An iterative scheme for finding $\Psi$ for a prescribed value of $E_{\rm b}$ involves working with quadratic functions with respect to the SET components. The stability and efficiency of such a scheme is questionable. Instead, we employ a bisection algorithm to find the value of $\Psi$ corresponding to $E_{\rm b}$. Typically, the ratio $E_{\rm b}/E_{\rm b;RKT}$ characterising the departure of the quantum state from the expected rigid-rotation profile ranges from $\sim 0.1$ for Dirichlet b.c.s to $\sim 2$ for von Neumann b.c.s. The dependence of $E_{\rm b}/E_{\rm b;RKT}$ on $\Psi$ for $\beta \in \{0.25, 0.5, 1\}$ is illustrated in Fig. 1(b).

Finally, we examine the profiles of the energy density and velocity when $\beta = 0.5$, $\Omega = 0.5$ and $R = 1$. Fig. 2(a) shows that the RBCs interpolate between the Dirichlet and von Neumann b.c.s. In the former case, the energy density exhibits a strong decreasing trend in the vicinity of the boundary, as also remarked in Ref. 1. For the von Neumann b.c.s, the energy density is amplified next to the boundary, as compared to the RKT prediction for a rigidly-rotating Bose-Einstein gas. The velocity $v$, shown in Fig. 2(b), shows small variations with respect to $\Psi$.

## 5. Conclusion

In this paper, a procedure to correlate the parameter $\Psi$ of the RBCs for the massless KG field enclosed within a cylinder and the boundary values of the rigidly-rotating t.e.v. of the SET operator was introduced. The restriction $\Psi \geq 0$ was imposed in order to eliminate modes with negative co-rotating energy $\widetilde{\omega}$ which would otherwise cause t.e.v.s to diverge. Employing the Landau frame decomposition to obtain the

macroscopic four-velocity of the state, the velocity on the boundary was shown to take values between 0 (Dirichlet limit) and a maximum value (von Neumann limit), which increases towards the value corresponding to rigid rotation as the temperature is increased. The energy density is strongly quenched compared to the relativistic kinetic theory prediction for a rigidly-rotating Bose-Einstein gas in the vicinity of the boundary when the Dirichlet b.c.s are employed. By contrast, it is amplified in the case of the von Neumann b.c.s.

# Electric-magnetic duality in the quantum theory

Adrian del Rio*

*Centro de Astrofísica e Gravitação (CENTRA), Departamento de Física, Instituto Superior Técnico (IST), Universidade de Lisboa - Lisboa 1049-001, Portugal*
**E-mail: adriandelrio@tecnico.ulisboa.pt*

It is known that an electric-magnetic duality transformation is a symmetry of the classical source-free Maxwell theory in generic spacetimes. This provides a conserved Noether charge, physically related to the polarization state of the electromagnetic field. We shall argue that this conservation law fails to hold at the quantum level in presence of a background classical gravitational field with non-trivial dynamics, as determined by the Chern-Pontryagin invariant. This is the spin-1 analog of the chiral anomaly for massless Dirac fermions.

*Keywords*: Quantum anomalies; quantum field theory in curved spacetimes; electromagnetic duality.

## 1. The classical electric-magnetic Noether symmetry

It is known from elementary courses in electrodynamics that Maxwell equations without electric charges and currents, as well as the electromagnetic stress-energy tensor, are manifestly invariant under and an "exchange" of the electric $\vec{E}$ and magnetic $\vec{B}$ fields, given by $\vec{E} \to \vec{B}$, $\vec{B} \to -\vec{E}$. In a manifestly covariant language, this amounts to say that

$$\nabla_\mu F^{\mu\nu} = 0, \qquad \nabla_\mu {}^\star F^{\mu\nu} = 0, \tag{1}$$

together with $T_{\mu\nu} = \frac{1}{2}\left[F_{\mu\rho}F^{\rho}{}_{\nu} + {}^\star F_{\mu\rho}{}^\star F^{\rho}{}_{\nu}\right]$, where $F$ denotes the electromagnetic 2-form field and ${}^\star F$ its Hodge-dual, remain invariant under the discrete transformation $F_{\mu\nu} \to {}^\star F_{\mu\nu}$, ${}^\star F_{\mu\nu} \to -F_{\mu\nu}$. Because this discrete transformation is nothing but the Hodge-duality mapping between 2-forms in a 4-dimensional spacetime, this invariance is usually regarded as the duality of Maxwell theory of electromagnetism.

Perhaps more interesting than this is that the invariance actually extends to *continuous* $SO(2)$ rotations between the fields, $F \to F\cos\theta + {}^\star F \sin\theta$, called electric-magnetic transformations. This continuous transformation not only leaves the above equations invariant, but it is also a symmetry of the source-free Maxwell action functional

$$S[A] = \int d^4x\sqrt{-g}F_{\mu\nu}F^{\mu\nu}\,, \tag{2}$$

as first found by Calkin[1]. Here we introduced the electromagnetic potential $A$, defined by $F = dA$. Some years later, this was reanalyzed in greater detail by Deser and Teitelboim[2] using the canonical approach, showing in particular that the symmetry holds even if the electromagnetic field propagates in a curved spacetime background. Noether's theorem enters the scene providing a conserved charge and current, with valuable physical information.

The Noether current takes the form (valid on-shell)[3]

$$j_D^\mu \approx \frac{1}{2}\left[A_\nu {}^\star F^{\mu\nu} - F^{\mu\nu} Z_\nu\right], \tag{3}$$

(where $Z_\nu$ is defined by $E^\mu = -\epsilon^{\mu\alpha\beta}\nabla_\alpha Z_\beta$) and it is conserved on-shell:

$$\nabla_\mu j_D^\mu = -Z_\nu \nabla_\mu F^{\mu\nu} \approx 0. \tag{4}$$

The electric-magnetic symmetry of the theory is generated by a conserved charge $Q_D$, which is the integral on a Cauchy surface of the "zero" component of the previous current:

$$Q_D = -\frac{1}{2}\int_{\Sigma_t} d\Sigma_t (A_\mu B^\mu - E^\mu Z_\mu), \tag{5}$$

and satisfies $\delta H = \{H, Q_D\} \approx 0$. This charge is gauge-invariant, it is a constant of motion $\dot{Q} \approx 0$, and it is not difficult to check that generates the correct transformation rule for the electric and magnetic fields in phase space:

$$\delta E = \{E, Q_D\} = B\,, \qquad \delta B = \{B, Q_D\} = -E\,. \tag{6}$$

In Minkowski spacetime, this charge shows interesting physics. Expanding the fields in Fourier modes with positive $h_+(k)$ and negative $h_-(k)$ helicity amplitudes, the equation above reduces to

$$Q_D = \int_{\mathbb{R}^3} \frac{d^3k}{(2\pi)^3\, k}\left[|h_+(\vec{k})|^2 - |h_-(\vec{k})|^2\right]. \tag{7}$$

As we can see, the Noether charge accounts for the net difference between right- and left-handed circularly polarized radiation (or photons, in the quantum theory). This is recognized as the usual V-stokes parameter, describing the polarization state of electromagnetic radiation. In some contexts this is also known as optical helicity[4]. One concludes that, as a direct consequence of the classical electric-magnetic duality symmetry, this physical magnitude is a constant of motion of source-free electrodynamics.

## 2. The anomaly in the quantum theory

An important question now is whether the symmetry still holds in the quantum theory, i.e. if $\langle \nabla_\mu j_D^\mu \rangle = 0$ for any given quantum vacuum state. Failing to satisfy this will imply that the electric-magnetic transformation is not a quantum symmetry. Given the well-known and diverse examples of anomalous symmetries in quantum field theory, this is not a trivial issue.

### 2.1. *Why is an anomaly expected?*

Anomalies in quantum field theory were first discovered by Adler, Bell, and Jackiw[5] for the Dirac chiral symmetry in the context spinor quantum electrodynamics, and

immediately after by Kimura[6] in the gravitational framework. The underlying reason for their appearance is renormalization. In short, the calculation of expectation values of quadratic field operators runs into problems due to UV divergences. They are ill-defined and as such we need renormalization to extract a well-defined physical quantity from them. The Noether currents are a prototype example of that. The key point is that renormalization subtractions do not necessarily respect the classical equations of motion. Then, quantum fluctuations lead to non-trivial off-shell contributions to the divergence of the current (4), causing the rupture of the classical invariance.

Of course, not every symmetry of a field theory is ruined by quantum fluctuations. One of the key points that makes the appearance of an anomaly very likely in this situation is the fact that the electric-magnetic transformation resembles an ordinary chiral transformation when working with self- and antiself-dual field variables. Indeed, if we define the self-dual fields $\vec{H}_\pm = \frac{1}{\sqrt{2}}\left[\vec{E} \pm i\vec{B}\right]$ then

$$\vec{H}_\pm \to e^{\mp i\theta}\vec{H}_\pm\,, \tag{8}$$

is an electric-magnetic rotation of the fields. Furthermore, under a Lorentz transformation both fields decouple, and their transformation rules are related to the two irreducible representations of the Lorentz group for fields of spin-1, written in standard terminology as $(0,1)$ and $(1,0)$. Compared with massless fermions of spin-1/2, $\vec{H}_+$ is the analog of a right-handed Weyl spinor — that transform under the $(0,1/2)$ Lorentz representation — and $\vec{H}_-$ is the analog of a left-handed Weyl spinor. So there is, indeed, full analogy with the fermion chiral transformation. Since this classical symmetry is known to be anomalous in the quantum theory if the Dirac field propagates in a curved spacetime, it becomes plausible that a similar feature will happen in the electromagnetic case too.

### 2.2. *Derivation of the quantum anomaly*

The strategy that we follow to compute $\langle \nabla_\mu j^\mu_D \rangle$ is to mimic as close as possible the chiral anomaly for Dirac fields.

The previous arguments strongly suggest to use self- and antiself-dual variables. The use of them actually makes the dynamics of the theory significantly more transparent. Source-free Maxwell equations (1) can be rewritten as

$$\alpha_I^{\mu\nu}\nabla_\mu H_+^I = 0\,, \tag{9}$$

with $\alpha_I^{\mu\nu}$ some matrices satisfying the $su(2)$ Lie algebra (again, this resembles the spin-1/2 theory of Weyl spinors). As in the standard formulation, this equation can be solved by introducing potentials. Defining complex potentials by $H_+^I = i\epsilon^{I\mu\nu}\nabla_\mu A_{+\,\nu}$ the equations of motion read now[3]

$$\bar{\alpha}_I^{\mu\nu}\nabla_\mu A_\nu^+ = 0\,. \tag{10}$$

The analogy with the Dirac theory goes even further. The standard Maxwell action functional (2) can be rewritten in terms of complex variables in the following form[3]

$$S[A^+, A^-] = -\frac{1}{4}\int d^4x\sqrt{-g}\ \bar{\Psi}\, i\beta^\mu \nabla_\mu \Psi\,, \tag{11}$$

where

$$\Psi = \begin{pmatrix} A^+ \\ H_+ \\ A^- \\ H_- \end{pmatrix}\,, \qquad \bar{\Psi} = (A^+, H_+, A^-, H_-)\,, \qquad \beta^\mu = i\begin{pmatrix} 0 & 0 & 0 & \bar{\alpha}^\mu \\ 0 & 0 & -\alpha^\mu & 0 \\ 0 & \alpha^\mu & 0 & 0 \\ -\bar{\alpha}^\mu & 0 & 0 & 0 \end{pmatrix}. \tag{12}$$

These new $\beta^\mu$ matrices satisfy the familiar Clifford algebra $\{\beta^\mu, \beta^\nu\} = 2g^{\mu\nu}$, and allow us to define a chiral matrix $\beta_5 = \frac{i}{4!}\epsilon_{\mu\nu\alpha\rho}\beta^\mu\beta^\nu\beta^\alpha\beta^\rho$. Then the chiral-type transformation of the fields

$$\Psi \to e^{i\beta_5\theta}\Psi\,, \tag{13}$$

defines the electric-magnetic rotation, and it is a symmetry of the above action. By applying Noether's theorem we immediately get the current $j^\mu_D = -\frac{1}{4}\bar{\Psi}\beta^\mu\beta_5\Psi$, which agrees with the one presented above.

Now we are equipped with sufficient tools to calculate the vacuum expectation value of (4). We took two different routes to obtain the result, each one illustrating different aspects of the anomaly.

The first method is a direct computation: we identify and regularize UV divergences, and subtract them in a covariant way. This is achieved by writing the divergence of $j^\mu_D$ in terms of the Wightman two point function $S(x,x') = \langle\bar{\Psi}(x)\Psi(x')\rangle$, subtract the corresponding UV asymptotic expansion up to 4 order in derivatives of metric (which contain UV divergences), and then taking the limit in which the two points merge:

$$\langle\nabla_\mu j^\mu_D\rangle_{ren} = \langle\nabla_\mu j^\mu_D\rangle - \langle\nabla_\mu j^\mu_D\rangle_{(4)} = \lim_{\vec{x}\to\vec{x}'\lambda\to 0}\frac{i}{2}\lambda\mathrm{Tr}\beta_5\left(S(x,x',\lambda) - S(x,x',\lambda)_{(4)}\right)\,.$$

The asymptotic expansion is evaluated using the Heat Kernel method[7]. After taking limits a non-vanishing term survives, yielding an anomalous non-conservation of the duality current[3]:

$$\langle\nabla_\mu j^\mu_D\rangle_{ren} = -\frac{\hbar}{96\pi^2}R_{\mu\nu\rho\sigma}{}^\star R^{\mu\nu\rho\sigma}\,. \tag{14}$$

The result comes entirely from the subtraction terms, which are independent of the vacuum state.

The second approach relies on Fujikawa's path integral viewpoint[8,9]. The partition function of the theory,

$$Z = \int d\mu[\Psi,\bar{\Psi}]e^{iS[\Psi,\bar{\Psi}]}\,, \tag{15}$$

remains invariant under a change of variables in phase space. An electric-magnetic duality rotation is a canonical transformation in phase space and as such it must leave $Z$ invariant. Noether's theorem states that the action changes as

$$S[\Psi', \bar{\Psi}'] = S[\Psi, \bar{\Psi}] - \int d^4x \sqrt{-g}\theta(x) \langle \nabla_\mu j^\mu_D \rangle_{ren} \ . \tag{16}$$

If everything else under the integral remained invariant, one would conclude that the current is conserved. However, as first pointed out by Fujikawa, the measure of the integral is not necessarily invariant and could change by a non trivial Jacobian, $d\mu[\Psi', \bar{\Psi}'] = Jd\mu[\Psi, \bar{\Psi}]$, $J \neq 1$. This is what yields the anomalous non conservation of the current in this framework. A detailed analysis following this approach gives back equation (14) again.

## 3. Conclusions and final comments

We argued that quantum fluctuations of the electromagnetic field spoil the classical conservation law of the Noether current associated to electric-magnetic rotations due to spacetime curvature, as calculated in (14). The result points out that $Q_D$ is no longer a constant of motion in the quantum theory: gravitational dynamics should distinguish between right and left photons. Physical implications of this quantum effect are still under investigation, but the analogy with the chiral anomaly [10] suggests that this is related to spontaneous electromagnetic circular polarization, as a result of asymmetric creation of right/left photons from the quantum vacuum due to background dynamics. If confirmed, our next goal will be to study the stimulated contribution to this asymmetric particle creation. This could be of interest in different astrophysical scenarios [11], ranging from stellar gravitational collapse to mergers of compact objects.

We extend the adiabatic regularization method for an expanding universe to include the Yukawa interaction between a quantized Dirac field and a homogeneous time-dependent scalar field. We present the renormalized semiclassical equations that are needed in order to take into account the backreaction of the produced Dirac fermions in both gravitational and scalar background fields.

*Keywords*: Quantum field theory in curved spacetime, adiabatic regularization, preheating, Yukawa interaction, semiclassical gravity.

## 1. Introduction

Any inflationary model predicts an exponentially fast dilution of the number density of any particle species. To repopulate the Universe with matter and radiation, the energy density of the inflaton needs to be converted to the standard model fields. This epoch is called reheating. A preheating stage, where particles are created due to the classical behavior of the inflaton field before the thermal equilibrium has been proposed for both scalar[1] and fermion fields[2]. In some models, including new inflation and chaotic inflation, inflation is produced due to a classical scalar field, which at the end of inflation it starts to oscillate around the minimum of its potential.

Gravitational particle creation was first discovered in the expanding universe[3–5] and later extended to black holes[4–7]. Time-dependent gauge fields can also create particles[8]. Due to the Yukawa coupling between a time-varying classical scalar field $\Phi$ and a quantum fermionic field $\psi$, spontaneous particle production also occurs. In order to take into account the backreaction of the produced particles on the classical background fields, via the semiclassical equations, one need to compute the expectation values $\langle T_{\mu\nu}\rangle$ and $\langle\bar{\psi}\psi\rangle$. This requires a regularization and

renormalization method to deal with the ultraviolet divergences appearing in expectation values quadratic in fields. A very powerful method to tame the ultraviolet divergences for isotropically expanding universes was originally proposed by Parker and Fulling[4,5,9] for scalar fields. This renormalization method is based on an adiabatic expansion of the field modes living in the expanding universe, and it is known as adiabatic regularization. The adiabatic method has been extended to Dirac fermions in Refs. 10, 11.

In this contribution we further extend the adiabatic regularization method to incorporate the Yukawa interaction, which is expected to be of major importance in the preheating epoch. First, we present the semiclassical equations for fermions in an expanding universe and Yukawa-coupled to a scalar field and then use the adiabatic regularization scheme to cure the divergences of the vacuum expectation values of $\langle T_{\mu\nu}\rangle$ and $\langle\bar{\psi}\psi\rangle$. (For a extended analysis, see Ref. 12).

## 2. Semiclassical equations for a quantized Dirac matter field with Yukawa coupling

We consider the theory defined by the action functional $S = S[g_{\mu\nu}, \Phi, \psi, \nabla\psi]$, where $\psi$ represents a Dirac field, $\Phi$ is a scalar field, and $g_{\mu\nu}$ stands for the spacetime metric. We decompose the action as $S = S_g + S_m$, where $S_m$ is the matter sector

$$S_m = \int d^4x\sqrt{-g}\ \left\{\frac{i}{2}[\bar{\psi}\underline{\gamma}^\mu\nabla_\mu\psi - (\nabla_\mu\bar{\psi})\underline{\gamma}^\mu\psi)] - m\bar{\psi}\psi - g_Y\Phi\bar{\psi}\psi\right\}\ , \qquad (1)$$

and $S_g$ is the gravity-scalar sector. In (1), both the metric $g_{\mu\nu}(x)$ and the scalar field $\Phi(x)$ are regarded as classical external fields. The curved-space Dirac matrices $\underline{\gamma}^\mu$ obey the relations $\{\underline{\gamma}^\mu, \underline{\gamma}^\nu\} = 2g^{\mu\nu}$. The Dirac spinor $\psi(x)$ will be our quantized field, living in a curved spacetime and possessing a Yukawa coupling to the classical field $\Phi$. The Dirac equation is

$$(i\underline{\gamma}^\mu\nabla_\mu - m - g_Y\Phi)\psi = 0\ , \qquad (2)$$

and the stress-energy tensor is given by

$$T^m_{\mu\nu} := \frac{2}{\sqrt{-g}}\frac{\delta S_m}{\delta g^{\mu\nu}} = \frac{i}{2}\left[\bar{\psi}\underline{\gamma}_{(\mu}\nabla_{\nu)}\psi - (\nabla_{(\mu}\bar{\psi})\underline{\gamma}_{\nu)}\psi\right]\ . \qquad (3)$$

The complete theory, including the gravity-scalar sector in the action, can be described by

$$S = S_g + S_m = \frac{1}{16\pi G}\int d^4x\sqrt{-g}R + \int d^4x\sqrt{-g}\left\{\frac{1}{2}g^{\mu\nu}\nabla_\mu\Phi\nabla_\nu\Phi - V(\Phi)\right\} + S_m\ , \qquad (4)$$

where $S_m$ is the action for the matter sector given in (1).

The semiclassical Einstein and scalar equations are

$$G^{\mu\nu} + 8\pi G\left(\nabla^\mu\Phi\nabla^\nu\Phi - \frac{1}{2}g^{\mu\nu}\nabla^\rho\Phi\nabla_\rho\Phi + g^{\mu\nu}V(\Phi)\right) = -8\pi G\langle T^{\mu\nu}_m\rangle_{ren}\ , \qquad (5)$$

$$\Box\Phi + \frac{\partial V}{\partial\Phi} = -g_Y\langle\bar{\psi}\psi\rangle_{ren}\ . \qquad (6)$$

In order to obtain the renormalized quantities $\langle T_{\mu\nu}\rangle_{ren}$ and $\langle\bar{\psi}\psi\rangle_{ren}$ we extend the adiabatic regularization in the next section.

