 2. Since the prolongated system, however,

turns up the integrability conditon $A_{xx} - A_{yy} = 0$, the system is not involutive yet. Adding the integrability condition to the original system and repeating steps 1 and 2 one obtains the new beta coefficients ${\beta'}_2^{(1)} = 2$ and ${\beta'}_2^{(2)} = 1$ and rank 4 for the prolonged system. Thus the original system extended by the found integrability condition is found pre-involutive in step 2 and one indeed finds no further integrability condition in step 3. Thus

$$A_x + A_{yy} = 0 \qquad \text{and} \qquad A_y + A_{yx} = 0 \qquad \textit{and} \qquad A_{xx} - A_{yy} = 0 \tag{20}$$

is the involutive form of the original system (16) as obtained by the Cartan-Kuranishi algorithm.

For equations of motion $\Phi_B[A] = 0$ that follow from a matter action by variation, but are not already involutive, a slight adaptation of the calculation of the principal tensor is required, since the principal symbol

$$T_{\overline{B}\mathcal{N}}(k) := \sum_{\nu_1+\cdots+\nu_{\dim M}=\overline{q}} \frac{\partial \Phi_{\overline{B}}}{\partial A^{\mathcal{N}}_{,\nu}} (k_1)^{\nu_1} \cdots (k_{\dim M})^{\nu_{\dim M}} \tag{21}$$

of their involutive form $\Phi_{\overline{B}}[A] = 0$ — where the index $\overline{B}$ now not only covers the range of the original $B$ but also all the additional equations that had to be added in order to achieve involutive form and $\overline{q}$ is the highest derivative order encountered in the involutive system — generically constitutes a non-square matrix $T(k)$. In any case, the principal tensor density can be shown the be determined in this case by taking the determinant of the Gramian matrix of $T(k)$,

$$\widetilde{P}^{a_1 \ldots a_{\deg \tilde{P}}} k_{a_1} \cdots k_{a_{\deg \tilde{P}}} := \det(T^t(k) T(k)) \,. \tag{22}$$

Note that the Gramian matrix is a square matrix whose rows and columns are labeled by some $GL(4, \mathbb{R})$ representation, so that its determinant transforms as a scalar density of the appropriate weight.

For technical reasons, and since it does not affect the information encoded in the principal scalar density $\widetilde{P}(k)$, whether obtained from (15) or more generally from (22), we will not only routinely de-densitize it by multiplication with a suitable density factor, but also reduce its degree as much as possible by dropping repeated factors, so that

$$\widetilde{P}(k) = \omega_G^m P_1^{n_1}(k) P_2^{n_2}(k) \cdots P_F^{n_F}(k) \,, \tag{23}$$

where $m$ is an integer and $n_1, \ldots, n_F$ are positive integers while $P_1(k), \ldots, P_F(k)$ are irreducible polynomials in $k$ that transform as scalar fields for any substitution of a covector field $k$, gives rise to the reduced principal tensor $P$ uniquely determined by

$$P^{a_1 \ldots a_{\deg P}} k_{a_1} \ldots k_{a_{\deg P}} := P_1(k) P_2(k) \cdots P_F(k) \,. \tag{24}$$

Only this reduced form of the principal tensor $P$ will play a role in constructiuve gravity and will simply be called the principal tensor of the matter field equations in the following.

## 3. Kinematics induced by matter field equations

Three technical conditions on any given matter field equations must be satisfied in order to derive a complete kinematical interpretation for the underlying spacetime geometry. They all concern the principal tensor $P$ of the matter field equations obtained from an action $S_{\text{matter}}[A, G)$, and thus implicitly impose conditions on the geometric tensor $G$ in terms of which $P$ is expressed. Physically, these conditions correspond to classically hardly negotiable necessary requirements for the field equations and their geometric optical limit, namely that (a) there exist initial data surfaces for the field equations, (b) the spacetime structure can be interpreted in a temporal-spatial way and (c) that the spacetime structure allows for time-orientability and corresponding energy-orientability. Technically, these physical conditions amount to

(a) The homogeneous polynomial $P_x : T^*_x M \to \mathbb{R}$ defined in terms of the principal tensor by $k \mapsto P^{a_1 \dots a_{\deg P}}(x) k_{a_1} \cdots k_{a_{\deg P}}$ at each point $x$ of the manifold $M$ must be hyperbolic. This means, by definition, that there exists some $h \in T^*_x M$ with $P_x(h) \neq 0$ such that for all $q \in T^*_x M$ the equation

$$P_x(q + \lambda h) = 0 \tag{25}$$

possesses $\deg P$ real solutions $\lambda_1, \dots, \lambda_{\deg P}$, counting algebraic rather than geometric multiplicity. One can show that if $h$ satisfies the above condition, then there is an entire connected set of such vectors which constitute an open and convex cone $C_x(h)$, the so-called hyperbolicity cone of $P_x$ that contains $h$. Note that the hyperbolicity cones are uniquely determined by the principal tensor and that the latter has been uniquely constructed in terms of the spacetime geometry $G$, in a way that is crucially informed by the particular equations of motion of the matter field $A$, but is functionally independent of the latter.
Clearly, one can choose any other covector $h'$ in this hyperbolicity cone as an alternative representative, since $C_x(h) = C_x(h')$. Moreover, since $-h$ satisfies condition (25) if and only if $h$ does, but since $P(h) \neq 0$, $-h$ does not lie in the same connected component as $h$ and thus $C_x(h) \cap C_x(-h) = \emptyset$; thus there is always an even number of hyperbolicity cones at each point of spacetime. A time-orientation of the spacetime is chosen by prescription of some smooth and everywhere hyperbolic covector field $n$, which singles out one particular cone $C_x := C_x(n_x)$ at spacetime point $x$. We call these cones the local observer cones, since they contain all possible conormals (which set one may geometrically think of as all possible tangent hyperplanes) to initial data hypersurfaces through the respective spacetime point to which they are attached. This, indeed, is the relation to the question of well-posedness of the field equations.
We impose a positive sign convention, which will come in handy later on, namely that $P_x(C_x) > 0$ for all $x \in M$. If this does not hold in the first place, then we necessarily have $P_x(C_x) < 0$ for all $x \in M$, due to the continuity of the time-orienting hyperbolic covector field $n_x$ and the continuity of the principal

tensor field $P$, so that replacing the principal tensor $P$ by $-P$, which has no effect on the hyperbolicity condition, arranges for the desired sign.

(b) The dual polynomial $P^\#_x : T_xM \to \mathbb{R}$, which is uniquely determined by a given hyperbolic polynomial $P_x : T^*_xM \to \mathbb{R}$ up to a non-zero factor (which turns out to cancel for any use the dual polynomial is put to) must be hyperbolic. The dual polynomial $P^\#_x$ of a hyperbolic polynomial $P_x = (P_1)_x \cdots (P_F)_x$, which is decomposed into mutually different irreducible factor polynomials $P_1, \ldots, P_F$, is defined as the product

$$P^\#_x := (P_1)^\#_x \cdots (P_F)^\#_x \,, \tag{26}$$

of the duals of these irreducible factors. Thus it suffices to define the dual polynomial $Q^\#$ associated with an irreducible polynomial $Q$, namely as the likewise irreducible polynomial for which

$$Q^\#_x(DQ_x(k)) = 0 \quad \text{holds for all } k \in T^*_xM \text{ with } Q_x(k) = 0 \text{ and } DQ_x(k) \neq 0 \,, \tag{27}$$

where $DQ_x$ denotes the derivative of $Q_x$ with respect to the cotangent space fibre at $x$. The very existence of the dual polynomial $P^\#_x$ hinges on the hyperbolicity of $P_x$, which is equivalent to the hyperbolicity of each irreducible factor polynomial. The immediate physical relevance of the dual polynomial is revealed by the real projective relation

$$[DP^\#_x([DP_x([k])])] = [k] \tag{28}$$

for all $k \in T^*_xM$ with $P_x(k) = 0$ and $DP_x(k) \neq 0$ and $DDP_x(k) \neq 0$, where $[\cdot]$ denotes projective equivalence, since it reveals that any projective $P_x$-null covector $[k]$ (safe such on an exceptional subset of measure zero) is bijectively mapped to a projective vector $[DP_x([k])]$, with the inverse map given by $[DP^\#_x]$. Due to the generic non-linearity of these maps, this is highly non-trivial. In physics language, however, it establishes a easily understood fact: for each $P^\#$-null ray direction, which emerges in the geometric-optical limit of the underlying hyperbolic matter field theory, there is a unique $P_x$-null wave surface and vice versa. We will refer to $P_x$-null covectors also as massless momenta.

(c) The positive energy cone $E^+_x$ at each point $x$ of the spacetime $M$ is defined for any hyperbolic principal polynomial $P_x$ with hyperbolic dual polynomial $P^\#_x$, as required by conditions (a) and (b), as the closed convex cone

$$E^+_x := \{e \in T^*_xM \,|\, e(X) > 0 \text{ for all } X \in \ell_x^{-1}(C_x)\} \,. \tag{29}$$

The physical rationale for this definition is clear: a massless or massive momentum $p$ can only be said to be of positive energy if all observers (represented here by all possible oberserver worldline tangent vectors $X$) agree on the sign of the respectively seen energy $e(X)$. Any massive momentum $p$, as defined under (b) above, is automatically of positive energy, by construction of $C^\#_x$.

The final condition on the principal polynomial, and thus the underlying spacetime geometry $G$, is that any massless momentum $p$ at some point $x \in M$ must

lie either in the positive energy cone $E_x^+$ or the negative energy cone $E_x^-$. This energy distinguishing condition is physically required, since it is necesary to have all observer agree on whether a decay that involves a massless particle is kinematically possibly or not.
Together with the previously adotped hyperbolicity condition on the dual polynomial $P_x^\#$, the energy distinguishing conditions allows to unquely identify the hyperbolicity cone $C_x^\# \subset T_xM$ of $P_x^\#$ for which the observer cone $C_x \subseteq \ell_x(C_x^\#)$, where $\ell_x$ denotes the invertible Legendre map

$$\ell_x : C_x^\# \to \ell_x(C_x^\#) \subset T_x^*M\,, \qquad X \mapsto -\frac{1}{\deg P_x^\#}\frac{DP_x^\#(X)}{P_x^\#(X)}\,. \tag{30}$$

The corresponding restriction of the inverse $\ell_x^{-1}$ of this map to the observer cone $C_x$ is physically easily understood as the bijective map between the massive momenta $p$ of mass $m$ at the point $x \in M$, which are characterized by $p \in C_x$ and $P_x(p) = m^{\deg P}$ for some positive mass $m$, and the tangent vectors $\ell_x^{-1}(p)$ of their respective worldlines.

Matter dynamics satifying the above three conditions impose the kinematical interpretation of the spacetime geometry $(M, G)$, with the relevant information coming from the matter dynamics being encoded in the principal polynomial. The three kinematical constructions of immediate practical importance are

(1) A local observer is given by a curve $e : (a, b) \longrightarrow LM$ in the spacetime frame bundle $\pi : LM \xrightarrow{\pi} M$ such that *(i)* the first frame vector $e_0(\lambda)$ lies in the Legendre dual $\ell^{-1}_{(\pi\circ e)(\lambda)}(C_{(\pi\circ e)(\lambda))})$ of the cotangent space observer cone for all $\lambda \in (a, b)$ and *(ii)* the other frame vectors $e_1(\lambda), e_2(\lambda), e_3(\lambda)$ are Legendre-orthogonal to $e_0(\lambda)$, which is to say that they lie in the kernel of $\ell_{(\pi\circ e)(\lambda)}(e_0(\lambda))$ for every $\lambda \in (a, b)$. Physically, this means that for every point of every initial data hypersurface, one can find a local observer whose worldline $\pi \circ e$ pierces the hypersurface at this point and whose worldline tangent vector $e_0$ is Legendre orthogonal to the hypersurface's tangent directions. These latter tangent directions are the purely spatial directions seen by this particular observer.
(2) A first order action for the worldline $x : \mathbb{R} \longrightarrow M$ of a massless point particle is immediately implied by the dispersion relation $P(k) = 0$ that must hold for the momentum of such a particle, namely

$$S_{\text{massless}}[x, k, \mu] = \int d\lambda\,[k_a(\lambda)\dot{x}^a(\lambda) - \mu(\lambda)P_{x(\lambda)}(k(\lambda))]\,, \tag{31}$$

where $\mu$ is a Lagrange multiplier. But solving the corresponding equations of motion requires solving for $k$. By virtue of the inverse Gauss map $[DP^\#]$ and the homogeneity of $P^\#$, one can indeed solve for $k = \sigma DP^\#$ in terms of another Lagrange multiplier $\sigma$ (which absorbs the projective scaling ambiguity). Encoding this elimination directly into the action one finds the equivalent second

oder action

$$S_{\text{massless}}[x,\sigma] = \int d\lambda\, \sigma(\lambda) P^{\#}_{x(\lambda)}(\dot{x}(\lambda))\,, \tag{32}$$

which can be straighforwardly varied without knowledge of the generically non-linear kinematical machinery running in the background.

(3) For massive point particles, the same philosophy applies, but entirely different mathematics are at work. Instead of projective algebraic geometry and projective Gauss maps, as for the massless particle, it is now convex analysis and the Legendre map and its inverse that play the crucial role. Also in this case, an obvious first order action

$$S_{\text{massive}}[x,k,\mu] = \int d\lambda\, \left[k_a(\lambda)\dot{x}^a(\lambda) - \mu(\lambda)(\ln P_{x(\lambda)})\left(\frac{k(\lambda)}{m}\right)\right] \tag{33}$$

leads to the problem of inverting a non-linear velocity-momentum relation, which is now achieved by virtue of the Legendre map $k = m\ell_x(\dot{x}/(\lambda \deg P^{\#}))$, which can be used to arrive at the equivalent second order action

$$S_{\text{massive}}[x] = \int d\lambda\, P(\ell_{x(\lambda)}(\dot{x}(\lambda)))^{-1/(\deg P^{\#})}\,. \tag{34}$$

It is instructive to note how the kinematics of standard general relativity follow from the above general theory, starting from even the simplest possible field dynamics one wishes to have available on a Lorentzian metric manifold of signature $(+---)$,

$$S_{\text{KG matter}}[\phi] = \int d^4x \sqrt{-\det g(x)}\left(g^{ab}(x)\partial_a\phi(x)\partial_b\phi(x) - m^2\phi^2(x)\right) \tag{35}$$

whose equations of motion yield a second rank principal tensor field with components $P^{ab} = g^{ab}$, so that hyperbolicity of $P$ is equivalent to the supposed Lorentzian signature of the metric. The hyperbolicity cones of $P_x$ at each point $x$ are two disjoint open convex cones of covectors $k$ for which $g^{ab}_x > 0$ and a time-orientation identifies one of them as the observer cone $C_x$. The positive sign convention $P_x(C_x) > 0$ is immediately satisfied because of the mainly minus signature chosen for the metric. The dual polynomial is $P^{\#}_{ab} = g_{ab}$ and the projective Gauss maps $[D^a P(k)] = [g^{ab}k_b]$ and $[D^P_a \#(X)] = [g_{ab}X^b]$ simply raise and lower the index and are linear in this simple case. The positive energy cone is the closure $\overline{C_x}$ of the observer cone, and thus indeed captures all massive momenta contained in $C_x$ and all massless momenta on the boundary $\partial C_x$ that is not part of the open cone $C_x$ and none of the momenta in $-\overline{C_x}$ are captured. The Legendre map and its inverse evaluate to $(\ell_x(X))_a = -g_{ab}X^b/g_{mn}X^mX^n$ and $(\ell^{-1}_x(k))^a = -g^{ab}k_b/g^{mn}k_mk_n$, yielding precisely the velocity-momentum relation for massive particles and reveal the generically required Legendre orthogonality of purely spatial observer frame vectors to the temporal frame vector as simply their Lorentzian metric orthogonality in this simple case. The general action for massless and massive particles reduces to the known actions in general relativity,

$$S_{\text{massless}}[x,\sigma] = \int d\lambda\, \sigma(\lambda) g_{ab}(x(\lambda))\dot{x}^a(\lambda)\dot{x}^b(\lambda)$$

and

$$S_{\text{massive}}[x] = \int d\lambda \sqrt{g_{ab} x^a(\lambda) \dot{x}^b(\lambda)}\,.$$

The general theory presented before generalizes these cornerstones of general relativity to generalized tensorial spacetimes, in a way that is informed by the specific matter dynamics one stipulates on the given spacetime. From this point of view — which is indeed the view taken by Einstein when he distilled the kinematical lessons conveyed by Maxwell dynamics into the spacetime structure and its interpretation — the kinematical interpretation of a spacetime geometry $(M, G)$ cannot be extracted from, or be assigned to, the geometry per se. Indeed, had we not chosen Klein-Gordon theory (or any other standard model field) as the matter field theory on our Lorentzian manifold, but instead, say, a Proca theory with quartic self-interaction, we would have obtained a vastly different kinematical interpretation of the very same Lorentzian manifold. In essence, the kinematics impressed on a geometry follows only from the triple $(M, G, S_{\text{matter}}[A, G])$. This is an insight that was so far essentially ignored in the overwhelming majority of attempts to construct gravity theories beyond general relativity.