## 3. Fermion quantization and adiabatic regularization

In a spatially flat FLRW spacetime, we expand the field $\psi$ as

$$\psi(x)=\int d^3\vec{k}\sum_{\lambda}\left[B_{\vec{k}\lambda}u_{\vec{k}\lambda}(x)+D^{\dagger}_{\vec{k}\lambda}v_{\vec{k}\lambda}(x)\right]\ , \tag{7}$$

with

$$u_{\vec{k},\lambda}(x)=\frac{e^{i\vec{k}\vec{x}}}{\sqrt{(2\pi)^3a^3(t)}}\begin{pmatrix}h^I_k(t)\xi_\lambda(\vec{k})\\ h^{II}_k(t)\frac{\vec{\sigma}\vec{k}}{k}\xi_\lambda(\vec{k})\end{pmatrix} \tag{8}$$

and $v_{\vec{k},\lambda}(x)=Cu_{\vec{k},\lambda}(x)$. The modes $v_{\vec{k},\lambda}(x)$ can be obtained by applying a charge conjugate transformation $C\psi=-i\gamma^2\psi^*$. Here $\xi_\lambda$ with $\lambda=\pm1$ are two constant orthonormal two-spinors ($\xi^\dagger_\lambda\xi_{\lambda'}=\delta_{\lambda,\lambda'}$), eigenvectors of the helicity operator $\frac{\vec{\sigma}\vec{k}}{2k}\xi_\lambda=\frac{\lambda}{2}\xi_\lambda$. The time-dependent functions $h^I_k$ and $h^{II}_k$ satisfy the first-order coupled equations

$$h^{II}_k=\frac{ia}{k}\left(\frac{\partial h^I_k}{\partial t}+i(m+g_Y\Phi)h^I_k\right)\ ,\qquad h^I_k=\frac{ia}{k}\left(\frac{\partial h^{II}_k}{\partial t}-i(m+g_Y\Phi)h^{II}_k\right)\ . \tag{9}$$

The normalization condition for the above four-spinors reduces to

$$|h^I_k|^2+|h^{II}_k|^2=1\ . \tag{10}$$

For adiabatic regularization one can expand $h^I_k$ and $h^{II}_k$ as

$$\begin{aligned}h^I_k(t)&=\sqrt{\frac{\omega(t)+m}{2\omega(t)}}e^{-i\int^t\left(\omega(t')+\omega^{(1)}(t')+\ldots\right)dt'}\left(1+F^{(1)}(t)+\ldots\right)\\ h^{II}_k(t)&=\sqrt{\frac{\omega(t)-m}{2\omega(t)}}e^{-i\int^t\left(\omega(t')+\omega^{(1)}(t')+\ldots\right)dt'}\left(1+G^{(1)}(t)+\ldots\right)\ .\end{aligned} \tag{11}$$

Here, $F^{(n)}$, $G^{(n)}$ and $\omega^{(n)}$ are complex and real functions of $n$th adiabatic order. By substituting (11) into the equations of motion (9) and the normalization condition (10), one can obtain expressions for this functions by solving order by order in the adiabatic expansion. As usual, we consider $\dot{a}$ of adiabatic order 1, $\ddot{a}$ of adiabatic order 2, and so on. On the other hand, we consider the interaction term $s(t)$ of adiabatic order 1. For a recent discussion on a related issue see Ref. 13. We work out the first adiabatic order but the full computation until fourth adiabatic order can be found in Refs. 11, 12. In order to compute the three functions of the first adiabatic order contributions $F^{(1)}$, $G^{(1)}$ and $\omega^{(1)}$ we treat independently the real and imaginary parts by writing $F^{(1)}=f^{(1)}_x+if^{(1)}_y$ and $G^{(1)}=g^{(1)}_x+ig^{(1)}_y$.

From (11) and (10) we obtain for the real part

$$\begin{aligned}(\omega - m)(g_x^{(1)} - f_x^{(1)}) &= \omega^{(1)} - g_Y\Phi \ , \\ (\omega + m)(g_x^{(1)} - f_x^{(1)}) &= -\omega^{(1)} - g_Y\Phi \ , \\ (\omega + m)f_x^{(1)} + (\omega - m)g_x^{(1)} &= 0 \ , \end{aligned} \tag{12}$$

which has as solutions

$$f_x^{(1)} = \frac{g_Y\Phi}{2\omega} - \frac{mg_Y\Phi}{2\omega^2} \ , \qquad g_x^{(1)} = -\frac{g_Y\Phi}{2\omega} - \frac{mg_Y\Phi}{2\omega^2} \ , \qquad \omega^{(1)} = \frac{mg_Y\Phi}{\omega} \ . \tag{13}$$

On the other hand, the imaginary part of the system gives

$$\begin{aligned}(\omega - m)(g_y^{(1)} - f_y^{(1)}) &= \frac{1}{2}\frac{d\omega}{dt}\left(\frac{1}{\omega + m} - \frac{1}{\omega}\right) \ , \\ (\omega + m)(g_y^{(1)} - f_y^{(1)}) &= -\frac{1}{2}\frac{d\omega}{dt}\left(\frac{1}{\omega - m} - \frac{1}{\omega}\right) \ . \end{aligned} \tag{14}$$

These two equations are not independent. The obtained solution for $g_y^{(1)}$ and $f_y^{(1)}$ is

$$f_y^{(1)} = A - \frac{m\dot{a}}{2a\omega^2} \ , \qquad g_y^{(1)} = A \ , \tag{15}$$

where $A$ is an arbitrary first-order adiabatic function. We will choose the simplest solution

$$f_y^{(1)} = -\frac{m\dot{a}}{4\omega^2 a} \ , \qquad g_y^{(1)} = \frac{m\dot{a}}{4\omega^2 a} \ , \tag{16}$$

obeying the condition $F^{(1)}(m, g_Y\Phi) = G^{(1)}(-m, -g_Y\Phi)$. Therefore, the adiabatic expansion will also preserve the symmetries of the equations (9) with respect to the change $(m, g_Y\Phi) \to (-m, -g_Y\Phi)$. We have checked that physical expectation values are independent to any potential ambiguity in this kind of choice. We want to remark that this ambiguity is originated by the possibility of adding a time derivative in the integral of the exponent in (11) and compensating it by redefining the corresponding functions $F$ and $G$. Therefore, the local subtraction terms for renormalization can be unambiguously fixed. Nevertheless, an unambiguous adiabatic expansion of the modes can be constructed following the procedure described in Ref. 11. The next adiabatic orders are obtained by iteration.

## 4. Renormalized backreaction equations

The classical stress-energy tensor in a FLRW spacetime has two independent components. For a Dirac field, they are (no sum on $i$),

$$T_0^0 = \frac{i}{2}\left(\bar{\psi}\gamma^0\frac{\partial\psi}{\partial t} - \frac{\partial\bar{\psi}}{\partial t}\gamma^0\psi\right) \ , \qquad T_i^i = \frac{i}{2a}\left(\bar{\psi}\gamma^i\frac{\partial\psi}{\partial x^i} - \frac{\partial\bar{\psi}}{\partial x^i}\gamma^i\psi\right) \ . \tag{17}$$

In the quantum theory, using (7) the vacuum expectation values of the stress-energy tensor take the form

$$\langle T_{00}\rangle = \frac{1}{2\pi^2 a^3}\int_0^\infty dk k^2 \rho_k(t)\ , \qquad \rho_k(t) \equiv 2i\left(h_k^I \frac{\partial h_k^{I*}}{\partial t} + h_k^{II}\frac{\partial h_k^{II*}}{\partial t}\right)\ , \tag{18}$$

and

$$\langle T_{ii}\rangle = \frac{1}{2\pi^2 a}\int_0^\infty dk k^2 p_k(t)\ , \qquad p_k(t) \equiv -\frac{2k}{3a}(h_k^I h_k^{II*} + h_k^{I*} h_k^{II})\ . \tag{19}$$

On the other hand we have:

$$\langle\bar{\psi}\psi\rangle = \frac{-1}{\pi^2 a^3}\int_0^\infty dk k^2 \langle\bar{\psi}\psi\rangle_k\ , \qquad \langle\bar{\psi}\psi\rangle_k \equiv |h_k^I|^2 - |h_k^{II}|^2\ . \tag{20}$$

In general, adiabatic renormalization proceeds by subtracting the adiabatic terms of the integrand that contains the ultraviolet divergences. For $\langle\bar{\psi}\psi\rangle$ we need to subtract until third adiabatic order and for $\langle T_{\mu\nu}\rangle$ until fourth adiabatic order. It is important to remark that all contributions of a given adiabatic term of fixed (adiabatic) order must be taken into account in the subtraction, otherwise general covariance is not maintained. Also, one subtracts only the minimum number of terms required to get a finite result. For example, for the first adiabatic order for $\langle\bar{\psi}\psi\rangle_k$ introducing (11) in (20) and selecting the corresponding first adiabatic order term of this expansion for the the expectation values we obtain

$$\begin{aligned}\langle\bar{\psi}\psi\rangle_k^{(1)} &= \frac{\omega+m}{2\omega}\left(|F|^2\right)^{(1)} - \frac{\omega-m}{2\omega}\left(|G|^2\right)^{(1)} \\ &= \frac{\omega+m}{2\omega}\left(2f_x^{(1)}\right) - \frac{\omega-m}{2\omega}\left(2g_x^{(1)}\right) = \frac{g_Y\Phi}{\omega} - \frac{m^2 g_Y\Phi}{\omega^3}\ .\end{aligned} \tag{21}$$

The complete renormalized expressions for the energy momentum tensor and $\langle\bar{\psi}\psi\rangle_{ren}$ are

$$\langle T_{00}\rangle_{ren} \equiv \langle T_{00}\rangle - \langle T_{00}\rangle_{Ad} = \frac{1}{2\pi^2 a^3}\int_0^\infty dk k^2(\rho_k - \rho_k^{(0-4)})\ , \tag{22}$$

$$\langle T_{ii}\rangle_{ren} \equiv \langle T_{ii}\rangle - \langle T_{ii}\rangle_{Ad} = \frac{1}{2\pi^2 a}\int_0^\infty dk k^2(p_k - p_k^{(0-4)})\ , \tag{23}$$

$$\langle\bar{\psi}\psi\rangle_{ren} = \langle\bar{\psi}\psi\rangle - \langle\bar{\psi}\psi\rangle_{Ad} = \frac{-1}{\pi^2 a^3}\int_0^\infty dk k^2(\langle\bar{\psi}\psi\rangle_k - \langle\bar{\psi}\psi\rangle_k^{(0-3)})\ . \tag{24}$$

where $^{(0-n)}$ denotes the substraction terms of adiabatic order $0, 1, ..., n$.

These finite renormalized quantities are the ones that are introduced in the semiclassical equations of (5) and (6) in order to take into account the backreaction of the produced fields in both the gravitational and the scalar background fields.

We want also to briefly recall that the adiabatic method serves not only as a regulator but also as a renormalization mechanism. Each adiabatic subtraction of $\langle\bar{\psi}\psi\rangle_{ren}$ and $\langle T_{\mu\nu}\rangle_{ren}$ can be understood as the contribution of a generic Lagrangian containing all possible counterterms having couplings with non-negative mass dimension, up to Newtons's coupling constant[12]. The associated running of

the couplings due to this adiabatic renormalization scheme has also been recently studied in Ref. 14 for a Maxwell-Einstein theory. This is still an open problem for a Yukawa interaction. Another issue is the correct fixing of the initial conditions in order to perform a numerical analysis of the full renormalized semiclassical equations. This has already been done for a scalar field in expanding universe[15] but a generalization for Dirac fields and also for Yukawa couplings is still missing[16].

## 5. Conclusions

In order to take into account the backreaction of the produced Dirac particles during the preheating stage one needs to compute $\langle T_{\mu\nu} \rangle$ and $\langle \bar{\psi}\psi \rangle$, which are plagued with UV divergences. To renormalize these observables we have extended the adiabatic regularization to include a Yukawa interaction between the quantized Dirac fields and the classical scalar field background.

# Interacting quantum field theories and topological defects

Antonino Flachi and Vincenzo Vitagliano

*Department of Physics & Research and Education Center for Natural Sciences, Keio University, 4-1-1 Hiyoshi, Kanagawa 223-8521, Japan*

We present here the results of a recent analysis of interacting quantum field theories on a curved manifold with a topological defect constructed by geometrically deforming a lattice. We discuss an explicit example where curvature and boundary conditions compete in altering the way the quantum vacuum is destabilized. We show that the competing action of the locally induced curvature and of boundary conditions generated by the non-trivial topology allows configurations where symmetries can be spontaneously broken close to the defect core. Inspired by this effect, we propose a novel mechanism to induce a superconducting phase by triggering particle condensation along cosmic strings.

As the energy scales of a physical system become higher, non-perturbative effects get into the game and the system is said to have entered an strongly coupled regime. Remarkable examples of strongly coupled systems include QCD, high temperature superconductors and the very primordial plasma filling the universe a few instants after the big bang. Interactions are also important in describing the propagation of conducting electrons in graphene.

Precise study of strong coupled dynamics is only possible at the cost of demanding numerical simulations. On the other hand, general phenomenological guidelines for the study of strongly coupled systems can be precisely draft exploiting mathematical considerations on the underlying symmetries. The physics of symmetry breaking, in fact, notably relies on exact mathematical statements which are intimately non-perturbative, as in the case of the Goldstone theorem.

A seminal paper by Coleman and Weinberg[1] showed how symmetries can be spontaneously broken due to quantum fluctuations. This mechanism of *dynamical* symmetry breaking, originally developed in the context of scalar field self-interactions, can be naturally extended to fermions. In a field theory with massless fermions, the interactions between particles preserve helicity: the polarised left- and right-handed sectors evolve separately. However, in the celebrated Nambu–Jona-Lasinio model ($\lambda$ is the coupling constant and $N$ the total number of fermion dof,

$$S_{\rm NJL} = \int d^4x\sqrt{g}\left\{\bar\psi i\gamma^\mu\nabla_\mu\psi + \frac{\lambda}{2N}(\bar\psi\psi)^2\right\}\,,$$

and in its progeny of models for strong interactions, such symmetry is spontaneously broken by a non-vanishing order parameter: when the composite operator $\phi\sim\bar\psi\psi$ acquires a non-zero vacuum expectation value, then a dynamical effective mass for the fermions, $M_{\rm eff}\sim\langle\bar\psi\psi\rangle$, is generated. This mechanism is responsible for most of the observed mass of hadrons.

Transitions between symmetry broken and symmetry restored phases are generally triggered by changes in the external conditions. In particular a nonzero temperature leads to temperature-dependent mass generation and to restoration of broken symmetries once a certain critical value of the temperature is reached. Other factors modifying the phase diagram of self-interacting theories span from finite density effects to the action of a non-vanishing chemical potential or of an external gauge field. Here we will instead concentrate on geometrical effects, and how these challenge the vacuum stability of a theory with four fermions interactions.

Many are the configurations in which geometry affects the symmetry breaking of strongly interacting systems: in flat spacetime with $R^3 \times S^1$ topology and periodic boundary conditions, for example, the consequences of the non-trivial topology are very similar to those of nonzero temperature[2]; on the other hand, in curved spacetime the effects of external gravitational fields resemble those of an effective extra mass[3]. The combination of these external factors, and in particular topology, nonzero temperature, and curvature, acting on self-interacting theories is likely to have been of considerable importance in the early stages of the evolution of the universe. During those eras a spontaneous breaking of an internal symmetry group results in the production of topological defects – the well-known Kibble–Zurek mechanism[4,5].

Suppose the dynamical symmetry breaking for some particle model to be at the origin of the formation of a static straight cosmic string[6,7] lying along the $z$-axis, namely an infinitely long thin tube of false vacuum generated in the sudden temperature-driven transition from a phase to another (here, the transverse size of the cosmic string is neglected while 'sudden transition' means a transition with a rate that is fast if compared with the size of the system). Away from the defect, the spacetime associated with the gravitating string is accurately described by the vacuum Einstein equations. It turns out that at large distance from the string, the geometry is locally flat, $ds^2_{\rm con} = dt^2 - dz^2 - dr^2 - r^2 d\theta^2$, but with an important *caveat*: it is not globally Euclidean, since the angular coordinate does not run on the entire $2\pi$ circle; instead, $0 \leq \theta < 2\pi - \Delta$, with $\Delta > 0$ ($\Delta < 0$) being the deficit (excess) angle: surfaces at constant $t$ and $z$ are cones, not planes.

This is a remembrance of defects insertion in crystal lattices: starting from a (locally) flat lattice, the subtraction (or addition) of atoms is equivalent to the extraction (or insertion) of sections of the lattice with a given angle. The procedure results in an ice-cream-shaped lattice (or a saddle) which is locally flat everywhere apart for the apex. Note yet that the spacetime surgery does not come for free: the price to pay is the implementation of some non-trivial new boundary conditions along the cut, which will be a reminder of the deficit (excess) angle at the apex.

To investigate the role of the background geometry in modifying the vacuum structure, we will consider a $(2+1)$–dimensional honeycomb lattice, whose hexagonal structure is obtained by the superposition of two triangular sublattices: the breakdown of this discrete symmetry is behind the phenomenon of condensation

we will describe here[8]. The dynamics of the delocalized electrons on such a lattice is often described in terms of a generalisation of the Hubbard model, that in the continuum limit is mapped onto a field theory with nine different couplings[9]; however, considering the limit for a large number of fermion flavours $N$ and after bosonization, the Hubbard model for the honeycomb lattice has the following form

$$\mathcal{L}_{\mathrm{GN}} = \bar{\psi}_\sigma \imath \partial\!\!\!/ \psi_\sigma + \sigma \bar{\psi}_\sigma \phi \psi_\sigma + \frac{\phi^2}{2\lambda} \,, \tag{1}$$

where $\sigma = \pm$ is a spin index on which one sums. The final goal is to study the behaviour of the order parameter $\phi$ when moving toward the apex of the cone.

Using a regularization of the space generated by the topological 'stringy' defect with a family of smoothed versions of the conical solution (in Euclidean time), $ds^2 = d\tau^2 + f_\epsilon(r) dr^2 + r^2 d\theta^2$, where $f_\epsilon(r)$ is a regularising function: in the limit $\epsilon \to 0$ one might recover the singular cone. The Schrödinger–Lichnerowicz–Weitzenböck formula allows us to write the effective action as

$$\Gamma[\phi] = -\int d^3x \sqrt{g} \frac{\phi^2}{2\lambda} + \frac{1}{2} \sum_{p=\pm} \log\det\left(\Box + \frac{R}{4} + \phi_p^2\right), \quad \phi_\pm^2 = \phi^2 \pm \sqrt{g^{rr}}\phi' \tag{2}$$

where the metric here employed is the smoothed one, $ds^2$, rather than $ds^2_{\mathrm{con}}$. As previously mentioned, the change in the topology has a prominent role in altering the boundary conditions on the glued side of the lattice; the response to this change is captured by the employment of a modified covariant derivative, $D_\mu = \nabla_\mu + \imath \mathcal{A}_\mu$, acting on spinors and encompassing an effective non-dynamical gauge field, $\mathcal{A}_\mu$, that depends on the deficit angle[10].

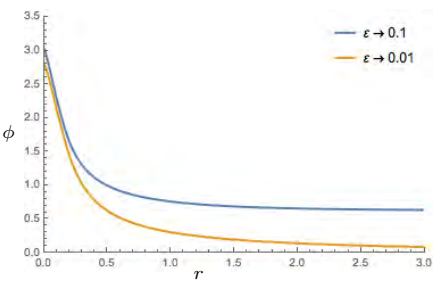

Fig. 1. Profile of the condensate $\phi$ as a function of the distance from the apex, $r$. Different colours refer to different values of the $\epsilon$ parameter regularising the cone.

Expressing the functional determinant of the (squared) Dirac operator in curved space in terms of its heat kernel expansion[11], and using zeta function regularization, it is possible to calculate the effective action (2) and find out the effective equations of motion of the order parameter $\phi$, whose solutions can be reconstructed numerically (See figure and see Ref. 12 for some examples). An alternative way to proceed could make use of the world-line formalism adapted to the present case (see Ref. 13 for a relevant calculation). Although the presence of curvature (which acts,

as for the chiral gap effect[14], as an effective mass term) is supposed to enhance a phase of symmetry restoration, the presence of the extra effective gauge field, another reminder of the geometry of the system, catalyse the formation of a bubble of condensed particles close the apex.

For relativistic cosmic strings, the possibility of particle condensation in the region surrounding the string core due only to configurational elements is a interesting way to induce a superconducting phase around the defect. However, it is worth mentioning that in a more realistic setup, phase transitions in the early universe did not seed the formation of a single straight string, but of a network of cosmic strings, which renders eventually even more striking and intriguing the connection with a crystal lattice, where a distribution of defects is more natural to occur. There is finally another interesting aspect: in order to simplify the discussion we have here considered the spontaneous symmetry breaking for the Gross–Neveu model catalysed by an external string defect, namely originated by the breakdown of some symmetry of a different field. Different would be the situation in which the responsible for the defect formation is the very same field, in which case one might take into account possible back-reaction effects.

# Primordial gravitational waves originating from an anisotropic pre-inflationary stage

Yu Furuya*, Yuki Niiyama and Yuuiti Sendouda

*Graduate School of Science and Technology, Hirosaki University, Hirosaki, Aomori 036-8561, Japan*
**E-mail: furuya@tap.st.hirosaki-u.ac.jp*

We discuss quantisation and time evolution of cosmological tensor perturbations in the Kasner–de Sitter space-time as a model of (pre-)inflation. We propose a prescription for reading off the quantum energy levels in the presence of the initial Kasner-like singularity.

*Keywords*: Cosmological perturbation theory, inflation, primordial gravitational waves.

## 1. Introduction

Unveiling the origin and mechanism of cosmic inflation [1,2] by means of observations is one of the ultimate challenges in modern cosmology. If there were preceding, 'pre-inflationary' stages before the onset of inflation, it is well anticipated that the space-time then was fairly anisotropic and/or inhomogeneous with a magnitude of the order of the scale of fundamental physics. For this purpose, primordial gravitational waves (PGWs) are expected to play an essential role as a probe for such an extremely high-energy universe.

Unfortunately, however, quantisation in cosmological backgrounds with a pre-inflationary, Kasner-like singularity has been a theoretical challenge, as the diverging spatial anisotropy renders the standard quantisation procedure inexecutable. [3,4] This is the central issue we have addressed in the present work.

One of the essential aspects of the problem of quantisation in an anisotropic early universe is that the ability in reading off the quantum spectra is restricted due to lack of a set of appropriate mode functions near the singularity. We argue that this difficulty may be simply circumvented if only there is a period, even if temporal, apart from the singularity where certain adiabatic conditions for an appropriately transformed variable are met. [5] Then the standard procedure of second quantisation can be carried out within the framework of the WKB approximation during such a period. It should be, however, stressed here that we are not addressing the issue of determining the quantum state of the pre-inflationary universe, which would need the knowledge of the more fundamental physics.

We demonstrate that our prescription for determining the quantum energy spectrum is useful in making physically meaningful predictions for PGWs in triaxially anisotropic Kasner–de Sitter (KdS) backgrounds. With a conservative assumption about the quantum state, we confirm that, on short wave-length scales, the resulting spectrum and directional distribution of the PGWs share the same feature with de Sitter inflation, namely, scale invariance and isotropy.

## 2. Setup

We begin with describing the basic setup for the calculation of PGWs in a KdS background.

### 2.1. *Background*

The line element of the KdS space-time is

$$g_{\mu\nu}\,\mathrm{d}x^\mu\,\mathrm{d}x^\nu = a(\eta)^2\,\left[-\mathrm{d}\eta^2 + \sum_{i=1}^{3}\left(\mathrm{e}^{\beta_i(\eta)}\,\mathrm{d}x^i\right)^2\right], \tag{1}$$

where

$$a(\eta) = a_{\rm iso}\,\sinh^{1/3}(3H_\Lambda t)\,, \quad \mathrm{e}^{\beta_i(\eta)} = \tanh^{q_i}\left(\frac{3H_\Lambda t}{2}\right) \quad (i=1,2,3) \tag{2}$$

with $a_{\rm iso}$ being a normalisation constant, $t$ the cosmic time defined by $\mathrm{d}t = a(\eta)\,\mathrm{d}\eta$, and $H_\Lambda \equiv \sqrt{\Lambda/3}$. The three exponents $q_i$ $(i=1,2,3)$ are usefully parametrised by an angular parameter $\Theta$ as

$$q_1 = \frac{2}{3}\,\sin\left(\Theta - \frac{2\pi}{3}\right), \quad q_2 = \frac{2}{3}\,\sin\left(\Theta - \frac{4\pi}{3}\right), \quad q_3 = \frac{2}{3}\,\sin\Theta\,. \tag{3}$$

In this work, we will take a particular combination $(q_1,q_2,q_3) = (1/\sqrt{3},0,-1/\sqrt{3})$ $(\Theta = 8\pi/6)$ as a typical background with a triaxial anisotropy. A KdS space-time with a triaxial anisotropy has an initial singularity at $t=0$, where a Weyl-curvature invariant $C_{\mu\nu\rho\sigma}\,C^{\mu\nu\rho\sigma}$ diverges.

The spatial metric is defined as

$$\gamma_{ij} = \mathrm{diag}(\mathrm{e}^{2\beta_1}, \mathrm{e}^{2\beta_2}, \mathrm{e}^{2\beta_3}), \quad \gamma^{ij} = \mathrm{diag}(\mathrm{e}^{-2\beta_1}, \mathrm{e}^{-2\beta_2}, \mathrm{e}^{-2\beta_3}), \tag{4}$$

and is used to raise and lower the indices of spatial tensors. The average Hubble rate $\mathcal{H}$ and the shear tensor $\sigma_{ij}$ are defined respectively by

$$\mathcal{H} \equiv \frac{a'}{a} = a_{\rm iso}\,H_\Lambda\,\frac{\cosh(3H_\Lambda t)}{\sinh^{2/3}(3H_\Lambda t)}\,, \tag{5}$$

$$\sigma_{ij} \equiv \frac{1}{2}\,\gamma'_{ij} = 3q_i\,a_{\rm iso}\,H_\Lambda\,\frac{\tanh^{2q_i}\left(\frac{3H_\Lambda t}{2}\right)}{\sinh^{2/3}(3H_\Lambda t)}\,\delta_{ij}\,, \tag{6}$$

where the prime denotes differentiation with respect to $\eta$.

The KdS universe has two regimes distinguished by the magnitude of the shear. In the earlier, 'Kasner-like' period for $t \ll H_\Lambda^{-1}$, the average scale factor $a$ and the spatial metric $\gamma_{ij}$ are approximated as

$$a(\eta) \sim a_{\rm iso}\,(3H_\Lambda t)^{1/3}\,, \quad \gamma_{ij}(\eta) \sim \left(\frac{3H_\Lambda t}{2}\right)^{2q_i}\,\delta_{ij}\,. \tag{7}$$

In the later, 'de Sitter-like' period for $t \gg H_\Lambda^{-1}$, $a$ and $\gamma_{ij}$ are approximated as

$$a(\eta) \sim 2^{-1/3}\,a_{\rm iso}\,\mathrm{e}^{H_\Lambda t}\,, \quad \gamma_{ij}(\eta) \sim \delta_{ij}\,. \tag{8}$$

The time $t = t_{\rm iso} \equiv H_\Lambda^{-1}$ appoints a moment around which the transition from the anisotropic to the isotropic regime occurs.

### 2.2. *Tensor perturbations*

We employ a gauge-invariant formalism for general Bianchi type-I cosmology developed by Pereira *et al.*[6] Here we only show the final form of the equations of motion for the '+'- and '×'-mode components of the gauge-invariant tensor perturbations:

$$\mu_+'' + \omega_+^2\,\mu_+ + \xi\,\mu_\times = 0\,, \tag{9}$$

$$\mu_\times'' + \omega_\times^2\,\mu_\times + \xi\,\mu_+ = 0\,, \tag{10}$$

with

$$\omega_+^2 \equiv \gamma^{ij}\,k_i\,k_j - \frac{a''}{a} - \frac{\left(a^2\,\sigma^{(\rm S)}\right)'}{a^2} - 2\,\left(\sigma_\times^{(\rm T)}\right)^2 - \frac{2}{a^2}\left(\frac{a^2\,\left(\sigma_+^{(\rm T)}\right)^2}{2\mathcal{H} - \sigma^{(\rm S)}}\right)'\,, \tag{11}$$

$$\omega_\times^2 \equiv \gamma^{ij}\,k_i\,k_j - \frac{a''}{a} - \frac{\left(a^2\,\sigma^{(\rm S)}\right)'}{a^2} - 2\,\left(\sigma_+^{(\rm T)}\right)^2 - \frac{2}{a^2}\left(\frac{a^2\,\left(\sigma_\times^{(\rm T)}\right)^2}{2\mathcal{H} - \sigma^{(\rm S)}}\right)'\,, \tag{12}$$

$$\xi \equiv 2\sigma_+^{(\rm T)}\,\sigma_\times^{(\rm T)} - \frac{2}{a^2}\left(\frac{a^2\,\sigma_+^{(\rm T)}\,\sigma_\times^{(\rm T)}}{2\mathcal{H} - \sigma^{(\rm S)}}\right)'\,, \tag{13}$$

where $k_i$ is the wave-vector and $\sigma^{(\rm S)}$ and $\sigma_\lambda^{(\rm T)}\,(\lambda = +, \times)$ are the polarisation components of the shear tensor.[6] Since the full expressions for the equations of motion are fairly involved, we refer the readers to Ref. 6, 7 for the details.

Due to the presence of the initial Kasner-like singularity at $a = 0$, the frequency squared $\omega_\lambda^2$ tends to blow up and the adiabatic conditions for the variables $\mu_\lambda$ are generally violated in the anisotropic era.[3,4,7] Now, let us focus on the wave-number term $\gamma^{ij}\,k_i\,k_j$ in $\omega_\lambda^2$ and, in order to make its divergent behaviour more transparent, introduce the following three functions of time:

$${}^{(i)}f = \tanh^{-q_i/2}\left(\frac{3H_\Lambda t}{2}\right) \quad (i = 1, 2, 3)\,, \tag{14}$$

with which the wave-number term can be written as

$$\gamma^{ij}\,k_i\,k_j = {}^{(1)}f^4\,k_1^2 + {}^{(2)}f^4\,k_2^2 + {}^{(3)}f^4\,k_3^2\,. \tag{15}$$

In a triaxially anisotropic background, the factors ${}^{(i)}f^4$ depend on time to the distinctive powers, so only one of the above three terms should dominate at any moment. Since $q_1 > 0$, the term proportional to $k_1^2$ necessarily diverges as $t \to 0$.

## 3. Quantisation and Time Evolution

The implications of the previous analysis urge us to seek for alternative quantities suitable for quantisation.[4,5] In what follows, we assume that the interaction terms in

the equations of motion, $\xi\,\mu_\lambda$, can be ignored, which can be justified on sub-horizon scales.[6]

For the purpose, let us consider a transformation using ${}^{(i)}f$:

$$ {}^{(i)}\chi_\lambda = {}^{(i)}f\,\mu_\lambda\,, \quad \mathrm{d}^{(i)}\tau = {}^{(i)}f^2\,\mathrm{d}\eta\,. \tag{16} $$

After this transformation, the equation of motion for the new variable ${}^{(i)}\chi_\lambda$ reads

$$ {}^{(i)}\ddot{\chi}_\lambda + {}^{(i)}\Omega_\lambda^2\,{}^{(i)}\chi_\lambda = 0\,, \tag{17} $$

where the dot denotes derivative with respect to the new time coordinate ${}^{(i)}\tau$ and the frequency squared for the new variable ${}^{(i)}\chi_\lambda$ is

$$ {}^{(i)}\Omega_\lambda^2 = \frac{\omega_\lambda^2}{{}^{(i)}f^4} + \frac{({}^{(i)}f^{-1})''}{{}^{(i)}f^3} = k_i^2 + \sum_{j\neq i} k_j^2\,\tanh^{-2(q_j-q_i)}\left(\frac{3H_\Lambda t}{2}\right) + \cdots\,, \tag{18} $$

where only the terms relevant to the norm of wave vector were shown in the last expression. Now, suppose there is some moment $t = t_*$ when a condition

$$ k_i^2 \gtrsim \sum_{j\neq i} k_j^2\,\tanh^{-2(q_j-q_i)}\left(\frac{3H_\Lambda t_*}{2}\right) \tag{19} $$

is satisfied, under which a variable ${}^{(i)}\chi_\lambda$ has an approximately constant frequency squared ${}^{(i)}\Omega_\lambda^2 \sim k_i^2$. In this case, we regard such a variable as 'suitable for quantisation' and perform its quantisation in a standard, canonical way. Hereafter, when unnecessary, we drop the superscript '$(i)$' for brevity.

In the canonical quantisation procedure, the positive-frequency modes are approximated by the (zeroth-order) WKB solutions

$$ u_\lambda^{\mathrm{WKB}}(k_i,\tau) = \frac{1}{\sqrt{2\,\Omega_\lambda(k_i,\tau)}}\mathrm{e}^{-\mathrm{i}\int^\tau \mathrm{d}\tau'\,\Omega_\lambda(k_i,\tau')}\,, \tag{20} $$

as long as the so-called WKB parameter

$$ Q_\lambda(k_i,\tau) = -\frac{1}{2\,\Omega_\lambda^2}\left[\frac{1}{\Omega_\lambda}\frac{\mathrm{d}^2\Omega_\lambda}{\mathrm{d}\tau^2} - \frac{3}{2}\left(\frac{1}{\Omega_\lambda}\frac{\mathrm{d}\Omega_\lambda}{\mathrm{d}\tau}\right)^2\right] \tag{21} $$

is tiny.[a] It is now clear from the previous analyses that modes with sufficiently large wave number $(k_1,k_2,k_3)$ have approximately constant $\Omega_\lambda^2$, hence $|Q_\lambda| \ll 1$. Also, for a wide range of wave number $(k_1,k_2,k_3)$, the ${}^{(1)}f$-transformed variable ${}^{(1)}\chi_\lambda$ behaves much like a harmonic oscillator with ${}^{(1)}\Omega_\lambda^2 \simeq k_1^2$ as long as it does not approach too close to $t = 0$ or $t = t_{\mathrm{iso}}$.

Figure 1 shows the evolution of the WKB parameter $|{}^{(1)}Q_\lambda|$ for ${}^{(1)}\chi_\lambda$ and its waveform for $k_1 = k_2 = k_3 = k/\sqrt{3} = (100/\sqrt{3})\,a_{\mathrm{iso}}\,H_\Lambda$. The initial condition for the numerical calculation at $t = t_* = 10^{-5}\,H_\Lambda^{-1}$ is so taken as to match the analytic

[a] The function $u_\lambda^{\mathrm{WKB}}$ satisfies $\frac{\mathrm{d}^2 u_\lambda^{\mathrm{WKB}}}{\mathrm{d}\tau^2} + [1-Q_\lambda]\,\Omega_\lambda^2\,u_\lambda^{\mathrm{WKB}} = 0$.

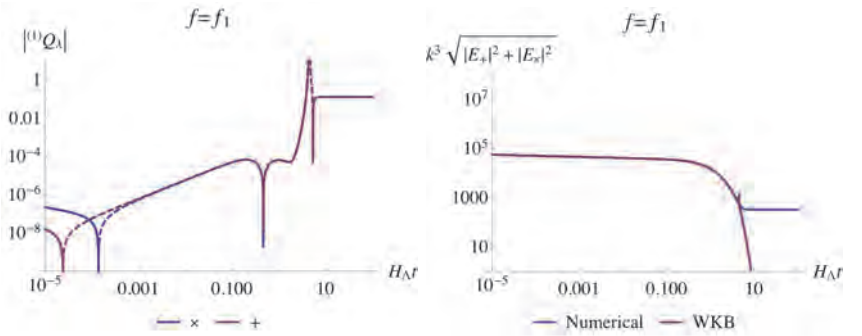

Fig. 1. Time evolution of the WKB parameter ${}^{(1)}Q_\lambda$ (left) and comparison of the WKB solution with the numerical solution (right) for a mode with $k_1 = k_2 = k_3 = k/\sqrt{3} = (100/\sqrt{3})\, a_{\rm iso}\, H_\Lambda$ . The lines for ${}^{(1)}Q_\lambda$ are dashed when the values are negative.

WKB mode function. As $t$ approaches to the time of isotropisation $t_{\rm iso}$ , the WKB mode function is isotropised as

$$|u_\lambda^{\rm WKB}|^2 \sim \frac{1}{2\,\Omega_\lambda} \to \frac{1}{2\,\sqrt{k_1^2+k_2^2+k_3^2}}\,. \tag{22}$$

Then, after the transition to ordinary, isotropic de Sitter inflation at $t = t_{\rm iso}$ , the tensor perturbations decay as $|E_\lambda| \propto a^{-1}$ until they exit the horizon when $a = k/H_\Lambda$ .

So far, we have not mentioned in which quantum state the universe is. Indeed, this is beyond the scope of this study, and we here simply assume that the quantum state is the ground state at $t = t_*$ . Then the power spectrum of PGWs after inflation is estimated as[5]

$$P_{\rm T} \equiv \sum_{\lambda=+,\times} 4\,|E_\lambda(a=k/H_\Lambda)|^2 = 64\pi\, G\, \left.\frac{|u_\lambda|^2}{a^2\, f^2}\right|_{a=k/H_\Lambda} \approx \frac{8\pi\, G\, H_\Lambda^2}{k^3}\,, \tag{23}$$

where the last expression depends only on the norm of wave number, $k = \sqrt{k_1^2+k_2^2+k_3^2}$ , and agrees with the one in de Sitter inflation, that is, isotropic and scale-invariant.

## 4. Sky Map of PGWs

A result of PGWs in a triaxially anisotropic KdS is shown in Fig. 2. One can see that the prediction in the triaxial KdS coincides with that of isotropic de Sitter inflation for the wave length considered and wide range of direction. This is consistent with our analytic evaluation of the power spectrum (23).

There are some features, though: In the polar regions where $|k_3| \gg |k_1|\,, |k_2|\,,$ there is an apparent enhancement of the PGWs. At this stage, we do not claim this should be a real signature of the initial anisotropy because there vast violations of the WKB approximation occur. The regions without value (in black) correspond

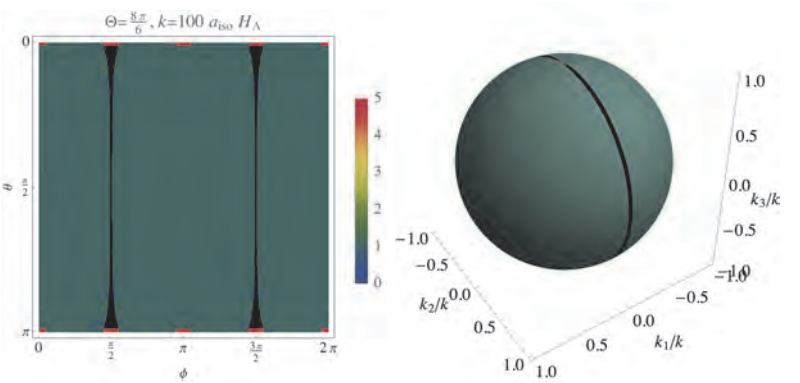

Fig. 2. An all-sky map of PGW intensity for a wave number $k = 10^2\, a_{\rm iso}\, H_\Lambda$ in the presence of a background anisotropy characterised by the indices $(q_1, q_2, q_3) = (1/\sqrt{3}, 0, -1/\sqrt{3})$ $(\Theta = 8\pi/6)$. The values are normalised by those of de Sitter inflation and they are approximately unity in the vast region. In regions without a value (black), all ${}^{(i)}\Omega_\times^2$ $(i = 1, 2, 3)$ are negative and we do not try to compute values.

to where all of ${}^{(i)}\Omega_\lambda^2$ $(i = 1, 2, 3)$ have negative values. We do not try to compute anything in such regions since our approximation method lacks a power of prediction. Note, however, that as we have shown in Ref. 7, the intensity of classical PGWs is enhanced in regions corresponding to the 'uncomputable' regions. This may imply that there is a possibility that such regions could play an important role in detecting the imprint of the anisotropic universe in future observations.

Wave-function collapse following a measurement process is a longstanding controversial issue of quantum physics. It introduces an element of strong non-linearity and irreversibility in an otherwise unitary and reversible dynamics. Several proposals of modification of Quantum Mechanics have been put forward in the past few decades in order to solve such a dichotomy. Among them, some approaches and explicit models considered the possible role of gravity in the wave-function collapse as a result of the incompatibility of general relativity and unitary time evolution of Quantum Mechanics. In this contribution we present some results based on one of such models, De Filippo's Nonunitary Newtonian Gravity, which shows several appealing features: while reproducing at a macroscopic level the ordinary Newtonian interaction, it presents a mass threshold for gravitational localization. In particular, it provides a mechanism for the evolution of macroscopic coherent superpositions of states into ensembles of pure states. On one hand, we show the results of a numerical simulation of a simple system, i.e. two particles in a harmonic trap interacting via an 'electrical' delta-like potential and gravitational interaction. Starting from an energy eigenstate within the ordinary setting, we find that, while energy expectation remains constant, a slow net variation of the von Neumann entropy for the system as a whole takes place, with a small modulation induced on the relative entanglement entropy of the two particles. On the other hand, we explicitly show how a one-parameter generalization of the model, reproducing the nonlinear Newton-Schrödinger equation as the parameter goes to infinity, is free from any causality-violation problem for any finite value of it.

*Keywords*: Gravity; Entanglement entropy; Newton-Schrödinger; Causality violation.

## 1. Introduction

The possible role of gravity in producing a fundamental nonunitary time evolution of the state vector in quantum mechanics (QM) has been invoked in the past few decades by a number of authors, on different grounds[1–3]. The long-standing difficulties posed by the two basic processes of QM, *i.e.* the Schrödinger deterministic evolution and the nonunitary process associated with the act of measurement, lead to the quest of how to reconcile these radically different processes and explain the transition to classicality. These foundational issues appear to be strictly connected with quantum gravity and, in particular, with the way in which gravitational fields are generated by quantum matter. It is still not even clear if gravity has to be quantized at all or it is intrinsically classic and should be properly treated. In the latter case a proposed route is the semi-classical gravity, based on the requirement

that the energy-momentum tensor appearing in Einstein equations is taken as an expectation on the quantum state. This prescription, together with the Newtonian limit, leads to the Newton-Schrödinger equation[4]. While its solutions for a lump of matter show interesting properties, this equation cannot be a valid candidate to give self-gravity at low energies because the nonlinearity allows for superluminal communications. Within this context, in the past years De Filippo introduced a nonunitary non-Markovian model of Newtonian gravity, NNG from now on (see e.g. Ref. 5, references therein). On the one hand this model can be seen as the non-relativistic limit of a classically stable version of higher derivative gravity, whose heuristic application to black hole singularity is in agreement with Bekenstein-Hawking entropy[6,7], given the smoothed singularity of the black hole[5]. On the other hand, it presents several appealing features to become a natural candidate as an effective low-energy model of gravity. For example, while reproducing at a macroscopic level the ordinary Newtonian interaction, it presents a mass threshold for localization, which for ordinary matter densities is about $10^{11}$ proton masses[5,8]. As a key result, it provides a mechanism for the evolution of macroscopic coherent superpositions of states into ensembles of pure states. Furthermore the evolution of the density matrix is compatible with the expectations leading to the phenomenological spontaneous localization models[3], as it was argued that they should be both nonlinear and nonunitary. However, at variance with them, it does not present obstructions consistent with its special-relativistic extension[9]. As to the non-Markovian character of the model, it is interesting to mention the works of Unruh, who studied some nonunitary toy models mimicking black hole evaporation, pointing out the quest for non-Markovianity in order to avoid net dissipation while keeping decoherence[10]. In the NNG model such a feature is built-in.

On the black hole entropy side, in the last decades it has been shown how the decoherence associated to black hole formation and evaporation[11] appears to be a fundamental one, requiring a modification of the unitary time evolution of quantum mechanics in a nonunitary sense: that would allow a non vanishing probability for the evolution from pure states to mixed states. In this sense black hole entropy has been hypothesized[12] as due to the entanglement between matter-fields inside and outside the event horizon. Indeed, starting from suitable initial conditions, only a nonunitary quantum dynamics could allow for a microscopic derivation of the Second Law of thermodynamics for a closed system by resorting to the concept of von Neumann entropy, as pointed out in Ref. 13. In this way it should be possible in principle to shed new light on the long standing and still open problem of quantum foundations of the Second Law of thermodynamics[14–16] without resorting to the ambiguous and subjective procedure of coarse graining[17].

## 2. A two-particle simulation

In this Section we make a first step in demonstrating the ability of NNG to reproduce a gravity-induced relaxation towards thermodynamic equilibrium even for a

perfectly isolated system[18]. To do so, a simple system of two interacting particles is considered. While of course localization mechanism is not acting in this case, due to the far from threshold mass of the particles, some of the peculiar characteristic of the model can be verified in a more general context with respect to the single-lump problem.