## 4. Gravitational closure

Consider a foliation of the spacetime $M$ into initial data surfaces, described by a one-real-parameter family of smooth embedding maps $X_t : \Sigma \longrightarrow M$, where $\Sigma$ is a smooth three-dimensional manifold such that the image $X_t(\Sigma)$ is an initial data surface for the matter theory. We now define projection frames by choosing coordinate maps $y^\alpha$, for $\alpha = 1, \ldots, 3$ on $\Sigma$, whence we obtain a spacetime tangent basis

$$e_0(t,\sigma) = \ell^{-1}_{X_t(\sigma)}(n_t(\sigma)) \qquad \text{and} \qquad e_\alpha(t,\sigma) = X_{t*}(\left(\frac{\partial}{\partial y^\alpha}\right)_\sigma) \tag{36}$$

along each embedded hypersurface $X_t(\Sigma)$, where each $n(t,\sigma)$ is a spacetime covector field normal to the hypersurface and normalized with respect to $P^\#$,

$$n(t,\sigma)(e_\alpha(t,\sigma)) = 0 \qquad \text{and} \qquad P^\#_{X_t(\sigma)}(\ell^{-1}_{X_t(\sigma)}(n(t,\sigma)) = 1\,. \tag{37}$$

Employing this frame $e_a(t,\sigma)$ and the unique dual frame $\epsilon(t,\sigma)$, we obtain an obvious projection of the spacetime geometry $G$ to several one-real-parameter families of induced tensor fields on $\Sigma$. For a geometry dexcribed by a $(1,3)$-tensor field, for instance, we obtain eight one-real-parameter families of tensor fields on $\Sigma$ with valence $(0,0)$, $(0,1)$, $(0,1)$, $(0,2)$, $(1,0)$, $(1,1)$, $(1,1)$ and $(1,2)$, namely

$$\mathbf{g}_t^{\ {}^p{}_{qr}}(\sigma) = G_{X_t(\sigma)}(\epsilon^p(t,\sigma), e_q(t,\sigma), e_r(t,\sigma)) \tag{38}$$

for ${}^p{}_{qr} \in \{{}^0{}_{00}, {}^0{}_{0\gamma}, {}^0{}_{\beta 0}, {}^0{}_{\beta\gamma}, {}^\alpha{}_{00}, {}^\alpha{}_{0\gamma}, {}^\alpha{}_{\beta 0}, {}^\alpha{}_{\beta\gamma}\}$. Analogously for geometric tensor fields of different valence or even several such tensor fields of various valences. It proves useful to notationally collect the occurring index combinations in one caligraphy index $\mathcal{A}$, such that we can write $\mathbf{g}_t^{\mathcal{A}}(\sigma)$. Analogously, the dual $P^\#$ of the

principal tensor field yields $\deg P^{\#}+1$ one-parameter families of totally symmetric covariant tensor fields $\mathbf{p}_{t\,\alpha_1\ldots\alpha_n}(\sigma)$ for $n=0,1,\ldots,\deg P^{\#}$. An important point is that our projection frames are constructed such that the first two projections always take the values

$$\mathbf{p}_t(\sigma)=1 \qquad \text{and} \qquad \mathbf{p}_t{}^{\alpha}(\sigma)=0\,. \tag{39}$$

But since the dual of the principal polynomial is given ultralocally in terms of the spacetime geometry, one can write these two induced tensor fields, in particular, as functions of the induced geometric fields,

$$\mathbf{p}_t(\sigma)=p(\mathbf{g}_t^{\mathcal{A}}(\sigma)) \qquad \text{and} \qquad \mathbf{p}_t{}^{\alpha}(\sigma)=p^{\alpha}(\mathbf{g}_t^{\mathcal{A}}(\sigma))\,. \tag{40}$$

Thus the properties (39) impose a (generically non-linear) algebraic relation between the projected fields $\mathbf{g}_t^{\mathcal{A}}$. While these are automatically satisfied once the definition of the $\mathbf{g}_t^{\mathcal{A}}$ are employed, they become non-trivial if one turns to the canonical view of dynamics, which no longer considers the spacetime geometry $G$ as the fundamental variables of the theory and the projected fields $\mathbf{g}_t^{\mathcal{A}}$ as derived quantities, but precisely the other way around. This change in perspective is reflected by introducing tensor fields $g_t^{\mathcal{A}}$ on $\Sigma$ whose tensorial structure mimics that of the projections $\mathbf{g}_t^{\mathcal{A}}$, including the algebraic index symmetries the projections once inherited from the spacetime geometry, but are functionally no longer related to the spacetime geometry. But then the generically non-linear conditions (39) must be imposed explicitly as

$$p(g_t^{\mathcal{A}}(\sigma))=1 \qquad \text{and} \qquad p^{\alpha}(g_t^{\mathcal{A}}(\sigma))=0\,, \tag{41}$$

since they no longer follow automatically. But instead of dealing with such non-linear constraints, we introduce generalized configuration fields $\varphi^1,\ldots,\varphi^F$ on $\Sigma$ and parametrization maps $\widehat{g}^{\mathcal{A}}(\phi^1,\ldots,\phi^F)$ such that the tensor fields

$$g_t^{\mathcal{A}}=\widehat{g}^{\mathcal{A}}(\phi_t^1,\ldots,\phi_t^F) \tag{42}$$

generated from from one-real-parameter families of these configuratiomn fields satisfy the linear symmetry conditions and generically non-linear frame conditions (39) while the configuration variables diffeomorphically parametrize the remaining degrees of freedom. The latter is ensured by requiring also the existence of inverse maps $\widehat{\varphi}^A$ with for $A=1,\ldots,F$, such that

$$\widehat{g}^{\mathcal{A}}(\widehat{\varphi}^A(g))=g^{\mathcal{A}} \qquad \text{and} \qquad \widehat{\varphi}^A(\widehat{g}^{\mathcal{A}}(\varphi)=\varphi^A\,, \tag{43}$$

from which the important relation

$$\frac{\partial\widehat{\varphi}^A}{\partial g^{\mathcal{A}}}(\widehat{g}(\varphi))\frac{\partial\widehat{g}^{\mathcal{A}}}{\partial\varphi^B}(\varphi)=\delta^A_B \tag{44}$$

follows.

With the above preparations made, we can now calculate the two coefficient functions $F^A{}_{\mu}{}^{\gamma}(\varphi)$ and $M^{A\gamma}(\varphi)$ of the countable set of linear homogeneous partial

differential equations that must be solved in order to obtain the gravitational actions that are causally consistent with the given matter field dynamics. The first of these coefficients can be read off the right hand side of

$$(\mathcal{L}_{\vec{N}}\widehat{g})^{\mathcal{A}}(\varphi)\frac{\partial\widehat{\varphi}^{A}}{\partial g^{\mathcal{A}}}(\widehat{g}(\varphi)) =: N^{\mu}\partial_{\mu}\varphi^{A} + \partial_{\gamma}N^{\mu}F^{A}{}_{\mu}{}^{\gamma}(\varphi)\,, \tag{45}$$

where $\vec{N}$ is some vector field on $\Sigma$. The second one is calculated directly from

$$M^{A\gamma}(\varphi) = \frac{\partial\mathbf{g}^{\mathcal{A}}}{\partial\partial_{\gamma}X^{a}}e_{0}^{a}\frac{\partial\widehat{\varphi}^{A}}{\partial g^{\mathcal{A}}}(\widehat{g}(\varphi))\,, \tag{46}$$

which is easily calculated by expressing $\mathbf{g}^{\mathcal{A}}$ in terms of the spacetime geometry $G$ (for which $\partial G/\partial\partial_{\gamma}X^{a}$ vanishes) and using the relations

$$\frac{\partial e_{0}^{m}}{\partial\partial_{\gamma}X^{a}} = \frac{1}{1-\deg P^{\#}}e_{\sigma}^{m}p^{\sigma\gamma}(\widehat{g}(\varphi))\,, \tag{47}$$

$$\frac{\partial e_{\mu}^{m}}{\partial\partial_{\gamma}X^{a}} = \delta_{a}^{m}\delta_{\mu}^{\gamma}\,, \tag{48}$$

$$\frac{\partial\epsilon_{m}^{0}}{\partial\partial_{\gamma}X^{a}} = -\epsilon_{a}^{0}\epsilon_{m}^{\gamma}\,, \tag{49}$$

$$\frac{\partial\epsilon_{m}^{\mu}}{\partial\partial_{\gamma}X^{a}} = -\epsilon_{a}^{\mu}\epsilon_{m}^{\gamma} + \frac{1}{\deg P^{\#}-1}\epsilon_{m}^{0}\epsilon_{a}^{0}p^{\mu\gamma}(\widehat{g}(\varphi))\,. \tag{50}$$

The key result[1] of constructive gravity is that the gravitational dynamics for the spacetime geometry are given by the action

$$S_{\text{geometry}}[G(\varphi_{t},N_{t},\vec{N}_{t})] = \int d^{4}x\,N\mathscr{L}\left(\varphi_{t},K[\varphi_{t},N_{t},\vec{N}_{t}]\right) \tag{51}$$

where

$$K^{A}[\varphi,N,\vec{N}] := \frac{1}{N}\Big(\dot{\varphi} - (\partial_{\gamma}N)M^{A\gamma}[\varphi] - N^{\mu}\partial_{\mu}\varphi^{A} + (\partial_{\gamma}N^{\mu})F^{A}{}_{\mu}{}^{\gamma}(\varphi)\Big) \tag{52}$$

and the scalar density $\mathscr{L}$ of weight one is a functional of the $\varphi$ and a function of the $K$ that is determined by the gravitational closure equations, which in functional differential form are just the two following equations

$$\begin{aligned}
0 = {} & -K^{B}(y)\frac{\delta\mathscr{L}(x)}{\delta\varphi^{B}(y)} + (\partial_{\gamma}\delta_{x})\,(y)K^{B}(y)M^{A\gamma}{}_{:B}(x)\frac{\partial\mathscr{L}}{\partial K^{A}}(x) + \partial_{\mu}\left(\frac{\delta\mathscr{L}(x)}{\delta\varphi^{B}(\cdot)}M^{B\mu}\right)(y) \\
& + \partial_{\mu}\frac{\partial\mathscr{L}}{\partial K^{A}}(x)\Big[(\deg P^{\#}-1)^{-1}p^{\rho\mu}F^{A}{}_{\rho}{}^{\nu} - M^{B[\mu|}M^{A|\nu]}{}_{:B}\Big](x)\,(\partial_{\nu}\delta_{x})\,(y) \\
& - \frac{\partial\mathscr{L}}{\partial K^{A}}(x)\Big[(\deg P^{\#}-1)^{-1}p^{\rho\nu}\left(\partial_{\rho}\varphi^{A} + F^{A}{}_{\rho}{}^{\gamma}{}_{,\gamma}\right) \\
& + \partial_{\mu}\left(M^{B[\mu|}M^{A|\nu]}{}_{:B}\right)\Big](x)\,(\partial_{\nu}\delta_{x})\,(y) \\
& - (x \longleftrightarrow y).
\end{aligned} \tag{53}$$

and

$$
\begin{aligned}
0 = {} & \frac{\partial \mathscr{L}}{\partial K^B}(y)\, K^A(y)\, \left(\delta^B_A \delta^\gamma_\mu + F^B{}_\mu{}^\gamma{}_{:A}\right)(y)(\partial_\gamma \delta_y)(x) \\
& - K^A(y)\partial_\gamma \frac{\partial \mathscr{L}}{\partial K^B}(y) F^B{}_\mu{}^\gamma{}_{:A}(y)\delta_y(x) \\
& - \left(K^A \frac{\partial \mathscr{L}}{\partial K^A} - \mathscr{L}\right)(y)(\partial_\mu \delta_y)(x) + \partial_\mu \left(K^A \frac{\partial \mathcal{L}}{\partial K^A} - \mathscr{L}\right)(y)\delta_y(x) \\
& + \left(\partial_\mu \varphi^A + F^A{}_\mu{}^\gamma{}_{,\gamma}\right)(x) \frac{\delta \mathscr{L}(y)}{\delta \varphi^A(x)} + F^A{}_\mu{}^\gamma(x)\partial_\gamma \left(\frac{\delta \mathscr{L}(y)}{\delta \varphi^A(\cdot)}\right)(x)\,, \qquad (54)
\end{aligned}
$$

where the shorthand $Q_{:A}{}^{\alpha_1 \ldots \alpha_N} := \partial Q / \partial \partial_{\alpha_1 \ldots \alpha_N} \varphi^A$ has been used in both. Solving these equations for $\mathscr{L}$ then completely determines the gravitational action (51) that provides dynamics for the geometry employed in the matter action which is causally consistent with the initially stipulated matter field dynamics.

## 5. Solution techniques for gravitational closure equations

***General gravitational closure.*** While it is straightforward to set up the gravitational closure equations for any matter field action on any tensorial background geometry – as long as the principal polynomial of the resulting matter field equations of motion satisfy the three physicality conditions, which may require restriction of the geometry – it appears generically prohibitively hard to solve this countable set of linear homogeneous partial differential equations.

A notable exception is provided by standard model matter on a metric background. The restriction on the geometry, which makes the standard model fields satisfy the physicality conditions, boils down to the metric having Lorentzian signature. In this case, the closure equations are not only set up as swiftly as in any other case, but they can also be solved without further assumptions.

Maybe the difficulty to solve the gravitational closure equations for other matter models of physical interest, such as general linear – and thus birefringent – electrodynamics, is in part due to an unfortunate choice of field parametrization (42) of the field degrees of freedom. A well-considered choice of parametrization might render a general solution less difficult.

The most promising line of attack, however, is to better understand the structure of the closure equations themselves. A theoretically invaluable step would be to take them to involutive form, maybe in general and maybe case by case. At any rate, this would allow, for instance, a direct calculation of the dimension of their linear solution space. This dimension would then of course be equal to the number of physical constants that remain undetermined by constructive gravity and must hence be measured in experiments. While this number is 2 in the case of standard model matter – corresponding to an undetermined gravitational constant and an undetermined cosmological constant — we know that it is at least 11 for the gravitational theory that underlies general linear electrodynamics. Clearly, any gravitational theory with infinitely many undetermined constants is non-predictive

in general, although the number of relevant constants might become finite under special circumstances, such as symmetry assumptions.

From a practical point of view, however, a general solution to the gravitational closure equations for some given matter dynamics beyond the standard model is not required. For even if it was available, it would give rise to field equations that are at least as difficult to solve as Einstein's equations. At that stage, these elusive general gravitational field equations would have to be solved either by symmetry assumptions or perturbation theory. The obvious idea is to implement any desired symmetry assumption or perturbative technique already at the level of the gravitational closure equations. This is not entirely straightforward, and the following two subsections briefly outline the problem an the solution.

***Symmetric gravitational closure.*** Since the gravitational closure equations yield a gravitational action, any implementation of a Killing symmetry

$$\mathcal{L}_K G = 0$$

for the pertinent tensorial spacetime geometry at the level of the closure equations, if properly implemented, will be passed down to the action.

But this means that variation of the action, with the aim to obtain the gravitational field equations, must now be performed with respect to the symmetric field configurations that appear in the already symmetry-reduced action. Thinking of variation in field theory as a competition between a candidate field and slightly deformed competitors, one notes that the competition is severely limited by only considering competitors that also already satisfy the imposed symmetry condition. It is thus clear that variation of a symmetry-reduced action produces weaker symmetrized field equations than variation of the full action and subsequent symmetrization would have. This is the known issue of symmetric criticality[13] and further useful necessary and sufficient conditions for when a symmetry reduction at the level of the action yields the correct field equations have been identified[14,15].

It is clear from the above discussion that the implementation of spacetime symmetries at the level of the gravitational closure equations is possible under precisely the same conditions that apply to their implementation at the level of an action. Symmetric gravitational closure is discussed and illustrated in[16], where it is shown that one obtains the Friedmann equations as the cosmologically symmetry-reduced gravitational closure of standard model matter dynamics, without ever having to know Einstein's equations.

For matter models beyond the standard model, the simplification of the corresponding gravitational closure equations are tremendous[17] and thus put a solution in reach, see the contribution by Düll to these Proceedings.

***Perturbative gravitational closure.*** Perturbative solutions of gravitational closure equations my be performed under precisely the same assumptions that render them meaningful at the level of the equations of motion. Since the action needs to be known, roughly speaking, to second order if one wishes to derive field equations

that are valid to first order perturbations, care needs to be taken in the determination of terms that can be dropped or not. In practice, this is based on a subtle interplay of the order to which the coefficient functions of the gravitational closure equations must be expanded, the number of derivatives that act afterwards and the resulting overall order of a particular closure equation.

The perturbative treatment yields the 11-parameter weak gravitational field equations that underlie general linear electrodynamics[18] as well as the interesting bimetric gravity theory as it underlies the only superficially trivial matter model of two Klein-Gordon fields that couple to two different Lorentzian metrics, see the contribution by Wierzba to these Proceedings.

## 6. Applications

***Birefringence in the weak gravitational field of a point mass.*** The perturbative gravitational closure of general linear electrodynamics, which served as our opening example for a problem that was previously not solvable, yields a spacetime geometry

$$G^{abcd} = 2\eta^{a[c}\eta^{d]b} - \epsilon^{abcd} + H^{abcd}$$

that describes the gravitational field not too close to a point mass $m$ with the perturbative deviation $H^{abcd}$ from Minkowski space $H^{abcd}$ given in[18]. No birefringence is seen, to first order perturbation theory, where and only where[19]

$$\frac{1}{2}H^{ab}H^{cd} = \eta_{mr}\eta_{ns}H^{ambn}H^{crds} \tag{55}$$

holds to second order. Thus allowing for birefringence in principle, the weak gravitational field generated by a point mass indeed generates birefringence, whose strength depends on the mass and four more independent constants to be determined by only four experiments in that gravitational field; see also the contribution by Stritzelberger to these Proceedings.

***Gravitational effects in birefringent quantum electrodynamics.*** The quantization of birefringent electrodynamics is renormalizable in a gauge-invariant way to all perturbative orders on a flat background[20]. This result can be used to reliably calculate quantum field theoretic processes in locally essentially flat regions of a globally non-flat area metric geometry that arises as the solution of the underyling gravity theory that one obtains by gravitational closure of classical birefringent electrodynamics. This allows to search for signatures of birefringence in localized quantum electrodynamic processes, which are now dependent of the spacetime region where they occur. Of particular interest is a modification of the observationally important 21.1 cm line of hydrogen, which in the presence of birefringence is seen to depend qualitatively and quantitatively – in a way precisely predicted by constructive gravity – on the location of the hydrogen; see the contribution by Tanzi to these Proceedings.

***Gravitational radiation.*** An notable result[21] concerning the gravitational closure of birefringent electrodynamics is that the gravitational radiation emitted by two circularly orbiting masses contains only one massless trace-free tensor mode, as in general relativity, while additional scalar, vector and tensor modes are all massive. The production of these massive waves is shown to be significantly suppressed, since it requires the orbital frequency to surpass a certain threshold. Slowly orbiting binaries therefore only radiate waves of the type predicted by general relativity.

***Etherington distance relation.*** On a Lorentzian spacetime, the Etherington distance duality relation[22] connects the luminosity distance, angular diameter distance and redshift of an astrophysical light source independent of the gravitational dynamics. This is not the case for the refined spacetime geometry that underlies birefringent linear electrodynamics. Direct calculation, from the field equations obtained by gravitational closure, yields a modification of Etherington's relation that depends on the gravitational dynamics and indeed the particular spacetime solution[23]. This opens up the possibility of deriving new gravitational lensing effects or indeed a pathway for the explanation of known anomalies that is directly connected to carefully studied extensions of the standard model[24]. The reader is referred to the contribution by Werner to these Proceedings.

***Parametrodynamics.*** Parameters in matter field dynamics are usually considered as constants whose values must be determined by experiment. Gravitational closure, however, can be used to predict the values of non-scalar parameters that appear in any local field theory that is amenable to the closure equations[5]. To this end, one first promotes the constant parameters to fields, analogous to the promotion of the flat spacetime Minkowski metric in Maxwell theory to the metric tensor field in the general theory of relativity. Gravitational closure of the this modified matter action then yields a multi-parameter family of actions for these parameters (and, if one so chooses, also for the underlying geometry) as the unique dynamics that enjoys a consistent co-evolution with the matter fields of the initially stipulated matter theory. See the contribution by Wierzba to these Proceedings.

## 7. Conclusions

Constructive gravity is a method to determine, by calculation rather than stipulation, a family of gravitational actions that are compatible with a large class of matter field theories. Remarkably, it is any concrete representative of these matter field theories themselves that provides the relevant information for the calculation of the gravitational theory, essentially based on the requirement that the latter have a diffeomorphism gauge group and possess a canonical evolution that shares its initial data surfaces with those of the chosen matter theory. The availability of such a procedure allows to ask and answer questions that could not be posed before and reveal gravitational dynamics as a mere consistency requirement once the matter

contents of the universe is specified. While for a universe filled with standard model matter, there is no new physics predicted by the gravitational closure mechanism, this significantly changes once matter beyond the standard model is considered. This is where constructive gravity will likely find its key application.

There are numerous reasons to study modifications of general relativity and the Standard Model of particle physics, ranging from modelling inflation to exploring galaxy rotation curves and the nature of dark matter. Here we study the most general linear theory of electromagnetism, which admits vacuum birefringence, and derive weak gravitational field equations for the underlying area metric spacetime geometry. We discuss the weak gravitational field sourced by a point mass in an area metric spacetime and find first order corrections to the linearized Schwarzschild metric of general relativity.

*Keywords*: General linear electrodynamics; vacuum birefringence; area metric; constructive gravity; modified gravity.

## 1. Introduction

Could there be weak birefringence of light in vacuo? How can we predict whether and where such splitting of light rays in vacuo occurs? Standard Maxwell electrodynamics, for which the electromagnetic field couples to a metric spacetime geometry, *a priori* excludes the possibility of vacuum birefringence. The spacetime geometry must be refined, from a metric to a tensor field of the fourth rank, in order to obtain a linear theory of electrodynamics allowing for vacuum birefringence to occur. The such obtained matter theory is known as the theory of *general linear electrodynamics*[1–3] and the fourth rank spacetime tensor field as an *area metric*. Because the matter field equations of general linear electrodynamics depend on the area metric background, finding any concrete solution for the electromagnetic field requires to simultaneously solve some yet-to-be-determined field equations for the area metric, which thus take the role played by Einstein's field equations for a metric background. In particular, also the splitting of light rays depends crucially on such gravitational field equations underlying general linear electrodynamics. We can thus rephrase the question of whether and where birefringence of light in vacuo occurs as follows: What are the gravitational field equations underlying general linear electrodynamics, and what are the solutions to these field equations?
This question can be answered by means of the recently discovered procedure of gravitational closure[4,5], which employs the causal structure of given matter field equations in order to provide causally compatible canonical dynamics[6,7] for the underlying geometry. For instance, starting from Maxwell electrodynamics, one

obtains the familiar Einstein equations in this way. Exactly along the same lines, when starting instead from general linear electrodynamics, one obtains the gravitational field equations for an area metric geometry. Based on Ref. [8], this paper reviews the derivation of the *weak* gravitational field equations underlying general linear electrodynamics, followed by a discussion of a concrete solution to these equations, namely the weak gravitational field sourced by a point mass in an area metric spacetime, revealing first order corrections to the linearized Schwarzschild metric.

## 2. General linear electrodynamics

We start our discussion with a brief review of the theory of general linear electrodynamics[1–3,9–11]. The action of this matter theory is

$$S_{matter}[A, G)] = -\frac{1}{8}\int_M d^4x\, \omega_G F_{ab} F_{cd} G^{abcd}\,, \tag{1}$$

where $M$ is an orientable four-dimensional spacetime manifold, $F = \mathrm{d}A$ denotes the electromagnetic field strength tensor, the fourth-rank contravariant tensor field $G$ denotes the area metric spacetime geometry, and the scalar density $\omega_G = 4!(\epsilon_{abcd}G^{abcd})^{-1}$ is constructed by virtue of the canonical top form density $\epsilon$. In a spacetime equipped with a tensorial spacetime geometry, general linear electrodynamics is the most general theory of electrodynamics for which the classical linear superposition principle still holds. By virtue of the appearance of the fourth-rank tensor field in the above matter action, the algebraic symmetries

$$G^{abcd} = G^{cdab} \quad \text{and} \quad G^{abcd} = -G^{bacd} \tag{2}$$

may be assumed without loss of generality. Consequently, an area metric spacetime geometry features 21 independent degrees of freedom at each spacetime point, as opposed to only 10 independent degrees of freedom for a metric spacetime geometry. It is ultimately due to these additional degrees of freedom that general linear electrodynamics allows not only to describe all of Maxwell electrodynamics, but also various new phenomena such as vacuum birefringence.

The causal structure of the equations of motion of general linear electrodynamics is prescribed by the principal tensor field $P_G$, which was shown in Ref. [2, 3] to be a totally symmetric tensor field density of the fourth rank, determined entirely in terms of the spacetime geometry,

$$P_G^{abcd} = -\frac{1}{4!}\omega_G^2\, \epsilon_{mnpq}\epsilon_{rstu} G^{mnr(a} G^{b|ps|c} G^{d)qtu}\,. \tag{3}$$

The principal tensor field is the reason why generic area metric spacetime geometries feature vacuum birefringence: The null cone of general linear electrodynamics, that is the set of covectors annihilating the principal tensor field, is a quartic surface. However, if the splitting of light rays in vacuo was a large effect, it would most likely have been observed by now. Therefore, instead of studying generic area

metric spacetimes, this paper focuses on spacetime geometries which are small area metric perturbations $H$ around metric Minkowski spacetime $\eta$,

$$G^{abcd} = \eta^{ac}\eta^{bd} - \eta^{ad}\eta^{bc} - \epsilon^{abcd} + H^{abcd} \,. \tag{4}$$

Once we know the linearized gravitational field equations underlying general linear electrodynamics, we can derive the area metric perturbations $H$ for given small matter distributions. In the following two sections, we therefore discuss the derivation of these linearized gravitational field equations by means of gravitational closure.

## 3. Canonical geometry

The procedure of gravitational closure enables the derivation of causally compatible gravitational field equations for the spacetime geometry underlying any predictive and quantizable matter field theory[4–7]. The first step in this gravitational closure procedure is to determine the canonical geometry for which one ultimately wishes to obtain canonical dynamical field equations. The canonical geometry of an area metric spacetime geometry can be determined as follows. Let $\Sigma$ be a three-dimensional manifold and let $X_t : \Sigma \hookrightarrow M$ be a one-real-parameter family of embedding maps, which specifies a foliation of the spacetime manifold into initial data surfaces. For each point $\sigma \in \Sigma$ and each embedding parameter $t \in \mathbb{R}$, one can construct an orthonormal frame $\{\epsilon^0(t,\sigma), \epsilon^\alpha(t,\sigma)\}$, where $\alpha \in \{1,2,3\}$, which allows to project the area metric spacetime geometry onto the initial data surfaces,

$$(g_1)^{\alpha\beta}[X_t] := -G(\epsilon^0, \epsilon^\alpha, \epsilon^0, \epsilon^\beta) \,, \tag{5}$$

$$(g_2)_{\alpha\beta}[X_t] := \frac{1}{4}\frac{\epsilon_{\alpha\mu\nu}}{\sqrt{\det(g_1)}}\frac{\epsilon_{\beta\sigma\tau}}{\sqrt{\det(g_1)}} G(\epsilon^\mu, \epsilon^\nu, \epsilon^\sigma, \epsilon^\tau) \,, \tag{6}$$

$$(g_3)^\alpha{}_\beta[X_t] := \frac{1}{2}\frac{\epsilon_{\beta\mu\nu}}{\det(g_1)} G(\epsilon^0, \epsilon^\alpha, \epsilon^\mu, \epsilon^\nu) - \delta^\alpha_\beta \tag{7}$$

resulting in three one-real-parameter families of induced tenor fields. By construction, the induced tensor fields $g_1$ and $g_2$ are symmetric,

$$(g_1)^{[\alpha\beta]} = 0 \quad \text{and} \quad (g_2)_{[\alpha\beta]} = 0 \,. \tag{8}$$

Moreover, the orthonormality conditions satisfied by the four frame fields imply

$$(g_1)^{\sigma[\alpha}(g_3)^{\beta]}{}_\sigma = 0 \quad \text{and} \quad (g_3)^\alpha{}_\alpha = 0 \,. \tag{9}$$

Therefore, only 17 of the components of the induced tensor fields are independent degrees of freedom. In order to obtain the canonical geometry from this induced geometry, we need to parametrize the three induced tensor fields $\{g_1, g_2, g_3\}$ in terms of unconstrained canonical configuration variables $\{\varphi^1, \ldots, \varphi^{17}\}$. Note that since the four frame conditions (9) are non-linear, any parametrization $\{g_1(\varphi), g_2(\varphi), g_3(\varphi)\}$ respecting the symmetry conditions (8) and frame conditions (9) is non-linear in the canonical configuration variables. One possible parametrization—particularly

suited for the perturbative approach pursued in this paper—is the following. Consider a constant intertwiner $\mathcal{I}^{\alpha\beta}{}_A$, distributing the unconstrained configuration variables $\{\varphi^1, ..., \varphi^{17}\}$ over three second rank tensor fields,

$$(\varphi_1)^{\alpha\beta} := \sum_{A=1}^{6} \mathcal{I}^{\alpha\beta}{}_A \varphi^A, \quad (\varphi_2)^{\alpha\beta} := \sum_{A=7}^{12} \mathcal{I}^{\alpha\beta}{}_A \varphi^A, \quad (\varphi_3)^{\alpha\beta} := \sum_{A=13}^{17} \mathcal{I}^{\alpha\beta}{}_A \varphi^A. \tag{10}$$

Now let $\gamma$ denote a flat three-dimensional Euclidean metric on $\Sigma$ and let the intertwiner $\mathcal{I}^{\alpha\beta}{}_A$ and its inverse $\mathcal{I}^A{}_{\alpha\beta}$ satisfy the completeness relations

$$\mathcal{I}^{\alpha\beta}{}_A \mathcal{I}^B{}_{\alpha\beta} = \delta^B_A \quad , \qquad \sum_{A=1}^{6} \mathcal{I}^{\alpha\beta}{}_A \mathcal{I}^A{}_{\mu\nu} = \delta^{(\alpha}_{\mu} \delta^{\beta)}_{\nu},$$

$$\sum_{A=7}^{12} \mathcal{I}^{\alpha\beta}{}_A \mathcal{I}^A{}_{\mu\nu} = \delta^{(\alpha}_{\mu} \delta^{\beta)}_{\nu} \quad , \qquad \sum_{A=13}^{17} \mathcal{I}^{\alpha\beta}{}_A \mathcal{I}^A{}_{\mu\nu} = \delta^{(\alpha}_{\mu} \delta^{\beta)}_{\nu} - \frac{1}{3} \gamma^{\alpha\beta} \gamma^{\mu\nu} \ . \tag{11}$$

By means of this particular choice of intertwiner, the tensor fields $\varphi_1$ and $\varphi_2$ are symmetric, while $\varphi_3$ is symmetric and trace-free. We find that the parametrization

$$(g_1(\varphi))^{\alpha\beta} := \gamma^{\alpha\beta} + (\varphi_1)^{\alpha\beta}, \tag{12}$$

$$(g_2(\varphi))^{\alpha\beta} := \gamma^{\alpha\beta} + (\varphi_2)^{\alpha\beta}, \tag{13}$$

$$(g_3(\varphi))^{\alpha\beta} := (\varphi_3)^{\alpha\beta} + \sum_{n=1}^{\infty} (-1)^{n-1} \frac{1}{2^n} \underbrace{\Big\{\varphi_1, \Big\{\varphi_1, \Big\{ \ldots, \Big\{}_{n-1 \text{ anti-commutator brackets}} \underbrace{\varphi_1, \big[\varphi_1, \varphi_3\big]}_{\text{commutator bracket}} \Big\} \ldots \Big\}\Big\}\Big\}^{\alpha\beta} \tag{14}$$

meets all symmetry and frame conditions, leaving us with an explicit expression of the canonical geometry in terms of the 17 independent geometric degrees of freedom.