More specifically we consider the two particles in an harmonic trap, interacting with each other through 'electrostatic' and gravitational interaction, whose 'physical' Hamiltonian, in the ordinary (first-quantization) setting, is

$$H_P(\mathbf{x}_1,\mathbf{x}_2)=\sum_{i=1}^{2}\left(-\frac{\hbar^2}{2\mu}\Delta_{\mathbf{x}_i}+\frac{\mu}{2}\omega^2\mathbf{x}_i^2\right)+\sum_{i<j=1}^{2}\left(\frac{4\pi\hbar^2 l_s}{\mu}\delta^{(3)}(\mathbf{x}_i-\mathbf{x}_j)-\frac{G\mu^2}{|\mathbf{x}_i-\mathbf{x}_j|}\right); \tag{1}$$

here $\mu$ is the mass of the particles, $\omega$ is the frequency of the trap and $l_s$ is the s-wave scattering length. We are considering a 'dilute' system, such that the electrical interaction can be assumed to have a contact form with a dominant s-wave scattering channel. We take numerical parameters that make the electrical interaction at most comparable with the oscillator's energy, while gravity enters the problem as an higher order correction. Our model, in the (first-quantization) ordinary setting, is defined by the following general meta-Hamiltonian:

$$H_{TOT}=H_P(\mathbf{x}_1,\mathbf{x}_2)+H_P(\widetilde{\mathbf{x}}_1,\widetilde{\mathbf{x}}_2)+H_{NNG}(\mathbf{x}_1,\mathbf{x}_2;\widetilde{\mathbf{x}}_1,\widetilde{\mathbf{x}}_2),$$

with $H_{NNG}=G\mu^2\sum_{i<j}\left(-\frac{1}{|\mathbf{x}_i-\widetilde{\mathbf{x}}_j|}+\frac{1}{2|\mathbf{x}_i-\mathbf{x}_j|}+\frac{1}{2|\widetilde{\mathbf{x}}_i-\widetilde{\mathbf{x}}_j|}\right)$.

Then the time dependent physical density matrix is computed by tracing out the hidden degrees of freedom and the corresponding von Neumann entropy is derived as the entanglement entropy with such (fictitious) hidden degrees of freedom. This is obtained via a numerical simulation, by choosing as initial condition an eigenstate of the physical Hamiltonian. As a result, we find that entropy fluctuations take place, owing to the (nonunitary part of) gravitational interactions, with the initial pure state evolving into a mixture[18]. The behavior of one- and two-particle von Neumann entropy as a function of time is depicted in Fig. 1 for an initial state $|\phi_2\rangle$, equal to the eigenstate of the physical energy associated with the 2nd highest energy eigenvalue $E_2$ of the two-particle system under study. The following values of the physical parameters have been chosen: $l_s, \mu$ and $\omega$: $l_s = 5.5\cdot 10^{-8}m$, $\mu = 1.2\cdot 10^{-24}Kg$ and $\omega = 4\pi\cdot 10^3 s^{-1}$ (which are compatible with current experiments with trapped ultracold atoms[19] and complex molecules[20]) together with an artificially augmented 'gravitational constant' $G = 6.67408\times 10^{-6}m^3kg^{-1}s^{-2}$ ($10^5$ times the real constant).

Due to gravity-induced fluctuations the system entropy shows a net variation over very long times, at variance with the case $G = 0$, in which it would have been a constant of motion. At the same time, single particle entropy, which in the ordinary setting is itself constant, shows now a modulation by the system entropy itself. Incidentally, it has been verified that the expectation of physical energy is

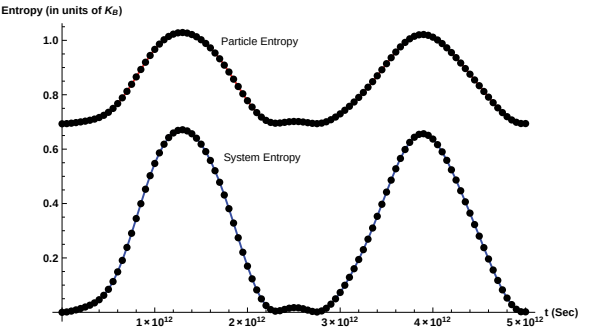

Fig. 1. Time evolution of one-particle and two-particle entropies (respectively, curve above and below) for the initial state chosen.

a constant, meaning that the non-unitary term has no net energy associated with itself, but is purely fluctuational. This constitutes a first necessary step: an extension of this work can be envisaged, which could show explicitly within a realistic setting the way in which thermodynamics could emerge in the framework of NNG, shedding new light on the possible role of gravity in the quantum foundations of thermodynamics in ordinary low-energy physics[5,21,22].

## 3. NNG as a natural cure for causality violations in Newton-Schrödinger equation

In this Section we look at the single particle Newton-Schrödinger equation as the mean-field approximation of an equation of $N$ identical copies of the particle, interacting via usual gravitational interaction, when $N$ goes to infinity (see Ref. 23 for details). The general $N$-copy model is a fully consistent quantum theory, in which superluminal communications are automatically avoided. This feature can be shown to be a consequence of the intrinsic mechanism of spontaneous state reduction, built in in our NNG model and completely suppressed in the Newton-Schrödinger limit.

Here we briefly discuss a specific (ideal) EPR-like experiment involving the superposition of two distinct Center of Mass position states of a massive body. This amounts to consider a sphere of matter of ordinary density of radius $R$, where the state $|Z\rangle$ denotes the sphere with center on the z-axis at $z = Z$, and to take the state of the sphere equal to $(|+Z\rangle+|-Z\rangle)/\sqrt{2}$ (within the ordinary QM setting). A probe mass moving along the $x-$ axis will, according to the non-relativistic quantum theory of gravity, become entangled with the state of the sphere, resulting in the state vector $(|+Z\rangle|up\rangle + |-Z\rangle|down\rangle)/\sqrt{2}$, where $|up\rangle$ ($|down\rangle$) means that the probe is deflected in the positive (negative) $z-$direction. Now, according to semi-classical gravity, the probe mass should be undeflected. A serious theoretical objection to semiclassical gravity is that it allows superluminal communication and then causality violation. To see this, consider the entangled state $(|+Z\rangle|0\rangle + |-Z\rangle|1\rangle)/\sqrt{2}$, where the state $|0\rangle$ and $|1\rangle$ denote orthogonal states of a two state system (qbit)

which is at a large distance from the sphere, but close to a "sender". A probe mass is then used as before. If the sender chooses not to measure the system, the "receiver", who is close to the sphere and uses the probe mass as described above, finds it undeflected. If, on the other hand, the sender chooses to measure the system, thereby finding it to be in the state $|0\rangle$ or $|1\rangle$, the sphere will immediately be in the state $|+Z\rangle$ or $|-Z\rangle$ respectively. Then the receiver will be able to see this because the probe mass will now be deflected up or down.

Let's translate now this conceptual experiment into our model of replicas. The entangled state of the *sphere+q-bit* is:

$$\begin{aligned}\|\Psi^{(N)}\rangle\rangle &= \bigotimes_{i=1}^{N} \frac{1}{\sqrt{2}}(\sqrt{p}|+Z^i\rangle|0^i\rangle + \sqrt{q}|-Z^i\rangle|1^i\rangle) \\ &= \sum_{k=0}^{N} \sqrt{\binom{N}{k}} \left(\frac{1}{2}\right)^{N/2} |+Z;0\rangle^{\otimes k}|-Z;1\rangle^{\otimes(N-k)}. \end{aligned} \tag{2}$$

Consider now the probe particle (supposed to have a mass much more smaller than the lump) shut just over the superposition. Including the probe in the system's description, we have that an initially unentangled (global) state of the probe and of the composite *sphere+q-bit* system evolves towards an entangled one,

$$\|\varphi_I^{(N)}\rangle\rangle \bigotimes \|\Psi^{(N)}\rangle\rangle \to \sum_{k=0}^{N} \sqrt{\binom{N}{k}} \left(\frac{1}{2}\right)^{N/2} \|\varphi_k^{(N)}\rangle\rangle|+Z;0\rangle^{\otimes k}|-Z;1\rangle^{\otimes(N-k)}, \tag{3}$$

where $\|\varphi_I^{(N)}\rangle\rangle = \bigotimes_{m=1}^{N} |\varphi_I^m\rangle$ is the product of identical copies of the probe's state (it is assumed that probe's mass is so small that gravity-induced internal entanglement among copies is irrelevant).

For simplicity let's consider the simplest case with $N = 2$, for which we have only three branches in the superposition (downward, central and upward trajectories). Generalization to a generic $N$ is straightforward. In order to detect a whatever deflection in the probe particle's trajectory, the size of the wave packets describing the particle's states in the superposition should be smaller than the deflection itself. Moreover, their spreading along the path have to be taken into account before the position measurement of the particle's position along the $z$-axis. Denoting with $v_x$ the velocity of the particle, $m$ its mass, and $M$ the mass of the sphere, the time during which the sphere's gravitational attraction is effective is of the order of $T \sim R/v_x$. Then it should be $\frac{GMT}{R^2} \gtrsim \frac{\hbar}{mZ}$.

On the other hand, a peculiar dynamical signature of the NNG model[5] is that, for a lump of mass $M$ above a threshold of $10^{11} m_p$, a superposition of the CM wave packets separated by a distance much smaller than the body's size undergoes a rapid state reduction after a characteristic time $\tau_g \sim \hbar G^{-1} M^{-5/3} \rho^{-1/3}$[24], leading from the initial superposition to an ensemble of localized states. The additional condition for the detection of a significant deflection of the probe is that the measurement

time should be smaller than this reduction time, which together with the constraint above gives the set of conditions that must be satisfied simultaneously:

$$\begin{cases} T \gtrsim \left(\frac{\hbar}{m}\right)^{1/3} \left[\frac{1}{2}\left(\frac{4}{3}\pi\rho\right)^{\frac{2}{3}} G M^{\frac{1}{3}}\right]^{-\frac{2}{3}} \\ T \ll \tau_g = \hbar G^{-1} M^{-5/3} \rho^{-1/3}. \end{cases} \tag{4}$$

These conditions cannot be satisfied together, as shown in Ref. 24. Thus we can conclude that gravity-induced state reduction is so rapid to forbid a sufficiently long measurement, which would otherwise permit a deflection discrimination with respect to the spreading of the wave packet. In other words the 'peaceful coexistence' between (deterministic) QM and special relativity indeed *imply* linearity, unless a certain amount of predictability loss is present.

It is well known that a receding mirror in Minkowski spacetime can model the formation of a black hole, producing Hawking-like radiation at late times. We ask what an observer would need to do to discern whether the radiation is fermionic or bosonic. Specialising to massless fields in 1+1 dimensions, we find that an Unruh–DeWitt detector accomplishes this: the late time transition rate of a detector coupled linearly to the scalar density of a spinor field is proportional to the Helmholtz free energy density of a fermionic thermal bath, hence showing a clear sign of Fermi–Dirac statistics, with no counterpart in the response of a detector coupled linearly to a scalar field or its derivative. By contrast, an observer examining just the stress-energy tensor sees no difference between a fermion and a boson, neither at late times nor early.

*Keywords*: Fermions; Hawking radiation; Moving mirror; Particle detector.

## 1. Introduction

In 1975, Hawking showed that an observer far away from a star undergoing gravitational collapse to form a black hole will see, at late times, thermal radiation with temperature[1]

$$T_{BH} = \frac{\kappa}{2\pi}, \tag{1}$$

where $\kappa$ is the surface gravity of the black hole. Two years later, Davies and Fulling showed that a receding mirror in Minkowski spacetime can produce similar radiation at late times.[2] This is provided the mirror follows a trajectory $z(t)$ satisfying

$$z(t) = -t - Ae^{-2at} + B \quad \text{as} \quad t \to \infty, \tag{2}$$

where $(t, z)$ are the standard Minkowski coordinates and $a, A, B$ are positive constants. The parameter $a$ plays the role of $\kappa$. An example of such a trajectory, illustrated in Fig. 1, is given by[3,4]

$$z(t) = \frac{1}{a} \ln \left( -\frac{e^{at}}{2} + \sqrt{\frac{e^{2at}}{4} + 1} \right). \tag{3}$$

## 2. Bosonic Radiation

A static observer at the finite distance $z = d$ to the right of the mirror may analyse the radiation by examining the stress-energy tensor of the quantum field. After subtracting the divergent Minkowski vacuum contribution, the renormalised expectation value of $T_{\mu\nu}$, evaluated at $(t, d)$ in the early times vacuum of a massless scalar

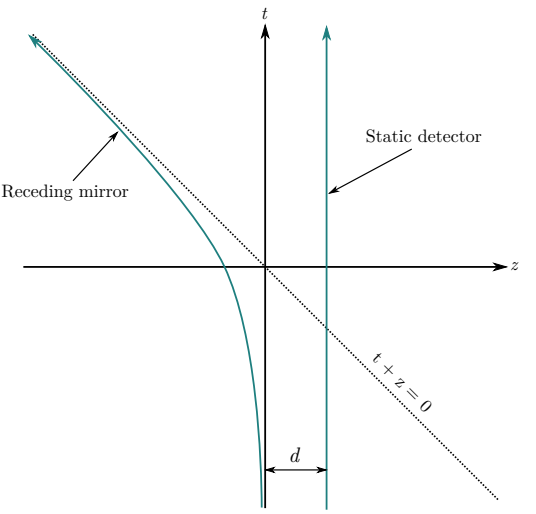

Fig. 1. An illustration of a mirror following the trajectory given in Eq. (3) and an Unruh–DeWitt detector resting at $z = d$. The mirror approaches an asymptote given by $t + z = 0$ at late times.

field, is given by[2]

$$\langle T_{tt}\rangle = \langle T_{zz}\rangle = -\langle T_{tz}\rangle = -\langle T_{zt}\rangle = -\frac{1}{12\pi}\frac{(1-\dot{z}^2)^{\frac{1}{2}}}{(1-\dot{z})^2}\frac{\mathrm{d}}{\mathrm{d}t_d}\left(\frac{\ddot{z}}{(1-\dot{z}^2)^{\frac{3}{2}}}\right). \quad (4)$$

The dot indicates a derivative with respect to the time coordinate $t_d$ of the mirror when it intersects the null line $t - d$.

Alternatively, the observer may probe the radiation using an Unruh–DeWitt detector.[5,6] The simplest version of such a detector is a two-level quantum system coupled to some scalar function $f$ of the field. For a single scalar field $\phi$, for instance, $f$ could be $\phi$ itself or its derivative $\partial_\tau\phi$ with respect to the detector's proper time $\tau$. Up to some detector-specific proportionality constant, the detector's transition probability from energy 0 to $\omega$, after the interaction is switched on and off at proper times $\tau_0$ and $\tau$ respectively, is given by the response function $F(\omega,\tau)$. The quantity that we are interested in is the detector's transition rate[7] $\dot{F}(\omega,\tau) := \partial_\tau F(\omega,\tau)$. Intuitively, $\dot{F}(\omega,\tau)$ measures how the transition probability would change if the detector interacts with the field at a constant coupling strength $c$ for an additional infinitesimal period of detector proper time.

When the interaction is switched on in the asymptotic past (i.e. $\tau_0 \to -\infty$), the late time (i.e. $\tau \to \infty$) transition rate of a static detector at $z = d$, coupled linearly to a scalar field $\phi$ and to its time derivative $\partial_\tau\phi$, is respectively given by[3,4]

$$\dot{F}(\omega,\tau) = -\frac{1}{\omega}\left[\frac{1}{2} - \cos(\omega|R|)\right]\Theta(-\omega) + \frac{a}{2\pi\omega^2} + \frac{1}{2\omega}\frac{1}{e^{2\pi\omega/a}-1} + o(1)\,, \quad (5)$$

$$\dot{F}(\omega,\tau) = -\frac{\omega}{2}\Theta(-\omega) + \frac{\omega}{2(e^{2\pi\omega/a}-1)} + o(1)\,. \quad (6)$$

The parameter $R$ actually diverges in this limit but we shall not concern with the issue here — see Ref. 3 for details. In each expression, we can see a term that is proportional to the Bose–Einstein statistics, indicating that the radiation is bosonic in nature.

## 3. Fermionic Radiation

Our new results[8] concern the radiation from a receding mirror when the field is a massless spinor field $\psi$. How do the local observations made by a static observer differ from those for the scalar field?

We model our totally reflecting mirror by a moving boundary that imposes the MIT bag boundary condition[9]

$$in_\mu \gamma^\mu \psi(t, z(t)) = \psi(t, z(t)), \tag{7}$$

where $n_\mu$ is the inward-directed unit normal to the mirror's worldline and $\gamma^\mu$ are the Dirac gamma matrices. After solving the equation of motion and quantising the field, we evaluate the renormalised expectation value of $T_{\mu\nu}$ via the point-splitting method.[10] We find that the result is exactly identical to Eq. (4). Hence, an observer analysing the radiation just by examining the stress-energy tensor will not be able to deduce that the radiation is made up of fermions, neither at late times nor early.

We then consider an Unruh–DeWitt detector coupled linearly to the scalar density $\overline{\psi}\psi$ of the field where $\overline{\psi}$ is the usual Dirac conjugate. This type of coupling introduces a divergent contribution to the response function[11,12] and hence the transition rate is undefined *a priori*. However, for a massless field in $1+1$ Minkowski spacetime, the divergent term can be dropped by a certain choice of operation ordering. The remaining terms then give a finite transition rate except when the interaction period coincides with the time taken for the field to be reflected back, backwards in time, to the observer. This, however, is not an issue in calculating the late time limit, $\tau \to \infty$.

When the interaction is switched on at a finite proper time $\tau_0$, we find that the late time transition rate is given by

$$\dot{F}(\omega, \tau) = \frac{a}{2\pi^2} \ln(1 + e^{-\frac{2\pi\omega}{a}}) + o(1)\,. \tag{8}$$

At first glance, it is not obvious that Eq. (8) is associated to fermions since there is no term proportional to the Fermi–Dirac statistics. However, recall that the Helmholtz free energy of fermions in a thermal bath at temperature $T = a/2\pi$ is given by[13]

$$F = -2L \int_0^\infty \frac{\mathrm{d}\omega}{2\pi} \left[\omega + \frac{a}{\pi} \ln(1 + e^{-\frac{2\pi\omega}{a}})\right], \tag{9}$$

where $L$ is the length of the system of fermions. Ignoring the first term in Eq. (9), which corresponds to the vacuum energy, we see that Eq. (8), when $\omega > 0$, is proportional to the Helmholtz free energy density of mode $\omega$ of the fermionic thermal

bath. Hence, an observer analysing the late times radiation with our detector will be able to deduce that the radiation consists of fermions.

## 4. Conclusion

We have analysed a receding mirror producing Hawking-like radiation at late times by calculating the renormalised stress-energy tensor and the transition rate of an Unruh–DeWitt detector. We find that the former is identical for massless scalar and spinor fields. Hence, an observer examining only the stress-energy tensor will see no difference between bosons and fermions, neither at late times nor early. In contrast, an observer equipped with an Unruh–DeWitt detector observes that the late time transition rate contains a term proportional to the Bose–Einstein statistics when the radiation is bosonic but is proportional to the Helmholtz free energy density of thermal fermions when the radiation is fermionic. The observer with a detector will hence be able to discern whether the late times radiation consists of bosons or fermions. Further technical details can be found in Ref. 8.

What is the black hole in quantum mechanics? We try this problem in a self-consistent manner. First, we analyze time evolution of a 4D spherically symmetric collapsing matter including the back reaction of particle creation that occurs in the time-dependent spacetime. As a result, a compact high-density star with no horizon or singularity is formed and eventually evaporates. This is a quantum black hole. We can construct a self-consistent solution of the semi-classical Einstein equation showing this structure. In fact, we construct the metric, evaluate the expectation values of the energy momentum tensor, and prove the self-consistency. Large pressure appears in the angular direction to support this black hole, which is consistent with 4D Weyl anomaly. When the black hole is formed adiabatically in the heat bath, integrating the entropy density over the interior volume reproduces the area law.

*Keywords*: Black hole evaporation; semi-classical Einstein equation; self-consistent solution; Weyl anomaly; black hole entropy.

## 1. The basic idea

In quantum mechanics, black holes evaporate by nature. We consider this property seriously and try to understand what the quantum black hole is. A physically reasonable way to do it is to investigate the time evolution of a collapsing matter and see what will be formed. In the spacetime of the formation process, which is time dependent, particle creation occurs, and its back reaction also needs to be considered. Here, it has been believed for a long time that the back-reaction effect should be negligible because the time scale of the evaporation ($\sim a^3/l_p^2$) is much longer than that of the collapse ($\sim a$), where $a \equiv 2GM$ is the Schwarzschild radius and $l_p \equiv \sqrt{\hbar G}$ the Planck length. However, it should be noted that $\Delta t \sim a^3/l_p^2$ is measured by a standing observer far from the matter while $\Delta\tau \sim a$ by a comoving observer along with the matter, and that it is not meaningful to compare two time scales measured by such two different clocks. Rather, we need to analyze time evolution of both the matter and spacetime in a single time coordinate.

Motivated by this, we provide our basic idea [1–5]. Suppose that a spherical "black hole" with mass $M = \frac{a}{2G}$ is evaporating, and the spacetime changes slowly in time. We consider what happens if we add a thin shell to it. The answer is remarkable: if we consider the time evolution of both the shell and spacetime together, the shell will never cross the Schwarzschild radius.

To see this, we assume, for simplicity, that Hawking radiation goes to infinity without reflection by such as the gravitational potential, and then describe the

spacetime outside the black hole by the outgoing Vaidya metric

$$ds^2 = -\frac{r - a(u)}{r}du^2 - 2dudr + r^2 d\Omega^2, \tag{1}$$

where $M(u) = \frac{a(u)}{2G}$ is the Bondi mass and $a(u)$ satisfies

$$\frac{da}{du} = -\frac{\sigma}{a^2}. \tag{2}$$

(See the right of Fig. 1.) $\sigma = kNl_p^2$ is the intensity of the Hawking radiation, where

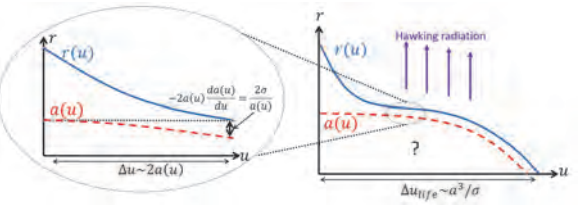

Fig. 1. Motion of a shell or a particle near the evaporating black hole.