## 4. Linearized gravitational dynamics

The second step in the gravitational closure procedure is to set up and solve a set of countably many linear homogeneous partial differential equations—the *gravitational closure equations*—whose coefficients are determined by the principal tensor field expressed in terms of the canonical configuration variables. A derivation of these coefficients can be found in section IV.C of [4]. Starting from general linear electrodynamics, the principal tensor field (3), together with the parametrization (12-14), allows to determine these coefficients in terms of the canonical configuration variables $\{\varphi^1, \ldots, \varphi^{17}\}$. The gravitational closure equations then in turn determine the coefficient functionals $C_{A_1 \ldots A_N}[\varphi]$ of a power series ansatz for the gravitational Lagrangian density

$$\mathcal{L}_{grav}[\varphi, k] = \sum_{N=0}^{\infty} C_{A_1 \ldots A_N}[\varphi]\, k^{A_1} \ldots k^{A_N}, \tag{15}$$

where $k$ are the velocities associated with the canonical configuration variables $\varphi$. Deriving gravitational field dynamics hence amounts to solving the gravitational

closure equations—which turns out to be a difficult task for a non-metric geometry. However, we here only wish to study small area metric perturbations, which require just *linearized* gravitational field equations. In order to obtain the gravitational field equations underlying general linear electrodynamics to linear order in $\varphi$ and $k$, we only need to derive the Lagrangian density to second order

$$\mathcal{L}_{grav}[\varphi, k] = C[\varphi] + C_A[\varphi]k^A + C_{AB}[\varphi]k^A k^B + \mathcal{O}(3)\,. \tag{16}$$

That is, we only need to solve the gravitational closure equations for $C[\varphi]$ to second order, $C_A[\varphi]$ to first order and $C_{AB}[\varphi]$ to zeroth order in $\varphi$. We now also see why the parametrization (12-14) is particularly suited for this perturbative approach: The configuration variables $\varphi$ can be directly employed as the perturbative degrees of freedom of an area metric perturbed around flat Minkowski spacetime $\eta = \mathrm{diag}(1, -1, -1, -1)$. We then perturbatively expand both the coefficients of the gravitational closure equations and the coefficient functionals $C_{A_1 \ldots A_N}[\varphi]$ in orders of $\varphi$, and evaluate the equations order by order. The such obtained gravitational Lagrangian, to second order in $\varphi$ and $k$, and the therefrom obtained linearized gravitational field equations can respectively be found in section III.D and IV.B of [8]. These field equations can now be solved for specific matter distributions of interest.

## 5. Solution around a point mass

For instance, let us consider the Hamiltonian $H_{matter}$ of a point mass $M$ at rest,

$$\frac{\delta H_{matter}}{\delta A(x)} = -M\delta^{(3)}(x)\,, \tag{17}$$

where $A$ denotes the perturbation of the lapse vector field. Solving the linearized gravitational equations of motion for this particular small matter distribution yields the following area metric perturbations,

$$H^{0\beta 0\delta} = \gamma^{\beta\delta}(2A - \tfrac{1}{2}U - \tfrac{1}{2}V) + \mathcal{O}(2)\,, \tag{18}$$

$$H^{0\beta\gamma\delta} = \epsilon^{\beta\gamma\delta}(-A + \tfrac{3}{4}U + \tfrac{3}{4}V) + \mathcal{O}(2)\,, \tag{19}$$

$$H^{\alpha\beta\gamma\delta} = 2\gamma^{\alpha[\gamma}\gamma^{\delta]\beta}(U + 2V) + \mathcal{O}(2)\,, \tag{20}$$

where the scalar perturbations $A$, $U$ and $V$ can be expressed in terms of the Euclidean radial distance $r$ and undetermined integration constants $\alpha$, $\beta$, $\gamma$ and $\mu$:

$$U = \frac{M}{4\pi r}\left(\alpha + \beta e^{-\mu r}\right), \quad V = \frac{M}{4\pi r}\gamma e^{-\mu r}\,, \quad A = \frac{M}{16\pi r}\left(\alpha - (\beta + 3\gamma)\, e^{-\mu r}\right). \tag{21}$$

Just like the gravitational and cosmological constants in the Einstein field equations of general relativity, these constants need to be determined by experiment. For the principal tensor field of an area metric spacetime sourced by a point mass we obtain,

$$P_G^{0000} = 1 + 2\Phi + \mathcal{O}(2)\,, \quad P_G^{\alpha 000} = \mathcal{O}(2)\,, \quad P_G^{\alpha\beta 00} = -\tfrac{1}{6}\gamma^{\alpha\beta} + \mathcal{O}(2)\,,$$
$$P_G^{\alpha\beta\gamma 0} = \mathcal{O}(2)\,, \quad P_G^{\alpha\beta\gamma\delta} = (1 - 2\Phi)\gamma^{(\alpha\beta}\gamma^{\gamma\delta)} + \mathcal{O}(2)\,, \tag{22}$$

where we defined $\Phi := \frac{M}{4\pi r}\left[-\frac{\alpha}{2} + \left(\frac{\beta}{2} + \frac{3\gamma}{4}\right) e^{-\mu r}\right]$. In order to decide whether light rays split, one would need to determine the solution of the gravitational field equations for the area metric to second order [12]. However, already to linear order, we find corrections to the usual linearized Schwarzschild metric in the form of a Yukawa potential. Allowing for vacuum birefringence, by assuming the electromagnetic field to be described by general linear electrodynamics, hence leaves its imprints on the spacetime geometry around a point mass. With the solution (22) one could now for instance study weak gravitational lensing in area metric spacetimes.

## 6. Conclusions

The weak gravitational field equations for the area metric spacetime geometry underlying general linear electrodynamics can be obtained by means of the gravitational closure mechanism. We find that modifying the spacetime geometry from a metric to an area metric, thereby allowing for vacuum birefringence, affects the canonical dynamical field equations and their solutions: For instance, for the weak field around a point mass in an area metric spacetime, we find first order Yukawa corrections to the Schwarzschild metric. The linearized gravitational field equations now also enable further studies, e.g. the propagation of gravitational waves [8] or modifications of the standard Etherington relation [13] in area metric spacetimes.

# Quantum signatures of area-metric deviations from a metric

Roberto Tanzi*

*University of Bremen, Center of Applied Space Technology and Microgravity (ZARM)*
*28359 Bremen, Germany*
**E-mail: roberto.tanzi@zarm.uni-bremen.de*

The most general theory of electrodynamics with linear field equations introduces a new geometry, the area metric, that regulates the propagation of light rays and massive particles instead of the usual Lorentzian metric. In the majority of the experimental situations, the area metric is expected to be a small perturbation around a metric background. In this perturbative case, two interesting results can be achieved. First, the dynamics of the area metric can be found explicitly. Second, the relative quantum theory of electrodynamics can be shown to be renormalizable and can be used to compute various fundamental processes.

I will show that, when one combines the results of quantum electrodynamics with the dynamics of an area-metric perturbation, the anomalous magnetic moment of the electron, the cross sections of Bhabha scattering, and the hyperfine splitting of the hydrogen pick up a dependence on the position. This way, measurements of the position dependence of these quantities provide a new channel to investigate area-metric deviations from a metric spacetime.

*Keywords*: general linear electrodynamics; constructive gravity; area metric; SME.

## 1. General Linear Electrodynamics and the Area Metric

The main subject of our discussion is the most general theory of electrodynamics with linear field equations, i.e., the most general theory of electrodynamics that still features the superposition principle. In particular, we wish to study the quantum effects that are produced when one considers this general linear electrodynamics as the fundamental description of the electromagnetic interactions instead of Maxwell's theory.

General linear electrodynamics has been extensively studied in the past years and many effects are currently known.[1] The starting point of our discussion is the action

$$S_{\text{GLED}}[A;\omega,G] = -\frac{1}{8}\int d^4x\,\omega F_{ab}F_{cd}G^{abcd}\,, \tag{1}$$

where $A$ is the one-form electromagnetic potential, $F = dA$ is the field strength, $G^{abcd}$ is a fourth-rank contravariant tensor field called the *area metric*, and $\omega$ is a scalar density employed to build the volume form. The area metric $G^{abcd}$ is required to satisfy, without loss of generality, the algebraic symmetries $G^{abcd} = G^{[ab][cd]} = G^{[cd][ab]}$ and to be cyclic, i.e., $G^{abcd}\epsilon_{abcd} = 0$.

Further conditions on the area metric come from the requirements that the field equations ensuing from (1) have a well-posed initial-value problem, that the spacetime is time orientable, and that general linear electrodynamic is canonically quantizable. We leave out the details of this important points since they do not play a relevant role in the present discussion. Indeed, starting from the next section, we

will consider only small area-metric perturbations around a flat metric background, in which case all the three conditions are satisfied.

At this point, it is important to note that not only does the action (1) cause a departure from Maxwell electrodynamics, but it also implies that the geometry of the spacetime is no longer described by a metric. One way to see this is by considering the geometric-optical limit of the field equations, which restricts the wave covector $k$ of light rays to satisfy the quartic dispersion relation

$$P(G,\omega)^{abcd}k_a k_b k_c k_d = 0 \tag{2}$$

rather than the familiar quadratic one $g^{ab}k_a k_b$ enforced by a Lorentzian metric $g$. In the expression above, the completely-symmetric tensor field that defines the dispersion relation is explicitly given in terms of $G^{abcd}$ and $\omega$ by the expression

$$P^{abcd} = -\frac{1}{24}\omega^2 \epsilon_{mnpq}\epsilon_{rstu} G^{mnr(a} G^{b|ps|c} G^{d)qtu}\,.$$

Furthermore, the motion of massive particles is affected in a similar way, as it was shown in Ref. 2. In particular, the momentum $p$ of a particle of mass $m$ satisfies the dispersion relation

$$P(G,\omega)^{abcd}k_a k_b k_c k_d = m^4\,. \tag{3}$$

Therefore, we see that the area metric $G^{abcd}$, together with the scalar density $\omega$, regulates the motion of point particles instead of the metric and, therefore, replaces this latter as the geometry of the spacetime.

Finally, in order to study an interacting theory of electrodynamics, it is necessary to introduce Dirac particles on an area-metric background. The general procedure to do so can be found in Ref. 3. Here, we limit ourself in quoting the fact that the $\gamma$-matrices need to satisfy the quaternary algebra

$$\gamma^{(a}\gamma^b\gamma^c\gamma^{d)} = P(G,\omega)^{abcd}\, I \tag{4}$$

rather than the usual binary one $\gamma^{(a}\gamma^{b)} = \eta^{ab}\, I$, being $I$ the identity matrix. This ensures that the Dirac field equations share the same initial-value surfaces of the field equations of general linear electrodynamics and that the causal structure of the spacetime is well defined.

### 1.1. *Linear deviations from a flat metric background*

When considered in its generality, area-metric electrodynamics (1) can produce effects that greatly differ, qualitatively and quantitatively, from Maxwell electrodynamics. However, the majority of these effects are experimentally excluded in vacuum with a fairly good accuracy. For this reason, we study the case in which the area metric is a small perturbation around Maxwell electrodynamics in a flat metric background. In particular, we consider the case in which

$$G^{abcd} = \eta^{ac}\eta^{bd} - \eta^{ad}\eta^{bc} + E^{abcd} \qquad \text{and} \qquad \omega = 1 + e\,, \tag{5}$$

where second-order corrections in $E^{abcd}$ and $e$ will be discarded.

In this perturbative regime, a great simplification is possible. It was indeed shown in Ref. 4 that it is always possible to find a (local) frame where the area-metric perturbations satisfy the conditions

$$E^{amb}{}_{m} = \frac{1}{4} E^{ij}{}_{ij} \eta^{ab} \qquad \text{and} \qquad e = -\frac{1}{8} E^{ij}{}_{ij} \,. \tag{6}$$

This frame has two major advantages. First, it is an observer frame as defined in Ref. 5, which means that results expressed in it are those measured by an observer. Second, the massive dispersion relation and the Dirac algebra reduce to the usual

$$\eta^{ab} k_a k_b = m^2 \qquad \text{and} \qquad \gamma^{(a} \gamma^{b)} = \eta^{ab} \, I \tag{7}$$

up to second order corrections. In particular, the description of massive fermions, such as the electron, is the same as in the standard theory. Finally, note that there is more than one frame in which (6) and (7) are satisfied; these frames are all related to one another by means of Lorentz transformations.

### 1.2. *The dynamics of the area metric*

So far, the area metric has been an *a priori* given and fixed geometry and we have mentioned some of the effects it produces on matter, such as the propagation of massless and massive particles. This still leaves open the questions of how matter affects the area metric and what the precise dynamics of this new geometry is.

The good news is that it is possible to *calculate*, without any need to postulate, the precise dynamics of the area metric starting from the matter action (1). This is precisely the purpose of the gravitational closure mechanism. [5] The (purely computational) bad news is that the gravitational action emerges as the solution of countably-many partial differential equations that have not been solved, so far, for a general area metric. Nevertheless, the solution to these differential equations was found explicitly in the case of linear area-metric perturbations around a flat metric background. [6] With these perturbative solutions, it is possible to find, in particular, the area metric linear perturbations sourced by a point mass. [7]

We now make the two assumptions that our experimental apparatus is at a fixed distance $R$ from the point mass and that, inside the laboratory, the area metric can be considered to be constant. Then, in one of the special frames described in the previous section, the area metric perturbations around a point mass take the form

$$\begin{gathered} E^{0\alpha 0\beta} = U(R)\, \delta^{\alpha\beta} \,, \qquad E^{0\alpha\beta\gamma} = 0 \,, \qquad E^{\alpha\beta\gamma\delta} = -U(R) \big( \delta^{\alpha\gamma} \delta^{\beta\delta} - \delta^{\alpha\delta} \delta^{\beta\gamma} \big) \,, \\ e = 3/2\, U(R) \,, \quad \text{where} \quad U(R) := -\frac{M\varepsilon}{4\pi R} e^{-\mu R} \,. \end{gathered} \tag{8}$$

In the expression above, $\varepsilon$ and $\mu$ are two integration constants of the countably-many partial differential equations and they need to be fixed by experiments.

All the results we derive will be expressed both in terms of a generic area-metric linear perturbation $E^{abcd}$ satisfying the restrictions (6) and in terms of the particular area-metric perturbation around a point mass displayed in (8).

### 1.3. *Quantization and renormalization*

The theory we consider is the general linear electrodynamics (1) in the linear-perturbation regime (5) with the restrictions (6) minimally coupled to the usual fermions. The Feynman rules can be derived with no difficulties using the path-integral formalism, as it is done in Ref. 4. One sees that the fermion propagator and the vertex are the same as in standard QED, whereas the photon propagator contains a new term linear in the area-metric perturbation. Moreover, fermion external legs can be treated in the same way as in standard QED. Photons external legs would require some extra care, but they are not needed in the processes we consider.

Finally, it is possible to prove that quantum electrodynamic with linear area-metric deviations from a flat metric background is renormalizable at every loop order in a gauge-invariant way. The complete proof, which uses the Batalin-Vilkovisky formalism, can be found in Ref. 4.

## 2. Results

We collect in this section the various processes that we have studied and the results that we have found. The derivation of these with detailed discussions can be found in Ref. 4.

### 2.1. *Bhabha scattering*

The first process is Bhabha scattering, that is the elastic scattering of an electron and a positron: $e^+e^- \to e^+e^-$. The tree-level cross section $d\sigma/d\Omega$ picks up a dependence on the area metric perturbations $E^{abcd}$ and on the angle $\phi$. Integrating out this latter, one finds

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2}{s}\left[\frac{1}{2}(1+\cos^2\theta) + \frac{1+\cos^4(\theta/2)}{\sin^4(\theta/2)} - 2\frac{\cos^4(\theta/2)}{\sin^2(\theta/2)} + \right.$$
$$\left. - \frac{\cos^4\theta + 12\cos^2\theta + 3}{8\sin^4(\theta/2)} E^{0303} - \frac{(1+\cos^2\theta)(7+\cos^2\theta)}{32\sin^4(\theta/2)} E^{ij}{}_{ij}\right] \quad (9)$$

for a generic area metric perturbation.

When one considers the area metric perturbations (8) caused by a point mass, one finds that the tree-level cross section loses its dependence on the angle $\phi$ and, actually, becomes proportional to the usual cross section of standard QED. In particular,

$$\frac{d\sigma}{d\Omega} = \Big(1 + 2U(R)\Big)\left[\frac{d\sigma}{d\Omega}\right]_{\text{QED}}, \quad (10)$$

where the proportionality factor $1 + 2U(R)$ depends on the distance $R$ from the point mass.

### 2.2. *The anomalous magnetic moment*

The second process is the scattering of an electron in an external magnetic field. Using the Born approximation on the one-loop non-relativistic scattering amplitude, one finds the interaction potential

$$V(\vec{x}) = 2\left[1 + \frac{\alpha}{2\pi}\left(1 - \frac{E^{ij}{}_{ij}}{12}\right)\right]\left\langle\frac{e\vec{s}}{2m}\right\rangle \cdot \vec{B} \; - \frac{\alpha}{2\pi}\widehat{E}^{\alpha\beta}\left\langle\frac{es_\alpha}{2m}\right\rangle B_\beta \qquad (11)$$

between the magnetic field $\vec{B}$ and the spin of the electron $\vec{s}$.

The first summand in (11) is the usual spin-magnetic field coupling which gives the anomalous magnetic moment in terms of the Schwinger correction $\alpha/2\pi$ times the area-metric-dependent factor $1 - E^{ij}{}_{ij}/12$. Around a point mass, the one-loop anomalous magnetic moment becomes

$$a_{\text{p.m.}}^{(1-\text{loop})} = \frac{\alpha}{2\pi}\Big(1 + U(R)\Big)\,, \qquad (12)$$

whose behavior is depicted in Fig. 1.

The second summand in (11) shows the emergence of a new interaction between the spin and the magnetic field by means of the tracefree tensor $\widehat{E}^{\alpha\beta} := E^{0\alpha0\beta} + E^{ij}{}_{ij}/12$. This qualitatively-new interaction is, however, not present in the case of the area metric perturbations (8) around a point mass.

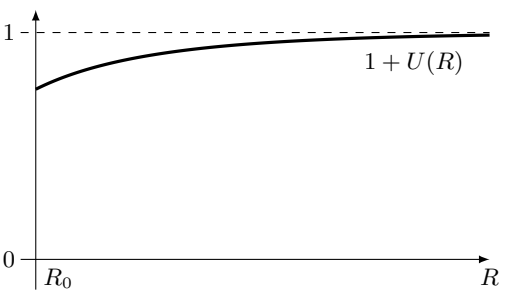

Fig. 1. The position dependence of the anomalous magnetic moment at one loop.

### 2.3. *Hyperfine splitting in hydrogen*

Finally, we consider the hyperfine splitting in the hydrogen atom. The situation is the one depicted in Fig. 2. The trace of the perturbation $E^{ij}{}_{ij}$ is responsible for a stretching of the triplet-singlet separation. The tracefree part $\widehat{E}^{\alpha\beta}$ removes the degeneracy of the triplet states. A quantitative description of these effects can be found in Ref. 4.

For the area metric (8) around a point mass, we see an explicit dependence of the singlet-triplet separation on the distance $R$ from the point mass, whereas the degeneracy of the triplet states is *not* removed.

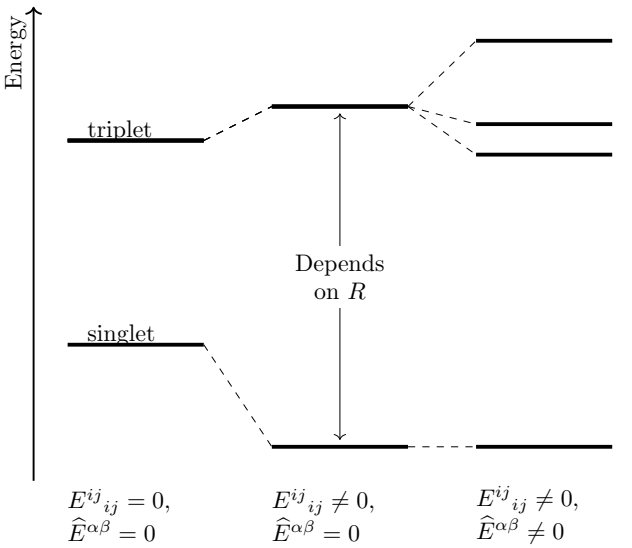

Fig. 2. The hyperfine splitting in the hydrogen atom due to the area metric perturbations.

## Acknowledgments

This talk is based on the paper[4] written in collaboration with Simon Grosse-Holz and Frederic P. Schuller. The results presented in section 2.3 were derived by Simon Grosse-Holz in his Master's thesis.

# Two suprisingly not-so-different employments of bimetric geometry

Alexander A. Wierzba

*Fakultät für Physik, Ludwig–Maximilians–Universität München, München, Bayern 80799, Germany*
**E-mail: alexander.wierzba@gmx.de*

The gravitational closure of given matter field dynamics provides diffeomorphism-invariant dynamics for the very background geometry that is ultralocally employed in the matter action. Conceptual and technical key to this construction is the principal polynomial of the initially given matter field equations, which crucially depends on how exactly the background geometry makes its appearance in the matter action. In this talk, we consider two very different matter theories that employ a background geometry consisting of two Lorentzian metrics in vastly different ways. Applying the gravitational closure mechanism we derive the remarkable result that they share the same underlying gravitational dynamics.

*Keywords*: Bimetric theories; Gravity; Gravitational closure.

## 1. Gravitational Closure

In theoretical physics, one usually postulates separately, on the one hand, dynamics for a collection of matter fields on a particular four-dimensional spacetime manifold and, on the other hand, dynamics for the geometry of that spacetime which is utilized in the matter field dynamics. The prime example for this is the standard model of particle physics with its matter fields, and the — independently postulated — theory of general relativity making dynamical the spacetime metric employed in the standard model Lagrangian. The same reasoning is applied in situations where either different matter theories or different gravity theories are used.[1]

This view, however, is ill-fated, as the two theories — matter and geometry — are not independent of each other. The need for the existence of a well-defined initial value problem of the combined full theory requires the existence and co-evolution of common initial data hypersurfaces. One can show this severely restricts the admissible dynamics for the spacetime geometry.

The *gravitational closure mechanism* provides a way of implementation of these restrictions and allows to *derive* the unique gravitational dynamics for the geometrical background that is compatible with the stipulated matter field theory.[3] Thus, if having been given a matter field theory, one must not postulate the dynamical theory for the geometric background used, but instead calculate that theory.

Indeed, if one starts with Maxwell electrodynamics as the matter field theory and the spacetime metric appearing in its action as the geometric background, application of the gravitational closure mechanism will give rise to the Einstein-Hilbert action of general relativity, with two undetermined constants, the gravitational and the cosmological, appearing as constants of integration in the process.

Similarly, if one now wants to use a different matter theory, one can immediately calculate the gravity theory determining its geometric background.[9]

This contribution will study two specific, considerably different toy model matter theories which both use a geometric background consisting of two spacetime metrics.[6,7] The focus will lie on the calculation of the principal polynomial of these matter field theories, which constitutes the first crucial step of the gravitational closure mechanism. In particular, it will also look at the case of a constrained system of matter field equations and the implications this has for the application of the mechanism.

## 2. Principal Polynomial

The central object underlying the gravitational closure program is the principal polynomial of the matter field theory one takes as a start. Its origin lies in the study of approximate local wave-like solutions to the field equations and the resulting dispersion-relations for massless modes.[4] Having linear field equations of the form

$$\sum_{i=0}^{n} Q^{a_1 \dots a_i}_{\mathcal{AB}}(x) \partial_{a_1 \dots a_i} A^{\mathcal{B}}(x) = 0, \tag{1}$$

for matter fields $A^{\mathcal{B}}$, one can read off, using the highest order derivative term, the *principal symbol* of these equations, as the matrix

$$T(k)_{\mathcal{AB}} := Q^{a_1 \dots a_n}_{\mathcal{AB}}(x) k_{a_1} \dots k_{a_i}, \tag{2}$$

with $k$ being a covector. The *principal polynomial* of the matter field equations is then the cotangent space polynomial given by

$$P(k) := \det\left(T(k)\right). \tag{3}$$

The importance of this polynomial in the study of the matter field theory, stems from the fact that it has to be a *hyperbolic* polynomial everywhere in spacetime in order to ensure the existence of a well-posed initial value problem.[4] Furthermore, it enters the hypersurface deformation algebra, and thus the Poisson algebra, used in the derivations of the gravitational closure mechanism.[3]

## 3. Constrained systems

An important observation is, that the method for calculation of the principal polynomial just described, has to be refined slightly for cases in which one deals with a constrained system of field equations, such as the one presented in section 5.2. In such a case there is information present in the lower derivative order terms of the equations that is of importance to e.g. the question of existence of a well-posed initial value problem. This information, however, is clearly not accessible by considering only the highest order derivative term as in equation (3).

The reason for this is that the field equations in such a case are not in *involutive* form, in which all the information implicitly contained in them is explicitly expressed in the form of additional partial differential equations.

Fortunately, every system of partial differential equations can be brought to involutive form by application of the *Cartan-Kuranishi algorithm.*[5] This method adds to the original system all the implicitly contained information in the form of additional partial differential equations. These additional equations are always satisfied for solutions of the original system of equations and thus do not change the solution space. Furthermore, applying this algorithm also works as a test, of whether or not a system of differential equations is already in involutive form in the first place.

Only after this step has been taken, one can calculate the principal polynomial of the matter field theory, starting from the derived enlarged system of field equations that now contains all necessary information explicitly.

## 4. Principal Polynomial of Non-Quadratic Systems

The enlarged system of partial differential equations derived using the Cartan-Kuranishi algorithm will, if the theory contained constraints, be larger than the original system. In particular, since the original system of equations derived by variation of an action contains as many equations as unknowns, this enlarged system will contain more equations than there are unknowns. Thus, the principal symbol $T(k)$ one reads off from the equations is a non-square matrix. Hence, for such a system, one cannot apply equation (3) to calculate the principal polynomial.

The underlying origin of the determinant in equation (3) is to encode a condition for the *non-maximality* of the rank of $T(k)$. This condition can be written in polynomial form also for a non-square $T(k)$, by either — but not exclusively — one of the three methods presented in the next sections. While all of these will in the end lead to the same principal polynomial, they may differ in the ease of applicability and/or the difficulty of calculations necessary, from case to case.

### 4.1. *Method 1: Elimination of a pure constraint*

The first possibility is to reduce the number of equations by dropping pure constraint equations. That is equations that will only restrict the initial data that may be provided on an initial value surface, but are immediately satisfied everywhere else as a result of the remaining equations of motions.

The process of finding such pure constraints differs from case to case and may at times be tedious. Examples for this approach can be found in Ref. 8 where it is illustrated for example for Proca electrodynamics.

### 4.2. *Method 2: Minors or Gramian matrix*

It is clear that a matrix of arbitrary form has non-maximal rank if and only if all its quadratic minors of maximal size have non-maximal rank, i.e., have determinant zero. Thus, for each such minor $T_i(k)$ one finds a polynomial condition $P_i(k) := \det(T_i(k)) \stackrel{!}{=} 0$, which all have to be satisfied simultaneously. This is the case if and

only if $P(k) := \sum_i P_i(k)^2 \stackrel{!}{=} 0$, where the second expression is, by the theorem of Cauchy-Binet, just the determinant of the Grammian matrix $T(k)^t T(k)$.

### 4.3. *Method 3: Lagrange multipliers*

For each equation $C[A] = 0$ in the enlarged system of field equations that does not follow directly from variation, but is added during the course of the involutive completion, one is free to add a term $\lambda C[A]$ to the Lagrangian, introducing a Lagrange multiplier $\lambda$. This does not change the solution space of the matter field theory, as we are merely expressing explicitly, at the level of the Lagrangian, equations that have to be satisfied as a result of the original field equations anyway.

For each equation that was added to the original system, one thus introduces one new unknown quantity, the corresponding Lagrange multiplier. Varying this new Lagrangian and reading off the principal symbol of the resulting equations will thus give rise to a quadratic matrix and one can use the expression from equation (3) for calculating the principal polynomial.

## 5. Bimetric Matter Theories

As a possible model application for the gravitational closure mechanism and in particular to showcase the importance and possible implications of the necesssary application of the Cartan-Kuranishi algorithm, we will consider two — at the first glance — completely different matter theories, which both employ a geometric background consisting of two metric tensor fields.

### 5.1. *Bi-Klein-Gordan theory*

The first bimetric matter theory is one for two scalar fields $\varphi$ and $\psi$, with dynamics being governed by the action

$$\mathcal{S}_{\mathrm{BKG}}\left[\varphi,\psi;g,h\right] = \int \mathrm{d}^4x \, \left(\sqrt{-g}\, g^{ab}\left(\partial_a\varphi\right)\left(\partial_b\varphi\right) + \sqrt{-h}\, h^{ab}\left(\partial_a\psi\right)\left(\partial_b\psi\right)\right), \qquad (4)$$

combining two individual Klein-Gordan actions. However each of the scalar fields couples to a different spacetime metric.

Variation of the action gives rives to the matter field equations

$$0 = \partial_a\left(\sqrt{-g}g^{ab}\partial_b\varphi\right), \qquad (5a)$$

$$0 = \partial_a\left(\sqrt{-h}h^{ab}\partial_b\psi\right), \qquad (5b)$$

which, upon application of the Cartan-Kuranishi algorithm, are found to be in involutive form, allowing to directly read off the principal symbol

$$T_{\mathrm{BKG}}(k) = \begin{pmatrix} \sqrt{-g}g^{ab}k_ak_b & 0 \\ 0 & \sqrt{-h}h^{ab}k_ak_b \end{pmatrix}. \qquad (6)$$

Upon taking the determinant and dropping the density factor (which is not of importance for the calculations of the gravitational closure mechanism), one thus finds the principal polynomial

$$P_{\mathrm{BKG}}(k) := g^{ab}h^{ab}k_a k_b k_c k_d. \tag{7}$$

### 5.2. *Refined Proca Theory*

The second matter theory making use of a bimetric geometry is a refinement of Proca theory for a covector field $A$. Instead of adding an "isotropic" mass term $\frac{m}{2}g^{ab}A_aA_b$ to the Maxwell Lagrangian, one introduces an "anisotropic" mass term utilising a second spacetime metric, giving rise to the action

$$\mathcal{S}_{\mathrm{RPT}}\left[A; g, h\right) = \int \mathrm{d}^4x\,\sqrt{-g}\left(-\frac{1}{4}g^{ab}g^{cd}F_{ac}F_{bd} + \frac{m}{2}h^{ab}A_aA_b\right), \tag{8}$$

and upon variation the matter field equations

$$0 = \partial_a\left(\sqrt{-g}g^{ab}g^{cd}F_{bd}\right) + m\sqrt{-g}h^{cd}A_d. \tag{9}$$

Two crucial differences to the first example theory are, first, the presence of a lower order derivative term in the field equations and, second, the highest order derivative term being completely determined by only one of the two metrics. This may lead one to the, as it will turn out wrong, assumption that the other metric $h$ cannot enter into the principal polynomial.

However, most importantly, these field equations constitute a constrained system and application of the Cartan-Kuranishi algorithm will lead to the enlarged system of field equations

$$0 = \partial_a\left(\sqrt{-g}g^{ab}g^{cd}F_{bd}\right) + m\sqrt{-g}h^{cd}A_d, \tag{10a}$$

$$0 = \partial_c\left(\sqrt{-g}h^{cd}A_d\right), \tag{10b}$$

$$0 = \partial^2_{mc}\left(\sqrt{-g}h^{cd}A_d\right). \tag{10c}$$

Using one of the proposed methods for calculating the principal polynomial, one finds that it takes the form

$$P_{\mathrm{RPT}}(k) := g^{ab}h^{ab}k_a k_b k_c k_d, \tag{11}$$

which is identical to the one found in the first model theory. In particular, one realises that the second metric $h$ does indeed enter into the principal polynomial as a result of the necessary application of the Cartan-Kuranishi algorithm to get an involutive set of field equations.

## 6. Conclusions

The previous sections showed that remarkably the two, very differently looking employments of a bimetric geometric background, have the same principal polynomial. Thus they provide the same starting point for the application of the gravitational

closure mechanism. As a result one will find that the gravitational dynamics governing the two theories are indeed the same. Using the mechanism to derive the linearised version of these dynamics, one will end up with equations containing 13 scalar constants, taking the role of the two constants found in general relativity.[6,7]

The study of the refined Proca theory furthermore showcased the importance of applying the Cartan-Kuranishi algorithm before trying to calculate the principal polynomial, and thus also before applying of the gravitational closure mechanism. In particular, this study demonstrates the impact that the addition of lower order derivative terms can have on the involutivity and thus on the calculation of the principal polynomial.

Such lower order terms also appear in that matter theory which is currently considered to be the most likely one to describe the physical reality, the standard model of particle physics. Therefore, if wanting to give dynamics to the spacetime metric (or possibly also to additional parameters like mass matrices or coupling constants) appearing in the standard model lagrangian, it is vital to apply the Cartan-Kuranishi algorithm here as well.[7]

# Causal structure of matter field equations

Florian Wolz

*Institute for Theoretical Physics, University of Hannover,*
*Appelstrasse 2, D-30167 Hannover, Germany*
**E-mail: florian.wolz@fau.de*

The causal structure of given matter field equations provides the crucial input from which the constructive gravity program starts. It is therefore of paramount importance to successfully address a number of subtle issues, which do not arise in the simplest examples in the mathematical literature, but urgently must be taken into account for physically realistic models. This talk presents a recipe to handle these complications. In particular, we will focus on how to deal with non-scalar systems of equations, gauge symmetries and implicit information that needs to be made explicit before the causal structure, encoded in the so-called principal polynomial, can be calculated correctly.

*Keywords*: Constructive Gravity

## 1. Introduction

The causal structure of field equations tells every physicist what events are connected to which events, and is intimately linked to the notion of initial value formulations. Not any mathematical theory, in the form of a partial differential equation, can be used to formulate a predictive theory, as is demonstrated already in the case of Maxwell electrodynamics on a metric background: only for a metric of Lorentzian signature we find an initial value formulation. This was used in the whole standard model of particle physics and general relativity by making sure that the causal structure does not differ from the causality that light propagates on. Unfortunately, this process led to the idea that as long as a Lagrangian is constructed in a Lorentz-invariant way, the resulting equations of motion will possess the well-known causal structure.