$N$ is the degrees of freedom of fields in the theory and $k$ is an $O(1)$ constant. Note that at this stage we don't specify anything about the interior.

If the shell comes close to $a(u)$, the motion is governed by the equation for ingoing radial null geodesics:

$$\frac{dr(u)}{du} = -\frac{r(u) - a(u)}{2r(u)}, \tag{3}$$

no matter what mass and angular momentum the particles constituting the shell have[3]. Here, $r(u)$ is the radial coordinate of the shell. This reflects the fact that any particle becomes ultra-relativistic near $r \sim a$ and behaves like a massless particle. We can obtain the solution of (3)[1–4] as

$$\begin{aligned} r(u) &\approx a(u) - 2a(u)\frac{da}{du}(u) + Ce^{-\frac{u}{2a(u)}} \\ &= a(u) + \frac{2\sigma}{a(u)} + Ce^{-\frac{u}{2a(u)}} \longrightarrow a(u) + \frac{2\sigma}{a(u)} =: R(a(u)). \end{aligned} \tag{4}$$

This means the following (see the left of Fig. 1): The shell approaches the radius $a(u)$ in the time scale of $O(2a)$, but during this time, the radius $a(u)$ itself is shrinking as (2). Therefore, $r(u)$ is always apart from $a(u)$ by $-2a\frac{da}{du} = \frac{2\sigma}{a}$. Thus, the shell never crosses the radius $a(u)$ as long as the black hole evaporates in a finite time.

We then assume that, after the shell comes close to $r = a + \frac{2\sigma}{a}$, the total system composed of the black hole and shell behaves like an ordinary black hole with mass $M + \Delta M$, where $\Delta M$ is the mass of the shell. This means that the radiation emitted from the total system agrees with that from a black hole with mass $M + \Delta M$.

Now, we consider a spherical collapsing matter with a continuous distribution and regard it as many concentric shells. We can apply the above argument to each

shell recursively because its evolution is not affected by the outside shells due to the spherical symmetry. Then, we can see that the matter will shrink as a whole and become a dense object. (See Left of Fig. 2.) In the formation, no horizon will

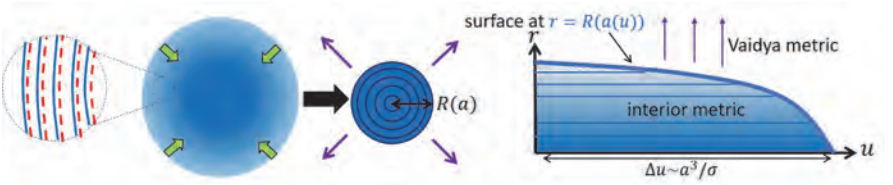

Fig. 2. A spherical matter becomes a dense object (left). The evolution of the object (right).

appear, but a surface will be formed at $r = a + \frac{2\sigma}{a}$, which is a boundary inside which the matter is distributed. From the outside, the object looks like an evaporating black hole in the ordinary picture. Thus, this should be a quantum black hole.

## 2. A self-consistent solution

In order to prove this idea, we have to analyze the dynamics of the coupled quantum system of matter and gravity. Here, we consider the semi-classical Einstein equation

$$G_{\mu\nu} = 8\pi G \langle T_{\mu\nu} \rangle, \tag{5}$$

where $\langle T_{\mu\nu} \rangle \equiv \langle \psi | T_{\mu\nu} | \psi \rangle$ contains the contribution from the collapsing matter and Hawking radiation, and $|\psi\rangle$ is any state that represents the matter at $u = -\infty$.

We solve this equation in a self-consistent manner[4]. First, we consider a physical model which assumes no reflection of Hawking radiation, and construct a candidate metric $g_{\mu\nu}$. Second, we evaluate $\langle T_{\mu\nu} \rangle$ on the obtained $g_{\mu\nu}$. More precisely, we show that all the components of $\langle T_{\mu\nu} \rangle$ can be expressed in terms of $\langle T_\mu{}^\mu \rangle$, assume conformal matter for simplicity, and use 4D Weyl anomaly formula

$$\langle T_\mu{}^\mu \rangle = \hbar c_W C_{\mu\nu\alpha\beta} C^{\mu\nu\alpha\beta} - \hbar a_W (R_{\mu\nu\alpha\beta} R^{\mu\nu\alpha\beta} - 4 R_{\mu\nu} R^{\mu\nu} + R^2). \tag{6}$$

Finally, by imposing the equality in (5), we can determine the self-consistent solution. Furthermore, to remove the artificial assumption, we introduce a phenomenological function $f$ that characterises how amount radiation is reflected by the gravitational potential or interaction with the other matters. It is defined by

$$\langle T_{UV} \rangle = f \langle T_{UU} \rangle, \tag{7}$$

where $(U, V)$ is a Kruskal-like coordinate, and $\langle T_{UU} \rangle$ is a purely radial outgoing energy flow. We expect that in the case of conformal matters the dimensionless function $f$ is constant. Thus, we can obtain the self-consistent solution of (5) as[1–4]

$$ds^2 = \begin{cases} -\frac{r - a(u)}{r} du^2 - 2 dr du + r^2 d\Omega^2, & \text{for } \ r \geq R(a(u)) \\ -\frac{2\sigma}{r^2} e^{-\frac{R(a(u))^2 - r^2}{2\sigma(1+f)}} du^2 - 2 e^{-\frac{R(a(u))^2 - r^2}{4\sigma(1+f)}} du dr + r^2 d\Omega^2, & \text{for } \ r \leq R(a(u)) \ . \end{cases} \tag{8}$$

See Right of Fig. 2. Here, the radius $a(u)$ decreases as (2) with the intensity

$$\sigma = \frac{8\pi l_p^2 c_W}{3(1+f)^2}, \tag{9}$$

where $c_W$ plays a role of $N$ in the basic idea.

This metric has interesting properties. First, the interior metric is static, which can be seen by choosing a time coordinate properly. The time-dependence of the system comes from the decreasing radius $R(a(u))$. Second, the exponential redshift factor freezes the interior in time, and the evolution occurs only in the surface region, which indicates that this object evaporates from the outside as if one peels off an onion. From a local point of view, however, the matter itself keeps shrinking by emitting the energy. In this sense, the interior will not be in equilibrium even if it is put into the heat bath. Finally, a classical limit $\hbar \to 0$ cannot be taken in the interior metric, and therefore, it is a non-perturbative solution of (5) w.r.t. $\hbar$.

## 3. Consistency check

We examine the consistency of the solution (8). First, the curvature $\mathcal{R}$ in the macroscopic region ($l_p < r \leq R(a)$) is $\mathcal{R} \sim \frac{1}{c_W l_p^2}$. Therefore, if the theory satisfies $c_W \gg 1$, the curvature is less than the Planck scale, and there is no singularity. This means that no quantum gravity effect is needed to describe the evaporating black hole as long as $a > l_p$. The Penrose diagram is given as in Fig. 3.

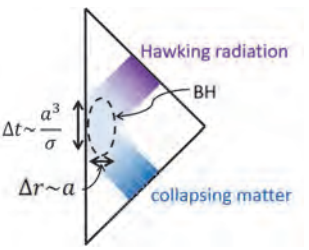

Fig. 3. The Penrose diagram for the metric (8).

The resolution of the singularity is a non-perturbative effect. The key equation in our self-consistent analysis is the trace part of (5), $G^\mu{}_\mu = 8\pi G \langle T^\mu{}_\mu \rangle$, where the r.h.s. is given by (6). This equation can be expressed schematically as $\mathcal{R} \sim N l_p^2 \mathcal{R}^2$. The interior metric of (8) has $\mathcal{R} \sim \frac{1}{N l_p^2}$, which satisfies this equation. Therefore, the metric is a result of solving (5) in a non-perturbative way w.r.t. $\hbar$.

Next, we can reproduce Hawking radiation in this picture. We can consider the collapsing process approaching to the metric (8), determine evolution of massless scalar fields in the eikonal approximation, and show that particle creation occurs in a Planck-like distribution of the time-dependent temperature $T = \frac{\hbar}{4\pi a(u)}$.

We check energy condition of the energy-momentum tensors in the interior:

$$-\langle T^t{}_t\rangle = \frac{1}{8\pi G r^2}, \quad \langle T^r{}_r\rangle = \frac{1}{8\pi G r^2}\frac{1-f}{1+f}, \quad \langle T^\theta{}_\theta\rangle = \frac{1}{8\pi G}\frac{3}{16\pi c_W l_p^2}. \tag{10}$$

The energy density is positive everywhere, and the radial pressure is so for $0 \le f < 1$. The angular pressure is much larger than the radial one, which means that the interior is anisotropic and not a fluid, and than the energy density, which breaks the dominant energy condition. This large pressure works as a outward radial pressure because of the spherical symmetry, which stabilizes the object against the gravitational attractive force.

We can see the reason why such a large pressure is produced. In (10), $\langle T^\theta{}_\theta\rangle \approx \frac{1}{2}\langle T^\mu{}_\mu\rangle$ holds, where the r.h.s. is given by (6). When derives the formula (6) in a spherically symmetric background spacetime, one expands fields into partial waves and sums up the modes with large angular momenta. Therefore, the large pressure $\langle T^\theta{}_\theta\rangle$ is a result of 4D dynamics.

We study the entropy of the object[3]. Imagine that in the heat bath we grow up the stationary black hole adiabatically. We can evaluate the entropy density inside the black hole as $s = \frac{1}{4\pi r^2}\frac{2\pi\sqrt{2\sigma}}{l_p^2}$, which means that $O(\sqrt{N})$ bits information are contained per the proper length. By summing it up over the interior volume, we can reproduce the area law:

$$S = \int_V dV\, s = \frac{A}{4l_p^2}. \tag{11}$$

This implies that the information is stored inside the black hole, not on the surface.

Finally, we make a comment on the information problem[3]. In this picture, Hawking radiation occurs inside the collapsing matter. We can expect that there is a small interaction between them, which reflects the initial information of the matter on the emitted radiation. This is reminiscent of the fact that in thermodynamics interactions bring a system into equilibrium states. Indeed, we can consider a simple model of collision of the radiation and matter, and evaluate the scattering time scale as $\Delta t \sim a \log \frac{a}{\lambda N l_p}$, where $\lambda$ is a dimensionless coupling constant.

# Inequivalent vacua in quantum field theory

Daniele Colosi

*Escuela Nacional de Estudios Superiores Unidad Morelia,*
*Universidad Nacional Autónoma de México,*
*Campus Morelia, C.P. 58190, Morelia, Michoacán, Mexico*
*E-mail: dcolosi@enesmorelia.unam.mx*

Implementing a path integral quantization of real massive scalar fields in a wide class of curved spaces we derive a general expression for the vacua in the Schrödinger representation. Using the general boundary formulation of quantum theory, we show how a symmetry of the space of classical solutions leads to a one-parameter family of quantum vacua. In this way we offer a new derivation of the alpha-vacua in de Sitter space.

*Keywords*: Vacuum, Curved spaces.

## 1. Introduction

Some aspects of the observed cosmic microwave background radiation[1] can found a description in terms of quantum fluctuations in the early universe. The study of properties of the quantum vacua for fields in curved spacetime may account for the large scale structure of our universe and has indeed received a great amount of attention.[2] In this contribution we consider a real massive scalar field in a wide class of curved spaces and construct a one parameter family of vacua. By expressing the solutions of the Klein-Gordon equation in a spacetime region $M$ in terms of the boundary configuration $\varphi$ satisfied by the field, i.e. $\phi|_{\partial M} = \varphi$, we point out the existence of two global symmetries. At the quantum level, both symmetries are broken since the resulting vacua, parametrised by a constant $\alpha$, lead to inequivalent quantum theories. In certain cases, the value of the parameter $\alpha$ is uniquely fixed according to general criteria such as demanding invariance under the group of isometry of the spacetime or other requirement the theory must satisfies.

After presenting the classical theory in Section 2, we quantize the field in Section 3 according to the general boundary formulation (GBF)[3] prescriptions. Section 4 is devoted to examples: In Minkowski and in Rindler space the parameter $\alpha$ is fixed to zero thanks to the symmetry of space. In contrast all the $\alpha$-vacua in de Sitter result to be invariant under the de Sitter group. Among these vacua the one defined by $\alpha = 0$ corresponds to the so called Bunch-Davies or Euclidean vacuum. Finally, Section 5 summarises our results and indicates future line of research.

## 2. Classical theory

The dynamics of a real scalar field with mass $m$ in a 4d Lorentzian spacetime with line element $\mathrm{d}s^2 = g_{\mu\nu}\mathrm{d}x^\mu \mathrm{d}x^\nu$, in a spacetime region $M$ is described by the action $S_M[\phi] = \frac{1}{2}\int_M \mathrm{d}^4x\,\sqrt{-g}\left[g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi - (m^2 + \xi R)\phi^2\right]$, where $g = \det(g_{\mu\nu})$ and $\partial_\mu$ denotes the partial derivative w.r.t. to $x^\mu$, $R$ is the scalar curvature of the spacetime, $\xi$ a dimensionless constant. We assume the following:[4]

(*i*) The region $M$ is foliated by hypersurfaces which are *not* required to be Cauchy surfaces. The foliation is described by the coordinates $(x^0, \underline{x})$ where $\underline{x} = (x^1, x^2, x^3)$. The leaves are parametrised by $x^0$ which in general is *not* a timelike coordinate.
(*ii*) The metric takes a block-diagonal form, i.e. $g^{0i} = 0 = g^{i0}$ for all $i \in \{1, 2, 3\}$.
(*iii*) Solutions of e.o.m. are obtainable by the method of separation of variables as

$$\phi(x^0, \underline{x}) = \big(X_a(x^0)Y_a\big)\,(\underline{x}) + \big(X_b(x^0)Y_b\big)\,(\underline{x}), \tag{1}$$

where $X_k(x^0)$ $(k = a, b)$ is a linear operator acting on the "initial" data $Y_k$ such that $\big(X_k(x^0)Y_k\big)\,(\underline{x})$ is a solution evaluated on the hypersurface of fixed $x^0$. We assume moreover that these operators commute among each other and are invertible.

Although restrictive, these conditions are encompassed by the most studied QFTs. If $M$ is the region $[t_1, t_2] \times \mathbb{R}^3$, solution (1) can be expressed in the form

$$\phi(x^0, \underline{x}) = \left(\frac{\mathcal{W}^{00}(x^0, t_2)}{\mathcal{W}^{00}(t_1, t_2)}\varphi_1\right)(\underline{x}) + \left(\frac{\mathcal{W}^{00}(t_1, x^0)}{\mathcal{W}^{00}(t_1, t_2)}\varphi_2\right)(\underline{x}), \tag{2}$$

where $\varphi_i = \phi|_{x^0=t_i}$ and $\mathcal{W}^{00}(t, t') = X_a(t)X_b(t') - X_a(t')X_b(t)$. The quotients have to be understood as operator acting on a mode decomposition of the boundary field configurations $\varphi_i$, $i = 1, 2$. The action of the field can be written in terms of $\varphi_i$ as

$$S_M(\varphi_1, \varphi_2) = \frac{1}{2}\int \mathrm{d}^3\underline{x}\,(\varphi_1\ \varphi_2)\,W\begin{pmatrix}\varphi_1\\ \varphi_2\end{pmatrix} \tag{3}$$

where the matrix $W$ has elements: $W^{11} = -\sqrt{\gamma|_{x^0=t_1}}\frac{\mathcal{W}^{10}(t_1,t_2)}{\mathcal{W}^{00}(t_1,t_2)}$, $W^{12} = -\sqrt{\gamma|_{x^0=t_1}}\frac{\mathcal{W}^{01}(t_1,t_1)}{\mathcal{W}^{00}(t_1,t_2)}$, $W^{21} = +\sqrt{\gamma|_{x^0=t_2}}\frac{\mathcal{W}^{10}(t_2,t_2)}{\mathcal{W}^{00}(t_1,t_2)}$ and $W^{22} = +\sqrt{\gamma|_{x^0=t_2}}\frac{\mathcal{W}^{01}(t_1,t_2)}{\mathcal{W}^{00}(t_1,t_2)}$, where $\gamma = \left|g^{(3)}g^{00}\right|$ with $g^{(3)}$ being the determinant of the induced metric on the hypersurface of constant $x^0$, and $\mathcal{W}^{10}(t, t') = (\partial_0 X_a)\,(t)X_b(t') - X_a(t')\,(\partial_0 X_b)\,(t)$ and $\mathcal{W}^{01}(t, t') = X_a(t)\,(\partial_0 X_b)\,(t') - (\partial_0 X_a)\,(t')X_b(t)$. The space of solutions of e.o.m. is equipped with the symplectic structure $\Omega(\phi_1, \phi_2) = \frac{1}{2}\int \mathrm{d}^3\underline{x}\sqrt{\left|g^{(3)}g^{00}\right|}$ $(\phi_1\partial_0\phi_2 - \phi_2\partial_0\phi_1)$, which is independent of the leaf of the foliation.

The key observation of this contribution consists in noticing that the classical solution (2) and the action (3) are left invariant by the global transformations $\Pi(X_a, X_b) = (\beta X_a, \beta^{-1}X_b)$ and $\tilde{\Pi}(X_a, X_b) = (\beta X_b, \beta^{-1}X_a)$ with $\beta \in \mathbb{R}\setminus\{0\}$. Since the parameter $\beta$ is real, both transformations project solutions of the Klein-Gordon equation into solutions. $\Pi$ preserves the symplectic structure $\Omega$, which in contrast changes sign under $\tilde{\Pi}$. In what follows we will consider only the transformation $\Pi$. Notice that the invariance of solutions, action and symplectic structure are a direct consequence of the representation of the field and the action in terms of the boundary configurations $\varphi_i$, $i = 1, 2$. This invariance will be broken at the quantum level, and the QFTs associated to different value of $\beta$ will result to be inequivalent.

## 3. Vacum state in the Schrödinger representation

The quantization of the theory is implemented in terms of the Feynman path integral combined with the Schrödinger representation in accordance with the axioms of

the GBF. In this formulation, as in TQFT, a Hilbert space is associated to each hypersurface. It must be emphasised that the novelty of the GBF is the possibility to implement this association for arbitrary hypersurfaces, not only Cauchy ones. Thus, for a hypersurface $\Sigma$ we denote the corresponding Hilbert space with $\mathcal{H}_\Sigma$. Quantum states are given by functional of field configurations, i.e. $\psi_\Sigma(\varphi) \in \mathcal{H}_\Sigma$ where $\varphi = \phi|_\Sigma$. The inner product between two states $\psi_\Sigma$ and $\eta_\Sigma$ in $\mathcal{H}_\Sigma$ is given by the integral $\int \mathcal{D}\varphi\, \overline{\psi_\Sigma(\varphi)}\eta_\Sigma(\varphi)$, where the overline indicates complex conjugation.

The quantum dynamics that unfolds in the spacetime region $M$ of interest is encoded in the so called field propagator: $Z_M(\varphi) = \int_{\phi|_{\partial M}=\varphi} \mathcal{D}\phi\, e^{\mathrm{i}S_M[\phi]}$, where the integration is extended over all spacetime configurations $\phi$ that reduce to $\varphi$ on the boundary $\partial M$. For the interval region presented in Section 2, the Hilbert space associated to the boundary decomposes as $\mathcal{H}_{\partial M} = \mathcal{H}_{t_1} \otimes \mathcal{H}^*_{t_2}$, where the star denotes the dualization of the Hilbert space due to the change in the orientation of the hypersurface at $x^0 = t_2$. The field propagator in this region reads $Z_M(\varphi_1, \varphi_2) = N_M e^{\mathrm{i}S_M(\varphi_1,\varphi_2)}$, where $N_M = \int \mathcal{D}\phi\, e^{\mathrm{i}S_M[\phi]}$ with $\phi|_{\partial M} = 0$, the action $S_M(\varphi_1, \varphi_2)$ is (3). Then, a state $\psi_{t_1} \in \mathcal{H}_{t_1}$ is evolved to a state in $\mathcal{H}_{t_2}$ by the field propagator as $\int \mathcal{D}\varphi_1\, \psi_{t_1}(\varphi_1) Z_M(\varphi_1, \varphi_2) \in \mathcal{H}_{t_2}$. In the GBF the vacuum state is obtained by requiring the functional invariance under such evolution; its general structure[4] is $\psi_{t,0}(\varphi) = C_t \exp\left(\frac{\mathrm{i}}{2}\int \mathrm{d}^2\underline{x}\, \varphi(\underline{x})\sqrt{\left|g^{(3)}g^{00}\right|}\frac{\partial_0 \Upsilon(x^0)}{\Upsilon(x^0)}\Big|_{x^0=t} \varphi(\underline{x})\right)$, where $C_t$ is a normalisation factor and the operator $\Upsilon$ is a linear combination of $X_a$ and $X_b$ with complex coefficients: $\Upsilon(x^0) = c_a X_a(x^0) + c_b X_b(x^0)$, where the coefficients $c_a$ and $c_b$ must satisfy the condition: $\Im(\overline{c_a} c_b) \neq 0$. In general the vacuum state is not invariant under the action of $\Pi$ since it transforms the vacuum in the new state

$$\psi^\beta_{t,0}(\varphi) = C_t \exp\left(\frac{\mathrm{i}}{2}\int \mathrm{d}^2\underline{x}\, \varphi(\underline{x})\sqrt{\left|g^{(3)}g^{00}\right|}\frac{\partial_0 \Upsilon_\beta(x^0)}{\Upsilon_\beta(x^0)}\Big|_{x^0=t} \varphi(\underline{x})\right), \tag{4}$$

with $\Upsilon_\beta(x^0) = c_a \beta X_a(x^0) + c_b \beta^{-1} X_b(x^0)$. The transformation $\Pi$ applied to $\Upsilon$ can be interpreted as a rescaling of the coefficients $c_a$ and $c_b$. This allows us to conclude that the state (4) is an acceptable vacuum state for the field. Moreover, the sign of the parameter $\beta$ does not play any role for this state and consequently its value can be restricted to be positive, i.e. $\beta = e^\alpha$ with $\alpha \in \mathbb{R}$. From now on we write $\Upsilon_\alpha$.