However, a surprising example that a Lagrangian that is constructed in a fully Lorentz-invariant fashion but still has a causality that differs from the standard Lorentzian causal structure was given by Velo-Zwanziger[1]. The analyzed Lagrangian is a modification of covariant Maxwell electrodynamics by a Proca mass term and a quartic term in the covector field $A$, i.e.

$$\mathcal{L}_{\mathrm{VZ}}[A] = -\frac{1}{4}F_{ab}[A]F^{ab}[A] + \frac{1}{2}m^2A^2 + \frac{1}{2}\lambda\left(A^2\right)^2 \tag{1}$$

The causal structure, encoded in the principal polynomial that describes the characteristic surfaces of the equations of motions, is given by

$$P(n) = (n^2)^3 \cdot \left[n^2 + \lambda m^{-2}(n^2A^2 + 2(n\cdot A)^2)\right] . \tag{2}$$

This is a product of the standard term $n^2$ and a modification term, resulting in massless modes propagating with another speed of light that – worst-of-all – depends on the particular solution $A_a$ to the equations of motion. Although the highest derivative order coefficient is the input for the calculation of the principal polynomial

and is seemingly not influenced by the modification terms, Velo-Zwanziger showed that one can derive a constraint that *does* change the characteristic surfaces.

Nowadays this is not surprising at all and is related to the fact that the equations of motion are no *involutive differential equations*. Intuitively, this type of differential equations has all information that is required to construct a formal power series solution explicitely present. In other words, they do not contain any *hidden* information that needs to be extracted by tedious steps, as is the case in the Velo-Zwanziger example. Due to the *Cartan-Kuranishi algorithm* it turns out, that any differential equation can be brought into involutive form in finitely many steps.

This article will first present the notion of involutive differential equations and explain the Cartan-Kuranishi algorithm [4]. Afterwards we tackle a practical example that represents a generalization of the case analyzed by Velo-Zwanziger.

## 2. Involutive differential equations

Before we can properly introduce the notion of an involutive differential equation, let us first give some definitions of the underlying mathematical theory. A system of differential equation – in the following simply referred to as differential equation – is formulated over *independent variables* $x^1, \ldots, x^n$ and *dependent variables* $u^1, \ldots u^m$. In the case of point particle equations of motions the only independent variable is the time coordinate $t$ and the generalized coordinates $q^i$ being the dependent variables. For field theories, the independent variables are given by spacetime points and the field values are the dependent variables of the theory. In the case of the system of differential equations called the gravitational closure equations of the constructive gravity program [3] the independent variables correspond to the local degrees of freedom of the gravitational field and their derivatives and the dependent variables are the coefficients of the gravitational Lagrangian.

Locally we treat a differential equations as a collection of implicit functions that depend on the independent variables $x^i$, the dependent variables $u^\alpha$ and their derivatives, i.e.

$$\Phi^\tau(x, u^\alpha, p^\alpha_\mu) = 0\,, \tag{3}$$

where $p^\alpha_\mu = \frac{\partial^{|\mu|} u^\alpha}{\partial x^\mu}$ are the corresponding derivatives in the direction of the independent variables, and $\mu$ being a multi-index. The order of the differential equations will be denoted by $q$ in this article.

An object of incredible importance is the *geometric symbol* of an differential equation. It is defined by the linear equation [2]

$$\mathcal{M}_q: \quad \sum_{|\mu|=q} \frac{\partial \Phi^\tau}{\partial p^\alpha_\mu}\, v^\alpha_\mu = 0 \tag{4}$$

which is the kernel of the coefficient $Q^{\tau\,\mu}_{\ \ \alpha} := \frac{\partial \Phi^\tau}{\partial p^\alpha_\mu}$. This matrix can be brought into reduced row echelon form in order to read off which coefficients $p^\alpha_\mu$ can be solved

for in the differential equation. For everything that follows it suffices to summarise this information in a collection of coefficients that are defined in the following way:

For each column of the matrix $Q$, i.e. the different derivatives of the dependent variables, we associate a *class*. For each multi-index $\mu = [i_1, \ldots, i_n]$ we define its class as the index $k$ of the first non-vanishing $i_k$. Then the columns of $Q$ can be sorted in a class respecting order (from highest to lowest), and after bringing the matrix into row echelon form we can look for the first non-zero entry of each row. The corresponding $p^\alpha_\mu$ of this entry is called the leader of the row of class $k$. Then let $\beta^{(k)}_q$ denote the leaders of a row of class $k$, i.e. the number of highest order derivative terms of class $k$ that could be solved for[2].

The symbol of the differential equation is then called *involutive* if the rank of the prolongation of the differential equation, i.e. the derivatives of the differential equation $\Phi^\tau$ by all independent variables, can be determined as the following sum[2]

$$\operatorname{rank} \mathcal{M}_{q+1} = \sum_{k=1}^{n} k \cdot \beta^{(k)}_q \tag{5}$$

Is this the case, one can derive a recursion relation to calculate the coefficients $\beta^{(k)}_{q+1}$ directly from the coefficients $\beta^{(k)}_q$, meaning that we can completely predict what coefficients we can solve for in the prolongations of the differential equation. If the symbol $\mathcal{M}_q$ is involutive, it turns out that the same will be true for all further prolongations $\mathcal{M}_{q+r}$, for any $r \geq 0$. Furthermore, it can even be shown that there always exist an integer $r$ such that the symbol $\mathcal{M}_{q+r}$ will be involutive, and thus all further prolongations. Note that this, however, does increase the differential order of the equation. In practise, this can lead to the scenario where a seemingly second order field equation is in fact of higher order and is then possible equipped with Ostrogradski ghosts[6].

"Hidden information" can still be contained in the differential equations. If we can algebraically manipulate the prolongation of the differential equations – equations of order $q+1$, such that we obtain an equation of order $q$ then this is considered an *integrability condition* and needs to be added to the system[2]. Of course, no new information is added, it is simply made explicit and can then properly be considered in all further calculations – as in the calculation of the causal structure.

If we revealed hidden integrability conditions the symbol of the equation at order $q$ possibly changed, so we need to make sure again that it is involutive in the way described above. Once the symbol is involutive again, we can search for new integrability conditions. If no condition exists, then it can be shown that for no further prolongation an integrability condition can be found: all hidden information is made explicit and the differential equations (with all the integrability conditions identified) is called *involutive*[2].

The algorithm to bring the differential equation into involutive form is the so-called *Cartan-Kuranishi* algorithm and can be performed for any differential equations[4]. Once this step is performed all information that can contribute to

the characteristic surfaces and the causal structure of the differential equation is present.

As a result, we can then properly calculate the principal polynomial of the differential equation and obtain the causal structure. If one applies all the steps of the Cartan-Kuranishi algorithm for the Euler-Lagrange equations of the Lagrangian considered by Velo-Zwanziger, it turns out that there are indeed hidden integrability conditions. Calculation of the principal polynomial then recovers their result. Note, however, that the result was obtained in a completely algorithmic fashion.

## 3. Example: Generalizations of Maxwell electrodynamics

We now want to put the algorithm presented above to good use by analyzing a specific example. The setup is the following:

$$\mathcal{L}[A;\eta) = -\frac{1}{4}F^{ab}F_{ab} + V(A)\,, \tag{6}$$

i.e. we take the Lagrangian of Maxwell electrodynamics on a flat Minkowskian background $\eta$ and add an arbitrary function of the covector field $A_m$.

The equations of motions are calculated by variation of the action with respect to $A$. This yields a differential equation of $2^{\text{nd}}$ order

$$0 = 2\,\eta^{m[n}\eta^{p]a}\partial_{mn}A_p + \frac{\partial V}{\partial A_a}(A)\,. \tag{7}$$

In this case, by the choice of our function $V$, we see that the geometric symbol coincides with the term obtained for standard electrodynamics. To obtain the four $\beta_2^{(i)}$ coefficients, we first pick an order for our independent variables. Since we want to solve for as many $\ddot{A}_m$ terms as possible in order to be able to distinguish between evolution equations and constraints, we make the choice $(x^\alpha, t)$, i.e. time comes *after* the spatial components and has the highest class. As the next step, we need to write down the geometric symbol and sort the columns in our chosen order. From this one finds that the coefficients read

$$\beta_2^{(1)} = 0 \qquad \beta_2^{(2)} = 0 \qquad \beta_2^{(3)} = 1 \qquad \beta_2^{(4)} = 3 \tag{8}$$

This just reflects the well-known fact that in Maxwell's equations we have three evolution equations and one constraint. In order to check if the geometric symbol is involutive, we need to calculate the rank at the next order and see if it is given by

$$\text{rank}\mathcal{M}_3 = \sum_{k=1}^{4} k\cdot\beta_2^{(k)} = 15 \tag{9}$$

Although tedious, the calculation can easily be performed by computer algebra software, with the result that the symbol is indeed involutive.

The next step consists in checking for hidden integrability conditions. By considering the divergence of the equations of motion (7) we find the integrability

condition

$$0 = \frac{\partial^2 V}{\partial A_m \partial A_n}(\partial_n A_m) =: H^{mn}(\partial_n A_m)\,, \tag{10}$$

which is of 1st order. This means we have to add it to the system to make the information explicit. For our new system, we repeat the steps from above, i.e. check if the symbol is involutive. Since the new equation (10) is of 1st order, the symbol remains unchanged and so it is still involutive. But clearly, if we prolong the integrability condition (10) we find another 2nd order equation that also has to be added to the system. The geometric symbol of the system has then changed, so we need to read off the $\beta_2^{(k)}$ coefficients again. We find that

$$\beta_2^{(1)} = 1 \qquad \beta_2^{(2)} = 1 \qquad \beta_2^{(3)} = 2 \qquad \beta_2^{(4)} = 4 \tag{11}$$

and that the geometric symbol is still involutive. If we now check for integrability conditions we find that there are no further conditions. As a result our final system

$$\begin{aligned} 0 &= 2\eta^{m[n}\eta^{p]a}(\partial_{mn}A_p) + \frac{\partial V}{\partial A_a}(A) \\ 0 &= H^{mn}(A)(\partial_n A_m) \\ 0 &= H^{mn}(A)(\partial_{np}A_m) + (\partial_p H^{mn}(A))(\partial_n A_m) \end{aligned} \tag{12}$$

is involutive and thus, all hidden information is made explicit.

We can now analyze the causal structure of this system. By making a Wentzel-Kramers-Brillouin approximation to lowest order via

$$A_m(x) = \mathrm{Re}\left\{\exp\left(iS(x)/\lambda\right)\left[a_m(x) + \mathcal{O}(\lambda)\right]\right\}\,, \tag{13}$$

only the highest derivative order terms survive and the derivative operators are replaced by the covector $n_a$ that is the derivative of the eiknonal function $S(x)$. This equation has non-trivial solutions in case that the principal polynomial, defined by

$$P(n) = \det\left(T^t(n)\cdot T(n)\right)\,, \tag{14}$$

vanishes, where $T$ are the coefficients of the differential equation in front of the amplitudes $a_m$ and the operation $t$ denotes the matrix transpose. One finds that in general we have the principal polynomial

$$P(k) = (\eta^{mn}k_m k_n)^3 \cdot (H^{pq}(A)k_p k_q)\,. \tag{15}$$

This gives, if we eliminate repeated factors, a principal polynomial of degree 4. We see that in general this is not the standard Lorentzian causal structure, but resembles the causality of a bi-metric theory, with the second metric being constructed by the four-potential $A$ itself. This particularly indicates that in this case the dichotomy of matter fields and a geometric field $\eta$ breaks down, since $A$ acts as both.

Note that in order to have a well-defined initial value problem and a canonically quantizable theory it is necessary that all factors of the principal polynomial are hyperbolic. This tells us that $H^{pq}$ has to be of Lorentzian signature[5].

Only for two special cases we recover the standard principal polynomial of the standard model: Since only the $2^{\text{nd}}$ derivative of $V$ appears in the principal polynomial, any linear term in the gauge field clearly obviously leaves the causal structure unchanged. This is not surprising, since this just contributes a coupling of the covector field $A_m$ to a current, i.e.

$$V(A) = j^m A_m \,. \tag{16}$$

The other case occurs in case the second derivative is proportional to the flat metric $\eta$, i.e.

$$\frac{\partial^2 V}{\partial A_p \partial A_q} \propto \eta^{pq} \,. \tag{17}$$

In this case $V$ only contributes as a repeated factor to the principal polynomial. This corresponds to a Proca mass term

$$V(A) = m^2 \, \eta^{ab} A_a A_b \,. \tag{18}$$

While this does break the $U(1)$ gauge invariance – which can be seen in the involutive system from the $\beta_2^{(4)}$ coefficient, since we now have four evolution equations and no constraint – the causal structure is not altered.

## 4. Conclusion

In this article, we presented how to perform the Cartan-Kuranishi to bring differential equations, especially equations of motions into involutive form in order to make all hidden information in the differential equations explicit. This is necessary in order to correctly calculate the principal polynomial that encodes the causal structure of the theory one considers.

We applied this to the example of a modification of Maxwell electrodynamics by adding an arbitrary function $V(A)$. If $V$ is not a linear term in $A_a$, i.e. a coupling to a current or a Proca mass term, in general the causal structure is modified. If one had not revealed all the hidden integrability conditions of the equations of motion, one would not have ended up with the result.

**THE MARCEL GROSSMANN MEETINGS**

**Series Editor:** REMO RUFFINI

**Publications in the Series of Proceedings**

Proceedings of the Fifteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2018)
Edited by E.S. Battistelli, R.T. Jantzen, R. Ruffini
World Scientific, 2021

Proceedings of the Fourteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2015)
Edited by M. Bianchi, R.T. Jantzen, R. Ruffini
World Scientific, 2017

Proceedings of the Thirteenth Marcel Grossmann Meeting on General Relativity
(Stockholm, Sweden, 2012)
Edited by K. Rosquist, R.T. Jantzen, R. Ruffini
World Scientific, 2015

Proceedings of the Twelfth Marcel Grossmann Meeting on General Relativity
(Paris, France, 2009)
Edited by T. Damour, R.T. Jantzen, R. Ruffini
World Scientific, 2012

Proceedings of the Eleventh Marcel Grossmann Meeting on General Relativity
(Berlin, Germany, 2006)
Edited by H. Kleinert, R.T. Jantzen, R. Ruffini
World Scientific, 2007

Proceedings of the Tenth Marcel Grossmann Meeting on General Relativity
(Rio de Janiero, Brazil, 2003)
Edited by M. Novello, S. Perez-Bergliaffa, R. Ruffini
World Scientific, 2005

Proceedings of the Ninth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2000)
Edited by V.G. Gurzadyan, R.T. Jantzen, R. Ruffini
World Scientific, 2002

Proceedings of the Eighth Marcel Grossmann Meeting on General Relativity
(Jerusalem, Israel, 1997)
Edited by T. Piran
World Scientific, 1998

Proceedings of the Seventh Marcel Grossmann Meeting on General Relativity
(Stanford, USA, 1994)
Edited by R.T. Jantzen and G.M. Keiser
World Scientific, 1996

Proceedings of the Sixth Marcel Grossmann Meeting on General Relativity
(Kyoto, Japan, 1991)
Edited by H. Sato and T. Nakamura
World Scientific, 1992

Proceedings of the Fifth Marcel Grossmann Meeting on General Relativity
(Perth, Australia, 1988)
Edited by D.G. Blair and M.J. Buckingham
World Scientific, 1989

Proceedings of the Fourth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 1985)
Edited by R. Ruffini
World Scientific, 1986

Proceedings of the Third Marcel Grossmann Meeting on General Relativity
(Shanghai, People's Republic of China, 1982)
Edited by Hu Ning
Science Press – Beijing and North-Holland Publishing Company, 1983

Proceedings of the Second Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1979)
Edited by R. Ruffini
North-Holland Publishing Company, 1982

Proceedings of the First Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1975)
Edited by R. Ruffini
North-Holland Publishing Company, 1977

## SPONSORS

International Center for Relativistic Astrophysics Network (ICRANet)
International Center for Relativistic Astrophysics (ICRA)
International Centre for Theoretical Physics (ICTP)
Istituto Nazionale di Astrofisica (INAF)
International Union of Pure and Applied Physics (IUPAP)

## FREEDOM OF MOVEMENT FOR SCIENTISTS

The Marcel Grossman Meetings were founded with the premise that scientists of all nations have a right to meet to exchange knowledge independent of national borders. As such we affirm the IUPAP declaration: "To secure IUPAP sponsorship, the organisers have provided assurance that MG15 will be conducted in accordance with IUPAP principles as stated in the IUPAP resolution passed by the General Assembly in 2008. In particular, no bona fide scientist will be excluded from participation on the grounds of national origin, nationality, or political considerations unrelated to science."