Notice that the theories defined by the vacuum (4) are inequivalent for different values of the parameter $\alpha$. Indeed, the Feynman propagator determined by (4) reduces to the standard Feynman propagator only if $\alpha = 0$. We conclude that for non vanishing values of the parameter $\alpha$ we obtain inequivalent quantum theories.

## 4. Fixing $\alpha$

For certain QFTs, the value of $\alpha$ can be fixed uniquely in terms of some general criteria. We present some examples, giving in particular the explicit expression of the vacuum states for the field in Minkowski, Rindler and de Sitter spaces. In the case of Minkowski and Rindler, the vacuum is unique thanks to the symmetry of the space. In de Sitter we specify the criteria that distinct the different vacua.

### 4.1. *Minkowski space*

Minkowski space is invariant under the Poincaré group. Requiring the same invariance for the vacuum state fixes the value of $\alpha$ to be zero. In the case of an interval region where $x^0$ is the Minkowski time $t$, we have that $X_a(t) = \cos(\omega t)$ and $X_b(t) = \sin(\omega t)$, with $\omega = \sqrt{-\partial^2_{\underline{x}} + m^2}$. Thus, the state (4) is left unchanged under the transformation $t \to t' = t + t_0$ only if $\alpha = 0$ and $c_a = 1, c_b = \mathrm{i}$. With this choice (4) reduces to the standard Minkowski vacuum[5–7], $\psi_0 = C \exp\left(-\frac{1}{2}\int \mathrm{d}^3\underline{x}\,\varphi(\underline{x})\omega\varphi(\underline{x})\right)$.

### 4.2. *Rindler space*

The line element of 2d Rindler space is $\mathrm{d}s^2 = \rho^2\mathrm{d}\eta^2 - \mathrm{d}\rho^2$ where $x^0 = \rho\sinh\eta$ and $x^1 = \rho\cosh\eta$, $x^0$ and $x^1$ being Minkowski coordinates. The same result as in Minkowski is recovered in Rindler space since, for the region $M = [\eta_1, \eta_2] \times \mathbb{R}^+$, $X_a(\eta) = \cos(\omega\eta)$ and $X_b(\eta) = \sin(\omega\eta)$ with $\omega = \sqrt{-(\rho\partial_\rho)^2 + m^2}$.[8] Invariance of the vacuum under a temporal translation is achieved only for $\alpha = 0$, and the vacuum on the hypersurface of constant $\eta$ results to be $\psi_0 = C\exp\left(-\frac{1}{2}\int \mathrm{d}\rho\,\frac{1}{\rho}\varphi(\rho)\omega\varphi(\rho)\right)$.

### 4.3. *de Sitter space*

The de Sitter group does not fix the value of the parameter $\alpha$. To see this we consider the de Sitter metric in the following coordinate system $\mathrm{d}s^2 = \frac{R^2}{(x^0)^2}\left((\mathrm{d}x^0)^2 - (\mathrm{d}\underline{x})^2\right)$, where $x^0 \in ]0, \infty[$, $\underline{x} \in \mathbb{R}^3$, and $R$ denotes the inverse of the Hubble constant. This coordinate system covers half of de Sitter space and the other half is covered by extending $x^0$ from $-\infty$ to 0. Solutions of e.o.m are parametrized by $X_a(x^0) = (x^0)^{3/2}J_\nu(kx^0)$ and $X_b(x^0) = (x^0)^{3/2}Y_\nu(kx^0)$, where $k = |\underline{k}|$,[a] and $J_\nu(z)$ and $Y_\nu(z)$ are the Bessel functions of the first and second kind respectively, with index $\nu = \sqrt{\frac{9}{4} - (mR)^2}$.[9] Vacuum states on a surface of constant $x^0$ read

$$\psi_0(\varphi) = C\exp\left(\frac{\mathrm{i}}{2}\int \mathrm{d}^3\underline{x}\,\varphi(\underline{x})\frac{R^2}{(x^0)^2}\frac{\partial_0\Upsilon_\alpha(x^0)}{\Upsilon_\alpha(x^0)}\varphi(\underline{x})\right), \tag{5}$$

with $\Upsilon_\alpha(x^0) = (x^0)^{3/2}\left(e^\alpha J_\nu(kx^0) + \mathrm{i}e^{-\alpha}Y_\nu(kx^0)\right)$, $\alpha \in \mathbb{R}$.

#### 4.3.1. Isometry of space

The de Sitter metric is invariant under 10 transformations: 3 spatial rotations, 3 spatial translations and the following transformation ($H = R^{-1}$, $x^0_0$ is a constant)

$$x^0 \to (x^0)' = e^{-Hx^0_0}x^0, \qquad \underline{x} \to \underline{x}' = e^{-Hx^0_0}\underline{x}. \tag{6}$$

[a] In order for the solution to be well defined in the whole spacetime, as well as in the interval type region, the components of the 3-vector $\underline{k}$ have to be real, so $k > 0$.

A vacuum state on the surface defined by $(x^0)' = e^{-Hx_0^0}x^0$ depends on the configuration $\varphi'(\underline{x}) = \int \frac{\mathrm{d}^3\underline{k}}{(2\pi)^{3/2}}\varphi'(\underline{k})e^{\mathrm{i}\underline{k}\cdot\underline{x}}$ and is left invariant by (6) if the coefficients $\varphi'$ satisfy the equality $\varphi'(\underline{k}e^{-Hx_0^0}) = \varphi(\underline{k})$. Therefore the invariance under the transformation (6) does not fix the value of $\alpha$. The one parameter family of vacua (5) are the so called $\alpha$-vacua in de Sitter.[10]

4.3.2. Minkowski limit

de Sitter space reduces to Minkowski space in the limit where the curvature is infinite, corresponding to the limits $R \to \infty$ and $x^0 \to \infty$ such that $\frac{R}{x^0}$ is kept constant. Using the asymptotic expression of the Bessel functions[11] we see that the Minkowski vacuum is recovered only if $\alpha = 0$. This is the Bunch-Davies vacuum for de Sitter.[12] Moreover, only for $\alpha = 0$ the singularities of the Feynman propagator in the limit $x \to x'$ are of the Hadamard form.

4.3.3. Energy expectation value

Another criterium to select a vacuum state is requiring that expectation value of the energy is the minimum when evaluated on the vacuum state. Denoting with $\rho^{T_{00}}(\psi_0)$ the expectation value of the 00-component of the energy momentum tensor on a vacuum state defined at a constant $x^0$ hypersurface in the region $M$, we have, in the case of a minimally coupled field, $\rho^{T_{00}}(\psi_0^\alpha) = \frac{1}{2\mathrm{i}}\lim_{x\to x'}(\partial_0\partial_0' + \partial_{\underline{x}}\partial_{\underline{x}'} + m^2)G_M^\alpha(x,x')$, where $\partial_0' = \partial/\partial(x_0)'$ and $G_M^\alpha$ is the Feynman propagator. This criterium select the Bunch-Davies vacuum in the asymptotic region $x^0 \gg 1$.

4.3.4. Wick rotation

The Bunch-Davies vacuum is also recovered through a Wick rotation, i.e., by performing an analytic continuation of the variable in terms of which the dynamics is described, namely $x^0 \to \mathrm{i}x^0$, in the field propagator, then taking the limit $x^0 \to \infty$ and setting the boundary configuration at infinity (say $\varphi_2$) to zero, in order to obtain the vacuum state[13], $\lim_{x^0\to\infty} Z_M(\varphi_1,\varphi_2)\big|_{\mathrm{i}x^0} = c\psi_0(\varphi_1)$, where $c$ is a constant.

## 5. Summary and outlook

For a wide class of field theories in curved spaces, we recognise the existence of two transformations under which classical solutions of the equation of motion are left invariant when expressed in terms of boundary field configurations. Also the action evaluated on these solutions are invariant under these transformations. Finally, one of the two transformations results to be a symmetry also for the symplectic structure associated with the space of solutions. Using the Schrödinger-Feynman quantization scheme of the GBF, we show that these classical symmetries are broken at the quantum level. Indeed, they generate a one parameter family of infinite vacua. For de Sitter space, these states are the well known $\alpha$-vacua.

It is important to underline the novelty of this approach for the derivation of the de Sitter $\alpha$-vacua. In literature theses states are usually obtained in terms of Bogoliubov transformation of the basis where the field is expanded. Moreover they are interpreted as squeezed states over the Bunch-Davies vacuum. An alternative, but equivalent derivation is based on the antipodal map of de Sitter that send a field evaluated at a point $x$ into a field evaluated at the antipodal point to $x$. Although our approach is similar from a mathematical point of view to the functional formalism[14], we underline the classical symmetries of the space of solutions, when expressed in terms of the boundary field configurations, from which the $\alpha$-vacua arise. This representation is the more adequate for the quantization of the theory according to the Schrödinger-Feynman prescription within the GBF. Moreover, the result presented here constitutes a successful test for the GBF itself.

In the GBF another quantization scheme has been implemented and the representation used there is the holomorphic one.[15] Moreover a one-to-one correspondence exists between vacuum states in the Schrödinger representation and complex structures used in the holomorphic representation.[16] A natural generalization of the result presented here is to investigate the representation of the transformation $\Pi$ in terms of the complex structure.

# Primordial gravitational waves in bouncing universe

Asuka Ito and Jiro Soda

*Department of Physics, Kobe University, Kobe 657-8501, Japan*

Both inflationary and ekpyrotic scenarios can account for the origin of the large scale structure of the universe. It is often said that detecting primordial gravitational waves is the key to distinguish both scenarios. We show that this is not true if the gauge kinetic function is present in the ekpyrotic scenario. In fact, primordial gravitational waves sourced by the gauge field can be produced in an ekpyrotic universe. We also study scalar fluctuations sourced by the gauge field and show that it is negligible compared to primordial gravitational waves. This comes from the fact that the fast roll condition holds in ekpyrotic models.

## 1. Introduction

Inflation has succeeded in solving several issues in big bang cosmology and explaining the temperature anisotropy of the cosmic microwave background radiation (CMB) and the large scale structure of the universe. However, it is known that bouncing universe models[1] such as the ekpyrotic scenario[2] based on superstring theory[3] can do the same job[4].[a] Therefore, it is important to clarify which scenario is actually realized in the early stage of the universe.

In the ekpyrotic scenario, the primordial fluctuations are produced in a slowly contracting (ekpyrotic) phase. The spectrum of the scalar and tensor vacuum fluctuations becomes blue-tilted in the phase. We therefore need an additional scalar field to explain the temperature anisotropy of the CMB[6]. Moreover, in the ekpyrotic scenario, the amplitude of primordial gravitational waves[7] is quite small and practically unobservable[8]. Hence, it is often said that, if we could detect the primordial gravitational waves, we would be able to disprove the ekpyrotic scenario. However, if there could exist another mechanism for producing gravitational waves in the ekpyrotic scenario, the story would be completely different. Indeed, we show that there exists a mechanism for producing abundant gravitational waves in the ekpyrotic phase.

The key is the presence of magnetic fields in the early universe. Observationally, there are several evidences for magnetic fields to exist on various cosmological scales[9]. Although the origin of primordial magnetic fields is unknown, the presence of magnetic fields on extra galactic scales[10] implies that the seed of magnetic fields must be produced in the early universe. Notably, there are attempts to make primordial magnetic fields with the gauge kinetic function in an inflationary universe[11] or in a bouncing universe[12].

This report is a review of our previous paper[13]. We first show that scale invariant magnetic fields can be produced in the ekpyrotic phase in the presence of the gauge kinetic function. Next, we show that the magnetic fields can be a source of abundant

[a] The pre-big bang scenario is also a kind of the models[5]. Our conclusion could apply to it too.

gravitational waves (such mechanism works also in inflation[14]). It turns out that the gravitational wave spectrum is nearly scale invariant (slightly blue) at the end of the ekpyrotic phase. Hence, it is difficult to discriminate between inflation and the ekpyrotic scenario by merely detecting primordial gravitational waves. We also study scalar fluctuations induced by the magnetic fields and show that the tensor to scalar ratio should be more than unity, which implies that scalar fluctuations in the CMB should be dominated by quantum fluctuations produced by an additional scalar field as is often assumed in the ekpyrotic scenario.

## 2. Ekpyrotic phase

The ekpyrotic scenario can be described by a four-dimensional effective theory with a scalar field $\phi$ moving in an effective potential $V(\phi)$ specified below. The action reads

$$S = \int d^4x\sqrt{-g}\left[\frac{M_{pl}^2}{2}R - \frac{1}{2}(\partial_\mu\phi)(\partial^\mu\phi) - V(\phi)\right] , \tag{1}$$

where $M_{pl}$ represents the reduced Planck mass, $g$ is the determinant of the metric $g_{\mu\nu}$ , and $R$ is the Ricci scalar. The scalar field represents the separation $l$ between two branes $l \sim e^{\phi}$. The contracting universe ($\dot{\phi} < 0$) is connected to the expanding universe ($\dot{\phi} > 0$) through a bounce (a collision of two branes). The scalar and tensor vacuum fluctuations are produced in the contracting phase where the scalar field rolls down a negative steep potential

$$V(\phi) \simeq V_0 e^{\lambda\frac{\phi}{M_{pl}}} , \tag{2}$$

where $V_0$ is a negative constant. Note that $\lambda$ is also negative and satisfies the fast roll condition $|\lambda| \gg 1$ to keep isotropy of the universe. Thus, we can take an isotropic metric ansatz in this phase as

$$ds^2 = a(\tau)\left[-d\tau^2 + dx^2 + dy^2 + dz^2\right] , \tag{3}$$

where we used a conformal time $\tau$. It is straightforward to derive scaling solutions from Eqs. (1)–(3):

$$a(\tau) = a_{end}\left(\frac{-\tau}{-\tau_{end}}\right)^{\frac{2}{\lambda^2-2}} , \quad \frac{\phi(\tau)}{M_{pl}} = \phi_0 - \frac{2\lambda}{\lambda^2-2}\ln(-M_{pl}\tau) , \tag{4}$$

where $\tau_{end}$ ($< 0$) and $a_{end}$ represent the moment and the scale factor at the end of the ekpyrotic phase, respectively. The obtained vacuum scalar and tensor power spectrums are blue-tilted, so that we need an additional scalar field to explain the CMB observation[6]. Then, the ekpyrotic scenario predicts the nearly scale invariant scalar power spectrum and the blue-tilted tensor power spectrum. The situation is different from inflation where both spectra are nearly scale invariant.

## 3. Scale Invariant Magnetic Fields

Let us consider a gauge field coupled with $\phi$ in the contracting phase as

$$-\frac{1}{4}f^2(\phi)F_{\mu\nu}F^{\mu\nu} \ , \tag{5}$$

where $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the field strength of the gauge field and $f(\phi)$ represents the gauge kinetic function. Now, we take the gauge kinetic function as exponential type functional form which is ubiquitous in models obtained from dimensional reduction

$$f(\phi) = f_0 e^{\rho\frac{\phi}{M_{pl}}} \ , \tag{6}$$

where it has been set to be unity at the end of the ekpyrotic phase, and then there is no strong coupling problem. As is discussed in Ref. 13, one can obtain a expression of Fourier coefficient of magnetic fields defined by $\vec{B}(\tau,\boldsymbol{x}) \equiv \frac{f}{a^2}\left(\nabla\times\vec{A}(\tau,\boldsymbol{x})\right)$ on the background (4) as

$$\mathcal{B}_k(\tau) = \frac{3\sqrt{2}}{8}(\lambda^2-2)^2 k^{-3/2}\left(\frac{-\tau}{-\tau_{end}}\right)^{-\frac{2\lambda^2}{\lambda^2-2}} H_{end}^2 \ . \tag{7}$$

Here, we have eliminated $\rho$ by requiring the scale invariance of magnetic fields at the end of the ekpyrotic phase. $\tau_{end}$ and $H_{end}$ are the conformal time and the Hubble parameter at the end of the ekpyrotic phase, respectively. For example, if we set $H_{end} = 10^{-5}M_{pl}$ and $\lambda = -17$, where back reaction from electromagnetic fields is negligible, the amplitude of the magnetic field at the end of the ekpyrotic phase is about $10^{49}$ G. Thus, the cosmological magnetic fields observed at present can be produced in the ekpyrotic scenario[9]. Remarkably, such magnetic fields can also induce abundant primordial gravitational waves.

## 4. Gravitational waves from Magnetic Fields

As is shown in Refs. 13, 14, one can get the tensor sector of the action (1) in the presence of the gauge field (5) as

$$S_{GW} = \int d\tau d^3x \left[\frac{M_{pl}^2}{8}a^2\left(h'_{ij}h'^{ij} - \partial_k h_{ij}\partial_k h^{ij}\right) + \frac{1}{2}a^4\left(E_iE_j + B_iB_j\right)h^{ij}\right] \ , \tag{8}$$

where $h_{ij}$ is the transverse traceless tensor, namely, gravitational waves. We see that electric and magnetic fields work as a source of gravitational waves. From above action with scale invariant magnetic fields (7), one can estimate the power spectrum of gravitational waves:

$$P_s(k) \simeq \frac{27}{16\pi^4}\lambda^8\left(\frac{H_{end}}{M_{pl}}\right)^4 \ln\left[\frac{k}{k_{in}}\right] \ . \tag{9}$$

There is a factor $\left(\frac{H_{end}}{M_{pl}}\right)^4$ in the spectrum (9) because of the nonlinear contribution of the magnetic fields (7). One can see that sourced gravitational waves have a

nearly scale invariant spectrum. This conclusion is different from the well-known blue-tilted spectrum in the ekpyrotic scenario[8]. Most importantly, there appears a factor $\lambda^8$ in $P_s(k)$. For example, if we set $H_{end} = 10^{-5}M_{pl}$ and $\lambda = -17$ to produce the observed magnetic field, the amplitude of the power spectrum is about $10^{-11}$. This is comparable with the gravitational waves in the inflationary universe $\sim \left(\frac{H_{end}}{\pi M_{pl}}\right)^2$. Therefore, we can not discriminate between inflation and the ekpyrotic scenario just by detecting primordial gravitational waves.

## 5. Scalar Fluctuations from Magnetic Fields

The power spectrum of scalar fluctuations induced by magnetic fields can be calculated as same as tensor fluctuations. The result is

$$\mathcal{P}_s(k) \simeq \frac{243}{1024\pi^4}\lambda^8 \left(\frac{H_{end}}{M_{pl}}\right)^4 \ln\left[\frac{k}{k_{in}}\right] \ . \tag{10}$$

From Eqs. (9) and (10), the tensor to scalar ratio $r_{source}$ is given by

$$r_{source} \simeq 7 \ . \tag{11}$$

Since the tensor to scalar ratio becomes larger than unity, we can say that the scalar fluctuations sourced by the scale invariant magnetic field are negligible in the ekpyrotic scenario. Therefore, the ekpyrotic model with a gauge field is compatible with the CMB data.

## 6. Conclusion

We studied the role of the gauge kinetic function in the ekpyrotic scenario and showed that abundant gravitational waves sourced by the gauge field can be produced. As a demonstration, we first showed that scale invariant magnetic fields can be produced in the ekpyrotic phase. It turned out that the magnetic fields induce nearly scale invariant gravitational waves (slightly blue) and the amplitude could be comparable with that of the inflationary universe. It turned out that it is difficult to disprove the ekpyrotic scenario by detecting primordial gravitational waves. In order to distinguish both scenarios, it is necessary to look at the details of the spectrum such as the tilt of the spectrum or the non-gaussianity[15]. Observing the distinction of higher order scalar perturbations is also important[16]. We should mention that the idea of finding an ekpyrotic model with observable gravitational waves on CMB scales using sourced fluctuations was put forward for the first time in Ref. 17 by investigating a different model with explicit parity violation. Our model has no explicit parity violation. Moreover, we also showed that the scalar fluctuations induced by the magnetic field are smaller than the sourced gravitational waves. Generally, as far as the fast roll condition is satisfied, the tensor to scalar ratio becomes more than unity in any ekpyrotic models with the gauge kinetic function. Therefore, our scenario would be compatible with the CMB data

provided that nearly scale invariant scalar fluctuations are produced in a standard way with an additional scalar field[6].

It should be noted that we must check the non-gaussianity of the primordial scalar fluctuations in the present model[18]. Moreover, we should consider a bounce process from contracting to expanding to connect the spectrum at the end of the ekpyrotic phase with observables. We have not looked into this issue in this paper since the mechanism is model dependent and the detailed analysis is beyond the scope of this paper[1]. However, actually, although we fixed the parameters such as $\rho, \lambda, H_{end}$ for simplicity in this paper, we can tune these parameters in our scenario so that our conclusion becomes valid for any ekpyrotic bouncing models. Therefore, our conclusion is robust.

Scalar field vacuum energy and particle creation in a 3D Casimir apparatus, freely falling in the Schwarzschild spacetime, are considered in the reference frame of a comoving observer. Following Schwinger's proper time approach, Casimir energy is evaluated from the effective action, resulting in a small correction to the flat spacetime case. Besides, a tiny amount of quanta excited out from the vacuum is found. Both effects are discussed, drawing attention to the role of the underlying spacetime dimensionality.

*Keywords*: Casimir effect; quantum fields in curved space-times; particle creation.

## 1. Introduction

Casimir effect[1–3] is one of the most intriguing as well as fascinating effects in the microscopical quantum world. Roughly speaking, it originates from a distortion in the modes of a quantum field constrained in a finite region of space by some boundaries. The latter can be material as well as due to the geometrical properties of the background spacetime. In the latter case, Casimir effect becomes an exciting arena in which General Relativity (GR) and Quantum Field Theory (QFT) face each other.

As we will see, an observer comoving with a Casimir cavity, freely falling in a Schwarzschild black hole, measures a small reduction in the (absolute) value of the (negative) Casimir energy[4–12] as the black hole horizon is approached. At a first glance, this may seem rather puzzling, as one would expect no change with respect to the usual flat spacetime result $\langle \epsilon_{Cas} \rangle_{stat} = -\frac{\pi^2}{1440 L^4}$, due to the Equivalence Principle. Actually, the *local* measurements performed by the comoving observer, are related to a *non-local* renormalized field stress-energy tensor $T^{\rm ren}_{\mu\nu}$. The latter is determined (by means of some regularization technique) by the low-energy contribution of $T_{\mu\nu}$, thus probing the *global* structure of the surrounding spacetime geometry. This, in turn, allows for a local measurement to be sensitive to the cavity fall.

The plan of the paper is as follows. In section 2 Lemaître coordinates are introduced. Section 3 is devoted to Schwinger's proper-time approach and to the evaluation of the effective action $W$. Section 4 deals with the static Casimir effect,

while particle creation is discussed in section 5. The last section is devoted to some concluding remarks. Throughout the paper use has been made of natural geometrized units. Greek indices take values from 0 to 3; latin ones take values from 1 to 3. The metric signature is $-2$, with determinant $g$.

## 2. Lemaître Coordinates

The Schwarzschild metric for a black hole of mass $M$ in the standard Schwarzschild coordinates $\{t, r, \theta, \phi\}$ reads

$$ds^2 = \left(1 - \frac{r_g}{r}\right) dt^2 - \left(1 - \frac{r_g}{r}\right)^{-1} dr^2 - r^2 d\Omega^2, \tag{1}$$

where $r_g = 2M$ is the gravitational (Schwarzschild) radius of the black hole and $d\Omega^2 = d\theta^2 + \sin^2\theta d\phi^2$. In such coordinates, we meet a *coordinate* singularity at the horizon. Being interested in the behaviour of a Casimir cavity falling into a black hole, we need a chart which is regular at the horizon, so the form (1) of the metric is not suitable. Among the various coordinate systems well behaved at the horizon, we will adopt the Lemaître chart. In the Lemaître coordinates, a freely falling test body has a constant value of the radial $\rho$ coordinate.

Consider a Casimir cavity, freely falling from spatial infinity. Adjust the cavity clock so that the proper time $\tau = 0$ when the cavity is at the radial horizon coordinate $r_0 = r_g$. Then the constant value is $\rho_0 = \frac{2}{3} r_g$ and the Schwarzschild metric in the Lemaître coordinates $\{\tau, \rho, \theta, \phi\}$ reads[13,14]

$$ds^2 = d\tau^2 - \frac{r_g}{r(\tau)} d\rho^2 - r^2(\tau) d\Omega^2, \qquad r(\tau) = r_g \left(1 - \frac{3\tau}{2r_g}\right)^{2/3}. \tag{2}$$

Notice that the travel from the infinity to the horizon is described by *negative* values of the proper time: $-\infty < \tau \leq 0$.

## 3. The Casimir Cavity and the Comoving Frame

The measurement of Casimir energy inside the falling cavity is performed by a *comoving* observer. The cavity plates (of area $A$ and separated by a distance $L$, such that $L \ll \sqrt{A}$) are taken orthogonal to the radial falling direction.[a] Furthermore

- the cavity is taken to fall from spatial infinity with zero initial velocity and zero angular momentum;
- the typical cavity size is much smaller than the gravitational radius of the black hole, so that, in particular, $L \ll r_g$, with $L$ being the plate separation
- the cavity is *rigid*; its dimensions and shape do not suffer any distortion, in spite of external tidal forces. Such assumption holds true provided $L \ll r_g$. Differently stated, we neglect tidal effects[15] inside the falling cavity. Tidal effects will be extensively studied in a lower-dimensional model in Ref. 15.

[a] Such a choice has been made only for the sake of definiteness.

- the cavity follows a true geodesic motion; hence we neglect other non-gravitational external effects.

## 4. Proper-time Schwinger's approach

For the sake of simplicity we will consider a massless scalar field. We also assume the field to obey the Dirichlet boundary conditions at the plates. In the tetrad frame adapted to the Lemaître chart the Klein-Gordon equation reads[16]

$$\left[\Box + \frac{1}{4}\frac{\xi^2}{(1-\xi\tau)^2}\right]\varphi = 0, \qquad \xi = \frac{3}{2r_g}. \tag{3}$$

From (3), the proper-time Hamiltonian $\hat{H}$ reads $\hat{H} = \hat{H}_0 + \hat{V}$, where $\hat{H}_0 = \partial_\tau^2 - \vec{\nabla}^2 \equiv -\hat{p}_0^2 + \hat{\vec{p}}^2$. As usual, we write the effective action $W = \lim_{\nu\to 0} W(\nu)$, where[17,18]

$$W(\nu) = -\frac{i}{2}\int_0^\infty ds\, s^{\nu-1}\mathrm{Tr}\, e^{-is\hat{H}}, \tag{4}$$

and the limit $\nu \to 0$ has to be taken at the end of calculations. The trace has to be evaluated all over the continuous as well the discrete degrees of freedom, including those of spacetime. After a quite long algebra we get

$$W(\nu) = -\frac{iA}{32\pi^{5/2}}\int_0^\infty ds \int_{-\infty}^T d\tau \sum_n \frac{s^{\nu-3/2-1}}{\beta^{1/2}} e^{-is(n\pi/L)^2} \times\left[\pi^{3/2} e^{-i/(2\beta)} H_0^{(1)}\big(1/(2\beta)\big) + 2G_{23}^{31}\left(-\frac{i}{\beta}\,\middle|\,\begin{matrix}0 & 1/2\\ 0 & 0 & 0\end{matrix}\right)\right], \tag{5}$$

where $\beta = \frac{s\xi^2}{(1-\xi\tau)^2}$ is a small adimensional parameter which will be used for further power expansion. $H_0^{(1)}$ and $G_{23}^{31}$ are a zero-order Hankel and a Meijer G-function, respectively. The $H_0^{(1)}$-dependent (real) part of $W(\nu)$ is responsible for the vacuum polarization (namely, the static Casimir effect), while the $G$-dependent (imaginary) part of $W(\nu)$ is responsible of the vacuum persistence amplitude (i.e., particle creation).

## 5. The Static Casimir Effect

From the real part of (5) we obtain $\langle\epsilon_{Cas}\rangle = -\lim_{\nu\to 0}\frac{1}{AL}\frac{\partial}{\partial\tau}\Re\mathrm{e}\, W(\nu)$, hence

$$\langle\epsilon_{Cas}\rangle = -\frac{\pi^{3/2}}{16L^4}\sum_{k=0}^\infty \frac{2^k\xi^{2k}a_k}{(1-\xi\tau)^{2k}}\left(\frac{L}{\pi}\right)^{2k}\Gamma\left(-\frac{3}{2}+k\right)\zeta(-3+2k). \tag{6}$$

Taking the leading ($k=0$) and the next to leading order ($k=1$) term, we get

$$\langle\epsilon_{Cas}\rangle = -\frac{\pi^2}{1440L^4} + \frac{1}{384L^2}\frac{\xi^2}{(1-\xi\tau)^2} + O(\xi^4). \tag{7}$$

The first term is the (expected) usual flat Casimir energy density. At the horizon crossing ($\tau \to 0^-$), we have (recall that $\xi = 3/(2r_g)$)

$$\langle \epsilon_{Cas} \rangle_{hor} = -\frac{\pi^2}{1440 L^4}\left[1 - \frac{135}{(4\pi)^2}\left(\frac{L}{r_g}\right)^2\right]. \tag{8}$$

Eq. (7) tells us how the corrections to the Casimir energy density change with the proper time as the cavity approaches the black hole horizon.

## 6. Bunch-Davies Vacuum and Particle Creation

Particle creation is related to the vacuum persistence amplitude, i.e., the imaginary part of the effective action $W$. In the in-out formalism we have

$$|\langle 0\,\mathrm{out}|0\,\mathrm{in}\rangle|^2 = e^{2i\Im \mathrm{m} W}, \tag{9}$$

so that the (usually small) number density of created particles inside the falling cavity is $\langle n \rangle \simeq \frac{2\,\Im \mathrm{m}\, W}{AL}$. Expanding the imaginary pert of $W(\nu)$ we obtain a divergent result; namely

$$\Im \mathrm{m} W = \frac{A}{24\pi^3 L^2}\left[-\frac{\xi^2 L^2}{(1-\xi\tau)^2}\zeta(1) + \frac{2\xi^4 L^4}{15(1-\xi\tau)^4} + \cdots\right]. \tag{10}$$

Inspection of (10) reveals that the first term in the square brackets is *divergent*. The origin of such divergence is likely to be related to the implicitly assumed *infinite* extension of the plates, as we will see below. We will avoid the difficulties stemming from the appearance of infinities in the imaginary part of the effective action exploiting the relationship between the Schwinger theory and the in-out formalism, based upon the Bogolubov approach.

The field modes related to (3) are proportional to

$$\chi_k(\eta) = \frac{1}{2}\sqrt{\frac{\pi}{\xi}\eta} H_0^{(1)}\left(\frac{\omega_k}{\xi}\eta\right), \qquad \eta = 1 - \xi\tau, \tag{11}$$

which have the required minkowskian (plane wave) behaviour at $\eta \to \infty$ (i.e. $\tau \to -\infty$), when the cavity is at the spatial infinity with respect to the black hole. The above modes satisfy the Bunch-Davies vacuum requirements[19–21]. Also, in the far past the field modes admit a plane wave solution

$$\chi_k(\tau) = \frac{\alpha}{\sqrt{2\omega_k}} e^{-i\omega_k \tau} + \frac{\beta}{\sqrt{2\omega_k}} e^{i\omega_k \tau}. \tag{12}$$

Matching the above solutions at the black hole horizon ($\eta \geq 1$), we easily compute the Bogolubov coefficients $\alpha$ and $\beta$[b]

$$|\alpha_k|^2 = 1 + \frac{\xi^2}{16\omega_k^2(1-\xi\tau)^2}, \qquad |\beta_k|^2 = \frac{\xi^2}{16\omega_k^2(1-\xi\tau)^2}, \tag{13}$$

[b](An interesting approach, requiring no detailed knowledge of state normalization, based upon the paper by Hamilton et al. (A. Hamilton, D. Kabat and M. Parikh, JHEP 0407, 024 (2004)), may be used as well to obtain the same result.)

satisfying $|\alpha_k|^2 - |\beta_k|^2 = 1$. The $\beta$ coefficient is related to particle creation. Note that, as $\tau \to -\infty$, $|\alpha_k|^2 \sim 1$ and $|\beta_k|^2 \sim 0$, i.e., we have no particle creation in the far past, as expected, meanwhile at the horizon crossing ($\tau = 0$) we have $|\beta_k|^2 = \frac{\xi^2}{16\omega_k^2}$. Although the number of created quanta is a divergent quantity, we can get a *finite* result for the energy density $\langle \epsilon_{\rm dyn} \rangle$ of the created quanta, writing

$$\langle \epsilon_{\rm dyn} \rangle = \frac{1}{AL}\left[\frac{A}{(2\pi)^2}\sum_n \int d^2k_\perp \frac{\xi^2}{16\omega_k^2\eta^2}\omega_k\right] = \frac{\xi^2}{384L^2(1-\xi\tau)^2}. \qquad (14)$$

Comparing the above result with (7), describing the vacuum energy density pertaining to the Casimir effect, we see, quite interestingly, that the small reduction observed in the static Casimir energy value *just* corresponds to the amount of energy of created field particles. This could suggest a close relationship between the two considered effects. Nevertheless, some care is required when speculating about such coincidence, as both the results have been obtained as first-order approximations.

## 7. Concluding remarks

We have considered the Casimir energy density corrections in a small cavity freely falling from the spatial infinity into a Schwarzschild black hole.

At a first glance, one could wonder that corrections to the static Casimir effect as well as particle creation are detected by an observer in a freely falling *inertial* frame. However, as anticipated at the end of section V, this is not so surprising. The Equivalence Principle (EP), deeply rooted in the theory of General Relativity (GR), applies well in the context of a *local* theory, just as GR is. On the other hand, when quantum fields are taken into account, the *non-local* character of the underlying quantum theory conflicts with the EP, causing the latter to be not straightforwardly applicable.

In the present scenario, the quantum field stress-energy tensor $T_{\mu\nu}$ behaves as a *non-local* object, thus probing the global spacetime structure, through the long wavelength field modes. The adopted renormalization procedure (whatever it may be) does transfer the spacetime details into the renormalized $T^{\rm ren}_{\mu\nu}$, which is basically the locally *measured* object. In such a way, information contained in the spacetime geometry surrounding the cavity bypasses - so to say - the EP, appearing both in the form of a small correction to the expected static Casimir energy and a tiny flux of created field quanta.

In deriving the above results several assumptions have been made. In particular, we have neglected other possible contributions related to from the cavity extension. Tidal effects, e.g., are expected to give rise to anisotropies in the energy density distribution inside the cavity; such aspect will be considered in detail (in the case of a 1+1D model) in a forthcoming paper[15].

It maybe that some of the divergencies met throughout the paper are due to the (in)finiteness of the Casimir plates. In that respect, it seems likely that a more

physically consistent analysis, based upon a *finite* 3D cavity, could help to remove the residual infinities encountered in the present approach.

Finally, an obvious improvement of the present research would be to extend the analysis of Ref. 15 to the 3+1D case, also including both *tidal* and *3D-finite-size* effects in evaluating the corrections to the Casimir effect. This we hope will be our next goal.

The supersymmetry arises in certain theories of fermions coupled to gauge fields and gravity in a spacetime of 11 dimensions. The dynamical brane background has mainly been studied for the class of purely bosonic solutions only, but recent developments involving a time-dependent brane solution have made it clear that one can get more information by asking what happens on supersymmetric systems. In this work, we present an exact supersymmetric solution of a dynamical M-brane background in the 11-dimensional supergravity and investigate supersymmetry breaking, the geometric features near the singularity.

*Keywords*: Dynamical brane background; Supersymmetry; 11-dimensional supergravity; Singularity.

## 1. Introduction

The dynamical $p$-brane solutions in a higher-dimensional gravity theory were studied by Refs. 1–9 and have been widely discussed ever since. However, some aspects of the physical properties, such as supersymmetry and its breaking in the context of string theory, have remained slightly unclear. The motivation for this work is to improve this situation. For this purpose, it is first necessary to construct supersymmetric brane solutions depending on the time as well as space coordinates.

In this work, we will find the supersymmetric dynamical M-brane as an exact solution of the supergravity field equations. What we will construct is a time-dependent M2-brane solution preserving supersymmetry in the 11-dimensional supergravity theory. The dynamical M2-brane background preserving supersymmetry is a kind of natural extension of the static M2-brane system, which can be described by an analogous Reissner-Nordström solution in the four-dimensional Einstein-Maxwell theory. We present an exact solution having a quarter of a full supersymmetry for a dynamical M-brane in an 11-dimensional supergravity and discuss how to break supersymmetries in Sec. 2. We describe some applications of the result, which are the behavior of the geodesic, the analysis of the geometrical structure in dynamical M2-brane background. In Sec. 3, we start our discussion of supersymmetric M2-brane solution by examining the basic features of the background geometry. By solving the radial null geodesic equations, we show that the naked strong curvature singularity appears. Section 4 contains some discussions and concluding remarks.

## 2. Supersymmetry in a dynamical M2-brane

In this section, we present the exact solution to the field equations of an 11-dimensional supergravity corresponding to a dynamical M2-brane configuration. The 11-dimensional gravitino (Killing spinor field) equation gives the time-dependent solution with the particular ansatz of fields. We find that the supersymmetric solution depends on the null coordinate along the M2-brane world volume, as well as the coordinates of the transverse space to the M2-brane. The 11-dimensional supersymmetric solution is given by

$$ds^2 = h^{-2/3}(x,r)\eta_{\mu\nu}dx^\mu dx^\nu + h^{1/3}(x,r)\left(dr^2 + r^2 u_{ab}dz^a dz^b\right)\,, \tag{1}$$

where the function $h(x,r)$ is given by

$$h(x,r) = c_\mu x^\mu + \bar{c} + \frac{M}{r^6}\,, \tag{2}$$

$\mu$, $\nu = 0$, 1, 2, and $i$, $j = 3, 4, \ldots, 10$, $\chi = \pm 1$, $c_\mu$, $\bar{c}$, and $M$ are constant parameters, $u_{ab}$ denotes the metric of the seven-sphere. It follows that if $c_\mu = \partial_\mu h_0$ is not null, there exists only a trivial solution to the Killing spinor equation, and the supersymmetry is completely broken. On the other hand, when $c_\mu$ is a null vector, the Killing spinor equation leads to

$$c_\mu \gamma^\mu \varepsilon = 0\,, \tag{3}$$

where $\gamma^\mu$ gives the SO(2, 1) $\gamma$-matrices satisfying

$$\{\gamma^\mu\,,\ \gamma^\nu\} = \eta^{\mu\nu}\,. \tag{4}$$

Then, one quarter of the possible rigid supersymmetries in the maximal case survives. Here, we check the degree of supersymmetry for the case of $M = 0$. The dynamical M2-brane to the plane wave background if we consider the following special case of vanishing M2-brane charge[10,11]. The integrability condition reduces to $c_\mu\,\gamma^\mu\varepsilon = 0$. Then, the dynamical M2-brane solution with $c_\mu \neq 0$, preserves a half of the maximal supersymmetries. Since the number of unbroken spacetime supersymmetries in the present background must be a half of the full supersymmetries,

Next we comment on the degree of the supersymmetry breaking for the dynamical M2-brane background. The measure of the supersymmetry breaking for the dynamical background is obtained from the consistency condition. The mass scale corresponds to $h^{-2}c_\mu c^\mu$, which could be identified with a kind of induced effective mass scale for the spinor field. The divergence at $h = 0$ means that the degree of the supersymmetry breaking increases as the background approaches the curvature singularity. On the other hand, the supersymmetry breaking becomes negligible near the M2-brane region $r \to 0$, as $h$ diverges there.

Let us consider the relation between the dynamics of the background and supersymmetry breaking in more detail. Introducing a new time coordinate $\tau$, which is defined by $\tau/\tau_0 = (c_0\,t)^{2/3}$, with constant $\tau_0 = (3/2c_0)$, we find the 11-dimensional

metric (1) as

$$ds^2 = \left[1+\left(\frac{\tau_0}{\tau}\right)^{3/2}\left(c_i x^i + \frac{M}{r^6}\right)\right]^{-2/3}\left[-d\tau^2 + \left(\frac{\tau_0}{\tau}\right)\delta_{ij}dx^i dx^j\right] + \left[1+\left(\frac{\tau_0}{\tau}\right)^{3/2}\left(c_i x^i + \frac{M}{r^6}\right)\right]^{1/3}\left(\frac{\tau}{\tau_0}\right)^{1/2}\left[dr^2 + r^2 d\Omega^2_{(7)}\right], \qquad (5)$$

where $x^i$ $(i = 1, 2)$ denotes the space coordinates of the world volume spacetime, the metric $\delta_{ij}$ is the spatial part of the three-dimensional Minkowski metric $\eta_{\mu\nu}$, and $d\Omega^2_{(7)}$ is the line element of the seven-sphere. When we set $c_1 = c_2 = 0$, the spacetime is an isotropic and homogeneous universe with respect to the world volume coordinates, whose supersymmetry is completely broken. On the other hand, the 11-dimensional spacetime becomes inhomogeneous and preserves supersymmetry if parameters $c_\mu$ satisfy $c_\mu c^\mu = 0$, and $c_\mu \gamma^\mu \varepsilon = 0$. Thus, in the limit when the terms $c_i x^i$ are negligible, which is realized in the limit $(\tau/\tau_0) \to \infty$, for small $r$, we find an 11-dimensional universe without supersymmetry. For concreteness, we discuss the dynamics in the region where the term $c_i x^i$ in the function $h(\tau, x, r)$ is smaller compared to the contribution of the M2-brane charge $M/r^6$. In the case of $(\tau/\tau_0) > 0$, we have found that the domains near the M2-brane has the supersymmetry. As the time increases, the background satisfies $(\tau/\tau_0)^{3/2} \gg c_i x^i$. Then, the contribution of the term $c_i x^i$ in the function $h(\tau, x, r)$ eventually becomes negligible in the 11-dimensional metric such that supersymmetries are completely broken, which is guaranteed by the region $c_i x^i \ll M/r^6$. Then, the dynamical M2-brane solution also behaves as a nonsupersymmetric cosmological solution in the asymptotic future.

## 3. Geometry of the supersymmetric dynamical M2-brane solution

As one may expect from the dynamical M2-brane solution, the spacetime with (1) has curvature singularity. For a fixed $x$, the spacetime asymptotically approaches the anisotropic solution at a large $r$, while the metric becomes approximately $AdS_4 \times S^7$ near the M2-brane region[10,11] (at $r \to 0$). Now we investigate the geometric feature near the curvature singularity. We consider the following time dependent M2-brane solution with the 11-dimensional metric

$$ds^2 = \left(cu + \frac{M}{r^6}\right)^{-2/3}\left(-2du\,dv + dy^2\right) + \left(cu + \frac{M}{r^6}\right)^{1/3}\left[dr^2 + r^2 d\Omega^2_{(7)}\right], \qquad (6)$$

$$u = \frac{1}{\sqrt{2}}(t - x), \qquad v = \frac{1}{\sqrt{2}}(t + x), \qquad (7)$$

where $c$, $M$ are constants. Since the function $h_1(r)$ dominates near $r \to 0$, the background geometry describes the extremal Reissner-Nordström solution with an infinite throat. The geometry of the dynamical M2-brane is not asymptotically flat while the extremal Reissner-Nordström solution gives the asymptotically Minkowski spacetime. Near the M2-brane, the metric becomes $AdS_4 \times S^7$. Since the square of

the four-form field strength diverges at the zeros of the function $h(u,r) = 0$, the curvature of the metric (7) can be singular at $h(u,r) = 0$.