## ACKNOWLEDGEMENTS

We acknowledge the outstanding job done before, during and after the meeting by the ICRANet/ICRA administrative and secretarial staff: Cristina Adamo, Silvia Latorre, Elisabetta Natale, and Cinzia di Niccolo and the conference agency support of Sistema Congressi (Marisa Santori, Ilaria Coccato, Lorena Moretti). Finally this meeting and its proceedings could not have functioned without the dedicated IT support of the ICRA system manager Vittorio Vannini for every MG meeting this century and the ICRANet system manager Gabriele Brandolini, with some temporary assistance from Valerio Antonucci and Damiano Verzulli.

## ORGANIZING BODIES OF THE FIFTEENTH MARCEL GROSSMANN MEETING:

### INTERNATIONAL ORGANIZING COMMITTEE

David Blair, Yvonne Choquet-Bruhat, Thibault Damour, Paolo De Bernardis, Francis Everitt, Riccardo Giacconi, Theodor Haensch, Stephen Hawking, Marc Henneaux, Christine Jones Forman, Roy Kerr, Hagen Kleinert, Jutta Kunz, Claus Laemmerzahl, Malcolm Longair, Tsvi Piran, Jorge Rueda, Remo Ruffini (Chair), Misao Sasaki, Humitaka Sato, Rashid Sunayev, Gerard 't Hooft, Steven Weinberg, Shing-Tung Yau

### LOCAL ORGANIZING COMMITTEE

Amati, L., Angelantonj, C., Barbiellini, G., Bassan, M., Battistelli, E. S. (chair), Belinski, V.A., Belli, L., Benedetti, R., Bernabei, R., Bianchi, M., Bianco, C.L. (co-chair), Bini, D., Buchert, T., Burgio, F., Capozziello, S., Chakrabarti, S.K., Chardonnet, P., Dall'Agata, G., De Angelis, A., De Bernardis, P., Della Valle, M., Di Virgilio, A., Frasca S., Fraschetti, F., Fré, P., Frontera, F., Giavalisco, M., Giommi, P., Gionti, G., Ingrosso, G., Jantzen, R.T., Jetzer, P., Lee, H.-W., Lerda, A., Liberati, S., Longo, R., Luzzi, G., Mandolesi, N., Marmo, G., Menotti, P., Merafina, M., Morselli, A., Pani, P., Pelster, A., Piacentini, F., Pian, E., Procesi, C., Quevedo, H., Ricci, F., Riccioni, F., Rosati, P., Ruffo, S., Scarpetta, E.V., Tavani, M., Titarchuk, L.G., Vereshchagin, G.V., Xue, S.-S., Zen Vasconcellos, C.

### INTERNATIONAL COORDINATING COMMITTEE

ALBANIA: Hafizi, M. ARGENTINA: Arguelles, C., Ghezzi, C.R., Mirabel, F., Romero, G.E. ARMENIA: Sahakyan, N. AUSTRALIA: Blair, D., Ju, L., Lun, A., Manchester, D., Melatos, A., Quinn, P., Scott, S.M., Steele, J.D., AUSTRIA: Aichelburg, P.C., Schindler, S. BELARUS: Kilin, S., Minkevich, A.V., Siutsou, I.A. ## MARCEL GROSSMANN AWARDS

## FIFTEENTH MARCEL GROSSMANN MEETING

### Institutional Award

Planck Scientific Collaboration (ESA) (ESA)

*"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding Bpolarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy."*
— presented to its Director General Johann-Dietrich Woerner

### Institutional Award

Hansen Experimental Physics Laboratory (HEPL) at Stanford University

*"for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology."*

### Individual Awards

Lyman Page
*"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and who now leads the Atacama Cosmology Telescope as its project scientist."*

Rashid Alievich Sunyaev
*"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe."*

Shing-Tung Yau
*"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics ."*

Each recipient is presented with a silver casting of the TEST sculpture by the artist A. Pierelli. The original casting was presented to His Holiness Pope John Paul II on the first occasion of the Marcel Grossmann Awards.

**FOURTEENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

European Space Agency (ESA)

**Individual Awards**

Frank Chen Ny Yang, Tsung Dao Lee, Ken'ichi Nomoto, Martin Rees, Yakov G. Sinai, Sachiko Tsuruta

**THIRTEENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

ALBANOVA UNIVERSITY CENTER, STOCKHOLM

**Individual Awards**

David Arnett, Vladimir Belinski and Isaak M. Khalatnikov, Filippo Frontera

**TWELFTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Institut des Hautes Études Scientifique (IHES)

**Individual Awards**

Jaan Einasto, Christine Jones, Michael Kramer

**ELEVENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Freie Universität Berlin

**Individual Awards**

Roy Kerr, George Coyne, Joachim Trümper

**TENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

CBPF (Brazilian Center for Research in Physics)

**Individual Awards**

Yvonne Choquet-Bruhat, James W. York, Jr., Yval Ne'eman

**NINTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Solvay Institutes

**Individual Awards**

Riccardo Giacconi, Roger Penrose, Cecile and Bryce DeWitt

**EIGHTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Hebrew University of Jerusalem

**Individual Awards**

Tullio Regge, Francis Everitt

**SEVENTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Hubble Space Telescope Institute

**Individual Awards**

SUBRAHMANYAN CHANDRASEKHAR, JIM WILSON

**SIXTH MARCEL GROSSMANN MEETING**

**Institutional Award**

Research Institute for Theoretical Physics (Hiroshima)

**Individual Awards**

Minora Oda, Stephen Hawking

**FIFTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The University of Western Australia

**Individual Awards**

Satio Hayakawa, John Archibald Wheeler

**FOURTH MARCEL GROSSMANN MEETING**

**Institutional Award**

The Vatican Observatory

**Individual Awards**

William Fairbank, Abdus Salam

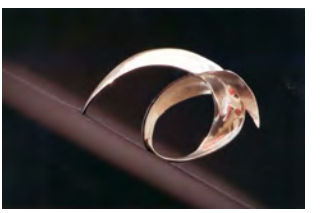

Fig. 1. TEST: sculpture by Attilio Pierelli

**PLANCK SCIENTIFIC COLLABORATION (ESA)**
presented to **Jean-Loup Puget**, the Principal Investigator of the High Frequency Instrument (HFI).

*"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding B-polarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy"*

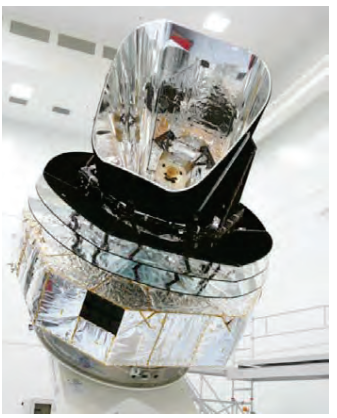

*Photo of the Planck satellite (Courtesy of ESA).*

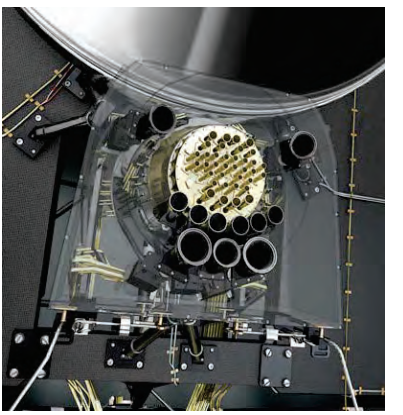


*Planck focal plane (Courtesy of ESA)*

Planck ESA's mission, was designed to image the temperature and polarization anisotropies of the CMB over the whole sky, with unrivalled angular resolution and sensitivity, pushing the technology to unprecedent limits. In the framework of the highly precision experimental cosmology the legacy Planck results on testing theories of the early universe and the origin of cosmic structure, has provided a major source of information crucial to many cosmological and astrophysical issues. Planck carried out two instruments:

- the High Frequency Instrument (HFI), Principal Investigator: Jean Loup Puget;
- the Low Frequency Instrument (LFI), Principal Investigator: Nazzareno Mandolesi.

The instruments were complementary and using different technology to cross check independently final results and systematic errors. They worked together to produce the overall mission results. The Planck space mission (ESA) has been a wonderful example of Team effort in a large international collaboration, involving scientific, technical and managerial aspects. The unprecedented accuracy of the Planck measurements have established new standards in the determination of fundamental cosmological parameters, as well as new insight in Galactic and extragalactic astrophysics. The Planck full-sky maps in temperature and polarization will remain a lasting legacy for at least dozen years to come. More than 100 papers signed by Planck collaboration have already 30 000 citations in scientific literature. The success of Planck HFI and LFI would not have been possible without the contribution of a large number of talented and dedicated scientists and engineers from many countries of Europe, USA and Canada. HFI was designed to produce high-sensitivity, multi-frequency measurements of the diffuse radiation permeating the sky in all directions in the frequency range of 84 GHz to 1 THz cooled at 100 mK. The instrument consisted of an array of 52 bolometric detectors placed in the focal plane of the telescope. LFI, a microwave instrument, was designed to produce high-sensitivity, multi-frequency measurements of the microwave sky in the frequency range of 27 to 77 GHz. The instrument consisted of an array of 22 tuned radio receivers located in the focal plane of the telescope, cooled at 20 K.

*Jean Loup Puget - PI of the HFI.*

*Nazzareno Mandolesi - PI of the LFI.*

## HANSEN EXPERIMENTAL PHYSICS LABORATORY AT STANFORD UNIVERSITY

presented to **Leo Hollberg**, HEPL Assistant Director

*"to HEPL for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology"*

### Brief History of Stanford's HEPL and Ginzton Laboratories

1947: WW Hansen (right) and team with the Mark I linear accelerator

In 1947, working in the Stanford Physics Department's Microwave Lab, Physics Professor, William W. Hansen and his research team, along with Assistant Professor of Physics and microwave expert, Edward L. Ginzton, completed development on the world's first traveling wave electron linear accelerator. Dubbed the Mark I (see photo) it generated a 1.5 million electron volt (MeV) beam. Hansen's entire report to the U.S. Office of Naval Research (ONR) that funded the project was just one sentence: "We have accelerated electrons."

This successful first step in linear electron acceleration spawned the birth of Stanford's High Energy Physics Lab (HEPL) and Ginzton labs. In 1990, HEPL was renamed the WW Hansen Experimental Physics Lab (also HEPL). HEPL and Ginzton were setup as Stanford's first independent labs. They were organized to facilitate cross-disciplinary research, enabling scientists, engineers, staff and students to work towards common research goals using cutting edge lab equipment and technologies on medium-scale projects. For the past 70 years, the HEPL and Ginzton Labs have spearheaded Stanford's leadership in cross-disciplinary physics and become nurturing homes to a variety of physics-based, research projects: including the following examples:

### Robert Hofstadter's Nobel Prize & Later Work

In 1961, Stanford Professor Robert Hofstadter was awarded the Nobel Prize for his HEPL Mark III Linear Accelerator work on nuclear form factors (nucleons). In the 1980s, Hofstadter became interested in astrophysics and helped design the EGRET telescope in the NASA Compton Gamma Ray Observatory (CGRO).

### Gravity Probe B (GP-B)

2003: Francis Everitt (left) and Brad Parkinson holding a GP-B gyro

In 1959, Physics Department Chair, Leonard Schiff, became interested in using gyroscopes in a satellite to measure the Earth's geodetic effect and the miniscule frame-dragging effect predicted by Albert Einstein's general theory of relativity. Schiff discussed this project with Stanford cryogenic physicist, William Fairbank, and gyroscope expert, Robert Cannon (Aero-Astro department).

In 1962, Fairbank invited post-doc, Francis Everitt, to join the research effort. The team sent a proposal to NASA's Office of Space Sciences requesting funding to develop gyroscopes and a satellite to carry out this unprecedented test. It took 40 years of R&D at Stanford and other places to create and ready the cryogenic satellite and all of its cutting-edge technologies for launch. In 1975, Leonard Schiff moved the GP-B program to HEPL, breathing new life into the lab. In 1981, Francis Everitt became Principal Investigator, a position he still holds. In 1984, Brad Parkinson became Project Manager and a Co-PI, along with Co-PI's John Turneaure and Daniel DeBra.

On 20 April 2004, GP-B launched from Vandenberg AFB into a polar orbit. Data collection began on 28 August 2004 and lasted 50 weeks. Data analysis took five years in order to remove confounding factors in the data. The final results, published in PRL on 31 May 2011, yielded highly accurate geodetic and frame dragging measurements, with 0.28% and 19% margins of error, respectively.

### GPS Spinoffs from GP-B

In the 1990s, Brad Parkinson's research on GPS solutions for positioning the GP-B satellite led to two revolutionary spin-off projects: 1) Wide Area Augmentation System (WAAS) provides highly precise positioning accuracy and itegrity for navigation and the automatic landing of airplanes and 2) Precision Farming adding GPS technology to tractors has enabled the automation of many aspects of farming and has spawned a $1 billion/year industry.

### Fermi Gamma Ray Space Telescope (GLAST)

Peter Michelson, Fermi LAT Principal Investigator

Stanford Physics Professor, Peter Michelson, is a former HEPL Director and the Principal Investigator for the Large Area Telescope (LAT) on board NASA's Fermi Gamma Ray Space Telescope, the successor to CGRO/EGRET. Launched on 11 June 2008, Fermi has been highly successful mapping the gamma-ray sky. Under Michelson's guidance, HEPL's collaborations with Italy are noteworthy. The development of cryogenic bar detectors of gravitational waves, in collaboration with Edoardo Amaldi and his colleagues, established new stringent upper limits to the gravitational waves incident on the Earth. Likewise, the Fermi LAT was developed by a collaboration between Italian INFN and ASI, NASA, and international partners in France, Japan, and Sweden, and used tracking detectors developed, integrated, tested, and qualified for the mission by Italy. GP-B provided the first evidence of frame-dragging on a spinning, superconducting gyroscope. The Fermi detector offers the potential of seeing, through the GeV emission in the Binary Driven Hypernova subclass of long GRBs, the emission from a newly born Black Hole, originating in the induced gravitational collapse of a supernova hypercritically accreting on a binary neutron star companion.

### Robert Byer's LIGO and ACHIP Projects

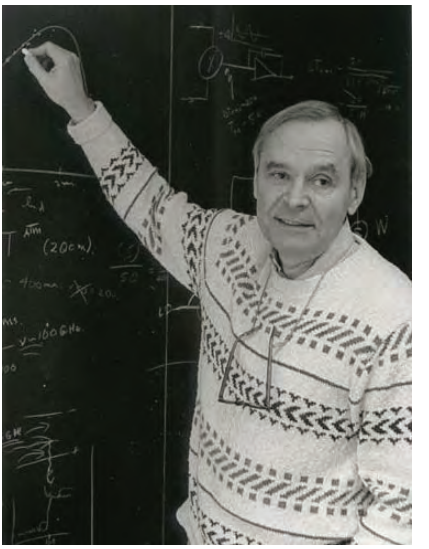
Professor Robert Byer

Robert Byer, former Stanford Dean of Research and former HEPL Director, nurtured the GP-B, GPS and Fermi programs to success during his tenure. He is currently an Applied Physics Professor specializing in lasers and optics. His LIGO Group provided seismic isolation, coatings and materials for the LIGO observatories. His ACHIP project is developing a particle accelerator on a microchip—bringing the HEPL/Ginzton Labs full circle to Hansen's 1947 research.

Professor **LYMAN PAGE**

*"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and as founding director of the Atacama Cosmology Telescope"*

*Lyman Page*



*David Wilkinson*

This award is given in recognition of Lyman Page's pivotal role in transforming cosmic microwave background observations into a high-precision experimental science over the past two decades. In particular Page provided major contributions to the success of the Wilkinson Microwave Anisotropy Probe (WMAP) space mission, which delivered outstanding measurements of the CMB anisotropy and polarization pattern. He is now continuing his effort by promoting a new generation of experiments like the Atacama Cosmology Telescope to study CMB polarization to greater precision.

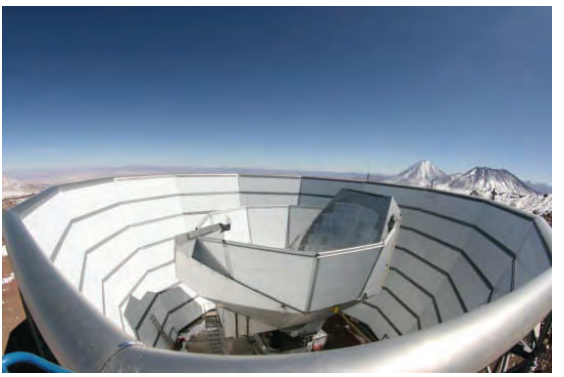


*Photo of the Atacama Cosmology Telescope*

The CMB, the faint afterglow of the Big Bang, is the most powerful probe of the early universe. From its study, we have learned the age of the universe, its major constituents, and have characterized the fundamental fluctuations in gravity that gave rise to cosmic structure. The desire to measure the CMB ever more precisely has driven the development of extraordinary detectors and techniques which will be reviewed in the Lectio Magistralis by Lyman Page. He will describe what we might hope to learn from the CMB in the next decade, including detecting gravitational waves from the birth of the universe if they exist at sufficient amplitude.

Professor **RASHID ALIEVICH SUNYAEV**
*"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe"*

*Rashid Sunyaev*

*Rashid Sunyaev and Yakov Borisovich Zeldovich*

Rashid Sunyaev gave extraordinary contributions to the understanding of physical processes in the universe which identified new and uniquely informative targets for observational cosmology. In particular, the Sunyaev-Zeldovich effect, now observed in thousands of clusters of galaxies over the entire sky, has become a cornerstone of cosmology and extragalactic astrophysics, so much so that it is now considered a research field in its own right. Furthermore, Sunyaev's studies of processes in the early universe responsible for angular anisotropy and frequency distortions of the cosmic microwave background have left a profound and lasting legacy for cosmology. In particular, Sunyaev and Zeldovich predicted the presence of acoustic peaks in the CMB angular fluctuation power spectrum and the existence of baryonic acoustic oscillations.
He is currently the project scientist leading the scientific team of the international high-energy astrophysics observatory Spektr-RG being built under the direction of the Russian Space Research Institute.

*Yakov Zeldovich and Remo Ruffini at the audience with Pope John Paul II*

Professor **SHING-TUNG YAU**
*"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics"*

*Shing-Tung Yau*

Shing-Tung Yau has made fundamental contributions to differential geometry which have influenced a wide range of scientific disciplines, including astronomy and theoretical physics. With Richard Schoen, Yau solved a longstanding question in general relativity by proving that the combined total energy of matter and gravitational field in an asymptotically flat universe is positive. In 1982 Yau was awarded the Fields Medal, the highest award in mathematics, and in 1994 he shared with Simon Donaldson the Crafoord Prize of the Royal Swedish Society in recognition of his development of nonlinear techniques in differential geometry leading to the solution of several outstanding problems.

Another outstanding achievement of Yau is his proof of the Calabi conjecture which allowed physicists to show that string theory is a viable candidate for a unified theory of nature. Furthermore in 2008 Yau (with M.T. Wang) introduced the concept of "quasi-local mass" in general relativity which can be of help to get around the old conundrum — the non-locality of the energy density in relativistic gravity.

During his scientific carrier Yau had more than 50 successful PhD students. At present he is a professor of mathematics at Harvard University where along with research he continues many pedagogical activities. For example, he has created the "Black Hole Initiative", an interdisciplinary center at Harvard University involving a collaboration between principal investigators from the fields of astronomy (Sheperd Doeleman, Avi Loeb and Ramesh Narayan), physics (Andrew Strominger), mathematics (Shing-Tung Yau) and philosophy (Peter Galison). This "Black Hole Initiative" is the first center worldwide to focus on the study of the many facets of black holes.

MG16 in 2021 will mark the $50^{th}$ anniversary of the mass-energy formula for black holes based on the Kerr metric. This timing is an omen that Yau and his school will soon further enlarge our knowledge of this formula with their powerful mathematical analysis.

# PREFACE

The Marcel Grossmann Meetings on Recent Developments in Theoretical and Experimental General Relativity, Astrophysics and Relativistic Field Theories have always had the goal of bringing together scientists from all over the world enabling them to share recent developments in general relativity and cosmology, paying attention to the interplay between physical predictions and mathematical foundations.

More than 800 scientists met at the University of Rome "la Sapienza" for the Fifteenth Marcel Grossmann Meeting (MG15) during the week of July 1–7, 2018 to discuss theoretical topics and the status of the experimental testing and observations of Einstein's theory of gravitation together with the broad spectrum of gravitational physics related phenomena. The topics discussed ranged from classical and quantum aspects of gravity, relativistic astrophysics, branes and strings, inflation theory, the thermal history of the Universe, to more concrete astrophysics experiments, observations, and modeling, reviewing the current state of the art in theory, observations, and experiments related to relativistic gravitation.

The meeting featured 39 plenary talks during the six mornings of the meeting, plus 6 public lectures given by experts in gravitation and cosmology. 73 parallel sessions, some of which were split over multiple days, kept participants busy with the crucial support of 33 students from Sapienza who managed the coordination of each parallel session and offered technical help.

Three scientists and two collaborations were presented with Marcel Grossmann awards. These were: Lyman Page, Rashid Alievich Sunyaev, Shing-Tung Yau, the Planck Scientific Collaboration (ESA) represented by Jean-Loup Puget, and the Hansen Experimental Physics Laboratory (HEPL) at Stanford University, represented by Leo Hollberg,

The detailed program of plenary and public talks is as follows:

**Shing-Tung Yau** (Harvard University): Quasi-local mass at null infinity
**Malcolm J. Perry** (University of Cambridge): Black hole entropy and soft hair
**Thomas Hertog** (KU Leuven): A smooth exit form eternal inflation
**Jean-Luc Lehners** (Max Planck Institute for Gravitational Physics): No smooth beginning for spacetime
**Ivan Agullo** (Louisiana State University): Loop quantum cosmology and the cosmic microwave background
**Elena Pian** (IASF Bologna):Kilonovae: the cosmic foundries of heavy elements
**Nial Tanvir** (University of Leicester): A new era of gravitational-wave / electromagnetic multi-messenger astronomy
**Tsvi Piran** (Hebrew University of Jerusalem): Mergers and GRBs: past present and future
**Stephan Rosswog** (Stockholm University): Neutron star mergers as heavy element production site

**David Shoemaker** (MIT LIGO Laboratory): LIGO's past and future observations of black hole and neutron star binaries
**Yu Wang** (ICRANet): On the role of binary systems in GW170817/ GRB170817A/AT2017gfo
**Hao Liu** (University of Copenhagen): An independent investigation of gravitational wave data
**Stefano Vitale** (University of Trento): Gravitation wave astronomy in ESA science programme
**Takaaki Kajita** (University of Tokyo): Status of KAGRA and its scientific goals
**Masaki Ando** (University of Tokyo): DECIGO : Gravitational-Wave observations from space
**Jun Luo** (Sun Yat-Sen University): TianQin: a space-borne gravitational wave detector
**Jo Van Den Brand** (Dutch National Institute for Subatomic Physics Nikhef, and VU University Amsterdam): Gravitational wave science and Virgo
**Ernst Maria Rasel** (Leibniz Universität Hannover): Science fiction turns into reality: Interferometry with Bose-Einstein condensates on ground and in space
**Manuel Rodrigues** (Université Paris Saclay): The first results of the MICROSCOPE test of the equivalence principle in space
**Victoria Kaspi** (McGill University): Fast radio bursts
**Bing Zhang** (University of Nevada): From gamma-ray bursts to fast radio bursts: unveiling the mystery of cosmic bursting sources
**Jean-Loup Puget** (CNRS): The Planck mission
**Jorge Armando Rueda Hernandez** (ICRANet): Binary-driven hypernovae and the understanding of gamma-ray bursts
**Remo Ruffini** (ICRANet): The essential role of the nature of the binary progenitors for understanding gamma ray bursts
**Heino Falcke** (Radboud University Nijmegen): Imaging black holes now and in the future
**Luc Blanchet** (Institut d'Astrophysique de Paris): Post-Newtonian theory and gravitational waves
**Jean-Loup Puget** (Université Paris): Frome Planck to Atacama Cosmology Telescope
**Razmik Mirzoyan** (Max Planck Institute for Physics): Gamma-ray and multimessenger highlights with MAGIC
**Elisa Resconi** (Technical University Munich): Neutrino astronomy in the multimessenger era
**Francis Halzen** (University of Wisconsin-Madison): IceCube: opening a new window on the universe from the South Pole
**James Lattimer** (Stony Brook University): The history of R-process
**Ralph Engel** (Karlsruhe Institute of Technology): What have we learned about ultra-high-energy cosmic rays from the Pierre Auger Observatory?

**Paolo De Bernardis** (Sapienza - University of Rome):
**Fabio Gargano** (INFN Bari): DAMPE and its latest results
**Markus Arndt** (University of Vienna): Experiments to probe quantum linearity at the interface to gravity & complexity
**Tobias Westphal** (University of Vienna): Micro-mechanical measurements of weak gravitational forces
**Shu Zhang** (Institute of High Energy Physics, Chinese Academy of Sciences):
**Lorenzo Amati** (INAF - OAS Bologna): Cosmology and multi-messenger astrophysics with Gamma-Ray Bursts
**Elisabetta Cavazzuti** (ASI): Gev LAT observations from GRBs and active galactic nuclei
**Remo Ruffini** (ICRANet): Concluding Remarks
**Roy Kerr** (University of Canterbury): Towards MG16

**Public Lectures**

**Jeremiah Ostriker** (Columbia University): Ultra-light scalars as cosmological dark matter
**Malcolm Longair** (University of Cambridge): Ryle and Hewish: 50 and 100 year anniversaries [Radio astrophysics and the rise of high energy astrophysics]
**Lyman Page** (Princeton University): Measuring the Cosmic Microwave Background
**Marc Henneaux** (Université Libre de Bruxelles): The cosmological singularity
**Anne Archibald** (Newcastle University): Does extreme gravity affect how objects fall?

# Concluding remarks by Prof. Remo Ruffini

For over more than four decades the Marcel Grossmann Meetings have been fostering the interaction between mathematics, relativistic field theories and observations in physics and astrophysics and has witnessed the birth and exponential growth of various new subfields within astrophysics. This has also occurred in 2018 during the MG15 (see Fig. 1), which has seen the participation of approximately one thousand participants from 71 different countries (see Fig. 2). In MG15, as is clear from the above program, we have seen considerable progress in theory on topics ranging from models of quantum gravity to the mathematical structure of Einstein's equations.

In particular, an MG15 individual award was given to Prof. Rashid Sunyaev, as a member of the relativistic astrophysics school of Zel'dovich-Sunyaev (see Fig. 3) and to Prof. Shing-Tung Yau, as a representative of the Chinese-American school of differential geometry and general relativity (see Fig. 4).

This has been accompanied by extensive developments in the exploration of the cosmic microwave background with announcements of the final results of the Planck satellite that followed earlier predecessors, like WMAP. In this sense, particularly meaningful have been the MG15

Awards presented to Prof. Jean-Loup Puget, who has successfully accomplished the ESA Plank mission (see Fig. 5) and to Prof. Lyman Page, one of the main participants of the glorious NASA WMAP mission, successfully lead by David Wilkinson (see Fig. 6). I was very fortunate to be in Princeton as an assistant professor at the time WMAP was initially conceived.

X-ray astrophysics gradually successfully evolved from the first rockets of Riccardo Giacconi discovering Scorpius X-1 using well tested Geiger counters, moving on to larger missions using X-ray mirrors in the Einstein Observatory, in XMM and on to the NASA Chandra mission, each new mission introducing new technologies based on previous successes. The

Chandra data on GRB 170817A were amply discussed in the MG15 meeting. Analogously, starting from the earlier gamma ray detectors on the Vela satellite, gamma ray astrophysics reached maturity with the Compton Observatory with the BATSE instruments on board. These two fields joined their separate expertise together in the hybrid Beppo SAX satellite. Equally impressive was the transition from Beppo SAX to the Neil Gehrels Swift Observatory and the Fermi Gamma-Ray Space Telescope that followed EGRET and opened up the field of high energy gamma-ray astrophysics, adding further successes to this ongoing story. One of the most significant contributions to the success of the Fermi mission has been the LAT detector, jointly led by the Hansen Experimental Physics Laboratory (HEPL) at Stanford University, which received the MG15 institutional award, presented to Prof. Leo Hollberg (see Fig. 7).

More recently we are witnessing the birth of TeV astrophysics springing from the ground-based MAGIC, HESS and Whipple telescopes, as well as neutrino astrophysics associated with underground (ICE Cube) and underwater laboratories. New tantalizing results concerning the spectrum and composition of cosmic rays have been reported by the Alpha Magnetic Spectrometer experiment on the international space station. All of these

together mark the gradual development of the largest observational effort in history, well recorded in these MG meetings (see Fig. 8). Today relativistic astrophysics is offering us the possibility of utilizing all of these multi-wavelength observations simultaneously in the study of GRBs and active galactic nuclei. Indeed the description of the distinct temporally discrete episodes for the GRB 130427A, one of the most complex astrophysical objects ever observed, requires the simultaneous knowledge of observations from all of these various wavelengths. This exponential growth in all these areas of astrophysics has been accompanied by attempts at data acquisition of gravitational wave signals arriving on the Earth. After the failure of the initial attempt by Misner and Weber in 1972, the new attempt by LIGO-VIRGO was discussed extensively in this MG15 meeting.

Indeed in addition to the many topics discussed in the plenary lectures, there was a special session dedicated to kilonova and gravitational waves chaired by Enrico Costa on July 3 and a session on gravitational waves chaired by Claus Lämmerzahl on July 4. Many intense discussions took place at the meeting, both in the plenary and parallel sessions, bringing together different points of view, at times controversial, which stimulated a large number of articles published in leading scientific journals in the months following the meetings. The impossibility of finding these discussions in these proceedings is simply explained: it is due to the incomprehensible decision by Sapienza University not to renew the collaboration agreement with ICRANet. What is incomprehensible is that both the research and teaching activities of ICRA and ICRANet are

recognized internationally at a worldwide level, in more than 70 nations. Locks were put on the ICRA Offices (see Fig. 9).

Fig. 9. Remo Ruffini shows to Barry Barish the locked offices of ICRA at Sapienza University.

The preparation of the proceedings was halted. It was not possible to follow up with post-conference interactions and the impossibility of access to our offices and interact with our students. The invited lecturers, clearly indicated in the conference program and some of the world leaders in their fields who had just presented their extremely interesting lectures stimulating widespread interest, mostly chose to publish their results in international journals giving rise to some of the most highly cited articles in recent times. Only a minority were published here. This was also the case for some of the ICRA-ICRANet lectures, which appeared in:

- J.F. Rodriguez, J.A. Rueda, R. Ruffini, *On the final gravitational wave burst from binary black hole mergers*, Astron. Rep. 62, 940 (2018).
- J.A. Rueda, R. Ruffini, Y. Wang, Y. Aimuratov, U. Barres de Almeida, C.L. Bianco, Y.C. Chen, R.V. Lobato, C. Maia, D. Primorac, R. Moradia, and J.F. Rodriguez, *GRB 170817A-GW170817-AT 2017gfo and the observations of NS-NS, NS-WD and WD-WD mergers*, JCAP 10, 006 (2018); and J.A. Rueda, R. Ruffini, Y. Wang, C.L. Bianco, J.M. Blanco-Iglesias, M. Karlica, P. Lorén-Aguilar, R. Moradi and N. Sahakyan, *Electromagnetic emission of white dwarf binary mergers*, JCAP 03, 044 (2019).

- R. Ruffini, R. Moradi, J. A. Rueda, L. Becerra, C. L. Bianco, C. Cherubini, S. Filippi, Y. C. Chen, M. Karlica, N. Sahakyan, Y. Wang, and S. S. Xue, *On the GeV Emission of the Type I BdHN GRB 130427A*, The Astrophysical Journal, 886, 82 (2019).

The dialogue we had started at MG15 undoubtedly had a very stimulating effect on the community which have been followed up and expanded upon in the subsequent MG16 meeting in 2021. Paradoxically, the moments of greatest difficulty for ICRA members have coincided with the flow of new ideas which promoted the steps forward towards the final identification of some fundamental laws of black hole electrodynamics. The very night ICRA offices were locked up and its electronic communications cut, we had submitted a paper to The Astrophysical Journal for publication containing the first fundamental steps for identifying the "inner engine" of GRBs as discussed in talks in this conference. After one year and four months a judge ordered Sapienza to return the ICRA offices.

I am looking forward to a renewed successful collaboration with Sapienza University, enjoyed for more than three decades, to pursue a new common "path" for the rapidly expanding knowledge of the largest distant objects in our Universe. There is still room for improvement: now that the differences have been identified in published articles, a joint effort on an attentive scientific analysis on both sides can lead to the understanding of the nature of these differences and to jointly converge to common solutions. For this to occur, dialogue and not obstruction of office space is needed. As soon as these clarifications will be achieved, we will be able to proceed in a broad scientific effort of common topics of interest in Einstein's theory, in relativistic astrophysics, ranging from the astrophysics of black holes, neutron stars, dark matter and primordial cosmology, observing the rules of basic academic relations.

I am grateful to all members of the IOC and to Carlo Luciano Bianco, Nathalie Deruelle, Rahim Moradi, Tsvi Piran, Jorge Rueda and Narek Sahakyan for advice and discussion.

Remo Ruffini