Now we discuss the cosmological evolution of the spatial geometry in the region $h > 0$ and assume $c < 0$, in the function $h(u,r)$. For $u < 0$, the function $h$ is positive everywhere and the spatial surfaces are nonsingular unless we treat the negative charge of the M2-brane $M < 0$. They are asymptotically anisotropic spacetime for a fixed $x$ coordinate. The spatial metric is still regular for $u = 0$ besides the region $r \to \infty$. As time increases slightly, a singularity appears at $r = \infty$ and moves in from spatial infinity. As $u$ evolves further, the singularity eventually wraps the horizon completely. We start by solving radial null geodesic equations for the affine parameter $s$ on the background (7). We now discuss the radial null geodesic near the timelike singularity. For the supersymmetric M2-brane background (7), $h = 0$ hypersurface corresponds to a timelike curvature singularity[12] because $g^{MN}\ell_M\ell_N > 0$ for $\ell_M = \nabla_M h$ near the singularity. Let us then consider the past directed null geodesics which can hit the curvature singularity within a finite affine parameter length. The geodesic equation gives

$$r(s) \simeq r_0 + r_1\,(s_0 - s)^{6/5}\,, \qquad h(s) = -\left(\frac{5cf}{9}\right)(s_0 - s)^{9/5} - (s_0 - s)^{6/5}\,, \tag{8}$$

where $c$, $f$ are constants, $r_0$ and $s_0$ denote the value of $r$ and $s$ at singularity.

We now turn our attention to calculate a geometrical quantity in a parallelly propagated frame along the null geodesic,

$$\Gamma \equiv C_{MPNQ}E_2{}^M E_2{}^N k^P k^Q\,, \tag{9}$$

where $C_{MNPQ}$ is the Weyl tensor, $k^M$ denotes the tangent vector of null geodesic, and $E_2{}^M$ is a parallelly propagated spacelike unit vector orthogonal to $k^M$. These are defined by

$$k = (du/ds)\partial_u + (dv/ds)\partial_v + (dr/ds)\partial_r\,, \quad E_2 = h^{1/3}\partial_y\,. \tag{10}$$

In terms of the metric (7) and 11-dimensional null vectors, we find

$$\Gamma \sim (s_0 - s)^{-2}\,. \tag{11}$$

The shear $\sigma$ and the expansion rate $d\theta/ds$ of the congruence along the null vector $k^M$ diverge near the singularity as

$$\sigma \sim \int^s \Gamma ds \sim (s_0 - s)^{-1}\,, \qquad \left(\frac{d\theta}{ds}\right) \sim -\sigma^2 \sim -(s_0 - s)^{-2}\,. \tag{12}$$

Then, we obtain

$$\int^s \theta\, ds = \int^s \left(\frac{d\ln A}{ds}\right) ds \sim \ln(s_0 - s)\,, \tag{13}$$

where $A$ is the volume element of the null geodesic congruence. This implies that the timelike singularity is a strong type of curvature singularity, as the volume element of any congruence along the radial null geodesic vanishes there.

## 4. Discussions

In the present work, we have constructed the dynamical supersymmetric M2-brane solution for the warped compactification of an 11-dimensional supergravity. The solution is given by an extension of a static supersymmetric M2-branes solution. In the case of a dynamical M2-brane background, a quarter of maximal supersymmetries exists. If the M2-brane charge vanishes, our solution gives a plane wave background which preserves a half of the full supersymmetry. Therefore, in the far region from the M2-brane, the background changes from the dynamical M2-brane to time-dependent plane wave background. This means that one quarter of the maximal supersymmetry is enhanced to a half of the possible rigid supersymmetries in the maximal case when one moves in the transverse space to the M2-brane. Although we have mainly discussed the single M2-brane solution in this work, it is possible to generalize it to the solution which describes an arbitrary number of extremal M2-branes in an expanding universe. We have found that the degree of the supersymmetry breaking is strongly related to the dynamics of the background. Then, the time evolution of the geometry is deeply connected with the hierarchy and supersymmetry breaking while the inhomogeneity of the M2-brane world volume coordinates makes preserving the supersymmetry. In the region where the effect of the inhomogeneity of the M2-brane world volume coordinates is smaller compared to the contribution of the M2-brane charge, our supersymmetric solution describes the breaking of the supersymmetry, which is the transition from the supersymmetric universe to a nonsupersymmetric one as time evolves.

The dynamical M2-brane solutions can always take a form in the function $h(x,r) = h_0(x) + h_1(r)$, where the function $h(x,r)$ depends on the linear function of the M2-brane world volume coordinates $x^\mu$ as well as coordinates of the transverse space to the M2-brane. Since the existence of the function $h_0(x)$ implies the dynamical instability in the moduli of internal space[13], it would be useful to study the stability of a solution.

Motivated by the construction of a new supersymmetric solution, we have studied the global structure of the dynamical M2-brane background. We have found that the time dependence changes the causal structure of a static M2-brane solution. Since the volume element of any congruence along the radial null geodesic vanishes at the curvature singularity, it turns out that this is a strong version of a timelike singularity. We have studied null geodesics which terminate a coordinate singularity in terms of an analytic extension across there and showed that there is a regular null hypersurface (or horizon) generated by a null Killing vector field. In particular, this null Killing vector field describes the generator of the horizon even if the bulk metric is asymptotically anisotropic geometry at a constant $x$ coordinate. Hence, the near horizon geometry in this solution gives the regular spacetime, and thus becomes $\mathrm{AdS}_4 \times \mathrm{S}^7$.

It is important to explore another analytic solution describing a supersymmetric M-brane or D-brane in the expanding Universe. One may present whether

supersymmetric dynamical brane solutions affect the formation of the naked singularity. Upon setting an appropriate initial condition, these solutions may allow us to violate the cosmic censorship[12,14].

We can also discuss a dynamical black hole solution whose spacetime gives a time dependent universe. The near M2-brane region of this black hole in the expanding Universe is the same as the static solutions while the asymptotic structures are completely different, giving the anisotropic spacetime at a fixed $x$ coordinate with scale factors for a dynamical universe. The effective M2-brane charge for the supersymmetric background depends on the world volume coordinates of the M2-brane. The supersymmetric solutions can contain the function depending on null coordinates of the M2-brane world volume direction. The results we have obtained are not unnatural because studies of the supersymmetric plane wave background showed that it is possible to obtain time-dependent supersymmetric solutions with a nontrivial dependence on spacetime coordinates[15]. Although this may be a limitation on the applications of our solution, it is interesting to explore if similar more general dynamical and supersymmetric solutions can be obtained by relaxing or extending some of our assumptions for the 10-, 11-, or lower-dimensional backgrounds. We will study this subject in the near future.

Gamma-Ray Bursts (GRBs) are probably one of the most enigmatic sources in current astrophysics, especially when their high-energy (HE, 100 MeV $\lesssim E \lesssim$ 100 GeV) emission is considered. Fermi-LAT observations unveiled many properties of GRBs emission in the GeV band, but its physical origin is not clearly understood yet. In this context, observations of GRBs at very-high-energies (VHE, $E \gtrsim$ 100 GeV) could provide a crucial contribution in the understanding of the physical processes driving GRB emission at the highest energies. For this purpose, ground facilities performing fast-follow up of GRBs above $\sim$ 100 GeV with high sensitivity are needed. In particular the MAGIC telescopes were designed to have a low energy threshold ($\sim$ 50 GeV) and to perform fast follow-up of GRBs thanks to their fast slewing movement. Up to date, 101 GRBs were followed-up by MAGIC in different observational conditions, providing a large data sample to search for VHE emission. This contribution will focus on the MAGIC GRBs follow-up campaign and highlight the observation of the short and nearby ($z = 0.16$) GRB 160821B, an interesting event showing a hint of VHE gamma-ray emission.

*Keywords*: Gamma-Ray Bursts; MAGIC; VHE emission.

## 1. Introduction

Gamma-Ray Bursts (GRBs) are transient events occurring at cosmological distances, releasing a huge amount of energy in electromagnetic radiation in a small time period.[1] After more than 50 years from their discovery, many aspects of GRBs are still puzzling. Among them, the origin of their high-energy (HE) emission and the possible presence of a very-high-energy (VHE) component are still debated topics in GRB physics. In the HE range, Fermi-LAT provides most of the information, from which it is seen that the GeV emission is delayed with respect to the lower energy emission and with a long lasting duration. Generally the HE spectra are well fitted using a power-law model, even if in some cases an additional spectral component is needed.[2] The latter could be linked with a process producing photons at VHE, pointing out to the importance of performing GRB observations in the energy range above $\sim$ 100 GeV. In this context, ground-based instruments like Imaging Atmospheric Cherenkov Telescopes (IACTs) can provide a good photon statistics in the VHE range. Among IACTs, MAGIC has some important figures of merit which are crucial for the follow-up of GRBs, namely a low energy threshold, a high sensitivity and a lightweight structure to allow fast repositioning.

In the following contribution we describe the MAGIC GRB follow-up program, focusing on the observational challenges of such a project and on the results obtained in the last years.

## 2. The MAGIC experiment

MAGIC is an IACT experiment with two identical telescopes of 17 m diameter.[3] It is located in one of the Canary Islands, La Palma (28.8° N, 17.8° W), at an altitude of 2200 m a.s.l. The MAGIC telescopes were designed to observe astrophysical sources of gamma-rays in stereoscopic mode above an energy threshold of $\sim 50$ GeV at trigger level and at zenith. The sensitivity which can be achieved by MAGIC is as low as 0.7% of the Crab Nebula flux above 220 GeV in 50 h.[4] For short timescales, which are important in the case of the follow-up of transient sources like GRBs, the flux sensitivity is at the level of 10% of the Crab Nebula flux above 100 GeV in 1 hour.

### 2.1. *GRBs follow-up with MAGIC*

The detection of Gamma-Ray Bursts in the VHE band is one of the primary scientific goals of MAGIC and each year a considerable amount of hours are devoted to their follow-up. The transient nature of GRBs makes their follow-up challenging for facilities like MAGIC, characterized by a limited field of view. For this reason, MAGIC was designed to be able to repoint in short time[a] in response to GRB alerts coming from the GCN (*Gamma-ray Coordinates Network*[b]). These alerts are processed by the MAGIC Automatic Alert System, which checks the visibility of the targets from the MAGIC site. If a GRB is observable, an automatic procedure repoints the telescopes in fast mode towards its sky position, while the different subsystems are prepared for data taking. This procedure was revisited in 2013 in order to be more robust against possible hardware failures. Beside the automatic follow-up, MAGIC performs so called *late-time observations* of GRBs detected by *Fermi*-LAT: the source is observed even after 24 h or more with respect to the trigger time of the event. The goal of such strategy is to detect a possible long-lasting VHE emission from GRBs.

In 15 years of operation, up to June 2018, MAGIC followed-up 101 GRBs in good observational conditions and not affected by any major hardware problem. See Fig. 1 for a skymap of such events. Despite the huge effort, MAGIC could not detect any VHE gamma-ray signal from GRBs (status up to June 2018). In one case though, described below, MAGIC data shows a hint of signal in the VHE band.

### 2.2. *GRB 160821B*

*Swift*-BAT detected the short GRB 160821B ($T_{90} = 0.48$ s in the 15-350 keV energy range) at 22:29:13 UT[6] and MAGIC received the alert at 22:29:26 UT. Using

[a] 25 s for a 180° rotation.
[b] `https://gcn.gsfc.nasa.gov/`.

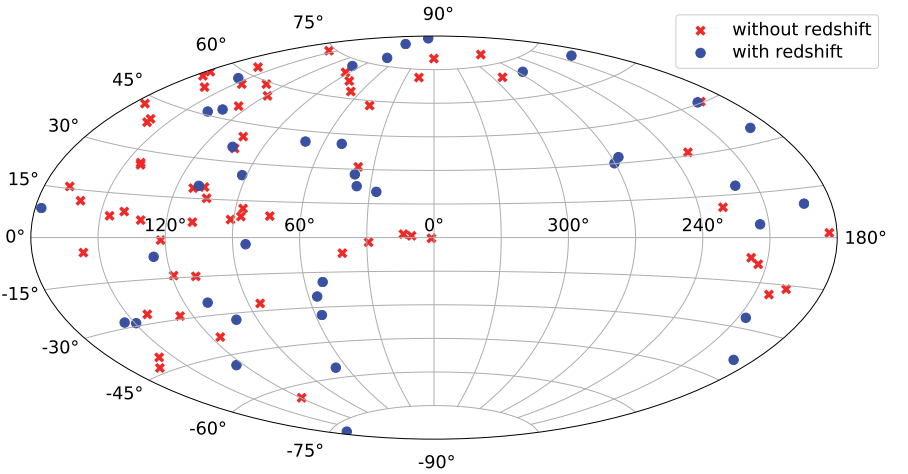

Fig. 1. Sky locations of the 101 GRBs followed-up by MAGIC up to June 2018. Filled blue dots are GRBs with redshift estimation, while red crosses are GRBs without redshift.

the automatic GRB procedure, MAGIC was on target just 24 s after the onset of the GRB. Thanks to optical observations by the William Herschel Telescope, the redshift of the GRB was estimated to be $z = 0.16$.[7]

MAGIC observation started under moderate moonlight conditions at a zenith of ∼34 degrees, with a night sky background (NSB) level between three and five times the one under dark moonless conditions. The first 1.5 hours of data were affected by a non optimal atmospheric transmission, due to the presence of clouds. For the rest of the observation the weather conditions were good and the NSB increased at a level between five and nine times with respect to dark conditions. The observation stopped after 4 hours from the trigger time, with the GRB reaching a zenith of ∼55 degrees.

A dedicated analysis was performed on GRB 160821B, for two reasons in particular: the presence of the Moon during observations and the low atmospheric transmission in the first part of data taking. The former issue is handled as as described in Ref. 5. In the latter case, the data are corrected for the low atmospheric transmission using the data collected by the LIDAR instrument installed on top of the MAGIC counting house building.[8] The dedicated analysis resulted in a hint of gamma-ray signal detection with a significance of $3.1\sigma$, as shown in Fig. 2.

If we make the assumption that this signal is real, this GRB would be the first to be detected at VHE energies and it would open a new window in the understanding of (short) GRBs emission. A detailed modeling and interpretation of such event will be the main topic of an upcoming paper, currently in preparation.

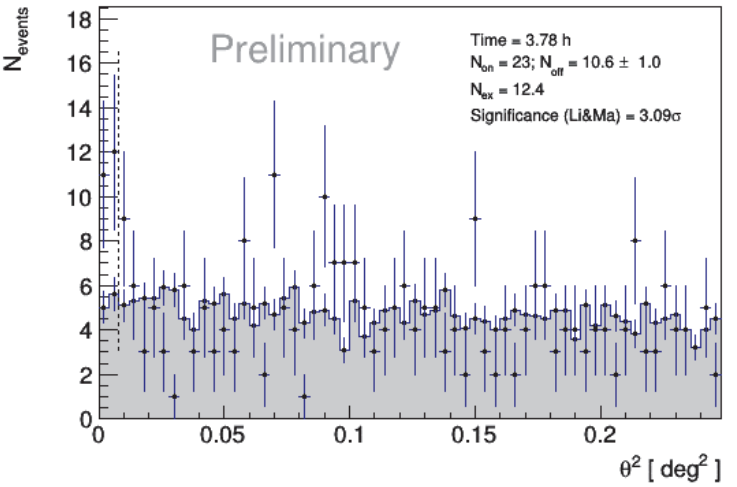

Fig. 2. $\theta^2$ distribution for data taken on GRB 160821B (points) and for the background events (grey shaded area). $\theta^2$ is defined as the squared angular distance between the nominal position of the source and the reconstructed arrival direction of the events.

## 3. Future prospects for GRB follow-up with MAGIC

MAGIC is currently one of the main actors in the follow-up of GRBs in the VHE band. The automatic procedure ensures to observe GRBs as fast as possible, without causing hardware failures. The efforts in pushing the capabilities of the telescopes under moonlight or non optimal weather conditions provide MAGIC with a higher chance to detect a GRB at very high energies, as indicated by the case of GRB 160821B. Even in this case, there is room for improvement. A change in the automatic procedure is foreseen in the nearby future, namely the inclusion of the Sum Trigger.[9] This novel trigger system, used successfully when MAGIC operated as a single telescope, is now in an advanced and stable state, providing an energy threshold as low as 30 GeV for low zenith angles. This feature is crucial for the observation of distant sources like GRBs.

Lorentz symmetries represent one of the cornerstones of modern physics, and yet independent approaches aiming at combining general relativistic with quantum effects often imply some form of departures from them. According to the simplest models, particles having different energies emitted at the same time from a given source should be detected at different times from a far-away detector, thereby producing a phenomenon of in-vacuo dispersion with a linear correlation between the time of observation and particles' energy. Given that, the search for energy-dependent time lags in gamma-ray bursts (GRB) has gradually become a standard way to make tests of fundamental physics and also look for the first signatures of the sought-after quantum theory of gravity. Most of the current studies, considering a single GRB or just the most energetic photon for each GRB analysed, allowed to set very tight constraints on the relevant scale, usually believed to be close to the Planck mass. However, due to the rather poor understanding of the spectral evolution of GRBs, statistical analyses over collections of GRBs would provide more reliable outcomes. Here we test in-vacuo dispersion by analysing all the photons with energy at the emission greater than 5 GeV emitted from 7 GRBs observed by Fermi-LAT. Remarkably, we find preliminary evidence of in-vacuo-dispersion-like spectral lags consistently with what has been noticed by some recent studies which, though, had focused only on the energy range above 40 GeV.

*Keywords*: Gamma-ray bursts.

## 1. Introduction

Over the last 15 years there has been considerable interest (see *e.g.* Refs. 1–9 and references therein) in quantum-gravity (QG) induced in-vacuo dispersion, the possibility that spacetime itself might behave essentially like a dispersive medium for particle propagation: there might be an energy dependence of the travel times of ultrarelativistic particles from a given source to a given detector.

The most studied[1–9] modelization of quantum-gravity-induced in-vacuo dispersion is

$$\Delta t = \eta_X \frac{E}{M_P} D(z) \pm \delta_X \frac{E}{M_P} D(z)\,, \tag{1}$$

where $z$ is the redshift of the relevant GRB and

$$D(z) = \int_0^z d\zeta \frac{(1+\zeta)}{H_0\sqrt{\Omega_\Lambda + (1+\zeta)^3\Omega_m}}\,. \tag{2}$$

$\Omega_\Lambda$, $H_0$ and $\Omega_m$ denote, as usual, respectively the cosmological constant, the Hubble parameter and the matter fraction[16]. $M_P$ denotes the Planck scale ($\simeq 1.2 \cdot 10^{28} eV$) and the values of the parameters $\eta_X$ and $\delta_X$ in (1) are to be determined experimentally. Here "$\pm\delta_X$" accounts for quantum-uncertainty (fuzziness) effects, while $\eta_X$ characterizes systematic effects. Finally, the label $X$ intends to allow for a possible dependence[1,9] on the type of particles and/or on their spin/helicity. We shall not consider either fuzziness or particle/spin dependent effects.

Eq. (1) tells us that, if we wish to test the in-vacuo-dispersion hypothesis, then we need far away transient sources emitting very-high energy particles. Given that, gamma-ray bursts (GRBs) perhaps represent the most suitable sources[1–4]. Many studies have been able to set very tight constraints on the QG scale (i.e. $E_{QG} \equiv M_P/\eta_X$ if $\delta_X = 0$) close to or, in some analyses, even beyond the Planck scale (see, e.g., Ref. 17 and references therein). However, the main challenge for this type of analyses consists in the difficulty to disentangle the QG effect from the intrinsic spectral lags. In absence of a satisfactory astrophysical mechanism to take into account source effects, there are two natural ways to face this problem: use multiple kind of sources and/or messengers, and increase the size of the data.

Some of us were involved in the first studies using IceCube data for searching for GRB-neutrino in-vacuo-dispersion candidates[8,10–12]. Analogous investigations were performed in a series of studies[13–15] focusing on the highest-energy GRB photons observed by the Fermi telescope. As summarized in Fig. 1 these studies provided rather strong statistical evidence of in-vacuo-dispersion-like spectral lags. For each point in Fig. 1 (black points are "GRB-neutrino candidates" [10], while the blue points are GRB photons with energy at emission greater than 40 GeV) we denote by $\Delta t$ the difference between the time of observation of the relevant particle and the time of observation of the first low-energy peak in the GRB, while $E^*$ is the redshift-rescaled energy of the relevant particle defined as $E^* \equiv (E \times D(z))/D(1)$. The linear correlation between $\Delta t$ and $E^*$ visible in Fig. 1 is just of the type expected for quantum-gravity-induced in-vacuo dispersion, and it has been estimated[10] that such a high level of correlation would occur accidentally (in absence of in-vacuo dispersion) only in less than 1% of cases, while GRB photons could produce such high correlation only in less than 0.1% of cases[12].

This "statistical evidence" motivated us to explore whether or not the in-vacuo-dispersion-like spectral lags persist at lower energies. Thus, we here contribute to the attempt to reduce the impact of intrinsic delays by extending the window of the statistical analysis down to 5 GeV. This increases the number of photons analyzed by more than an order of magnitude (only 11 photons are considered in Fig. 1, whereas the analysis we here report involves 148 photons). Indeed, given the poor

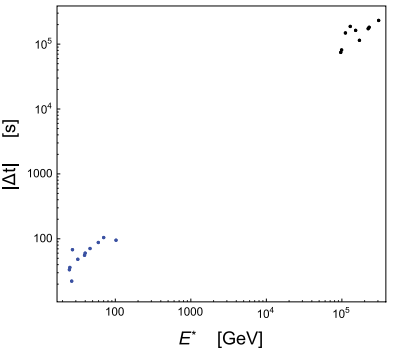

Fig. 1. Values of $|\Delta t|$ versus $E^*$ for the IceCube GRB-neutrino candidates discussed in Refs. 10, 12 (black points) and for the GRB photons discussed in Refs. 12, 15 (blue points). The photon points in figure also factor in the result of a one-parameter fit estimating the average magnitude of intrinsic time lags (details in Refs. 12, 15).

understanding of the GRB time spectra, analyses based on the time of observation of a single photon[18] may not uncover a feature, which though could be revealed by statistical analyses.

## 2. Data analysis: Widening the energy window

Our analysis focuses on the same GRBs whose photons took part in the analyses which led to the picture here summarized in Fig. 1, i.e. GRB080916C, GRB090510, GRB090902B, GRB090926A, GRB100414A, GRB130427A, GRB160509A, but includes all the photons with energy at the source greater than 5 GeV. Since we cannot assume all the GRB photons were emitted in coincidence with the first GRB peak as in Fig. 1, we consider a $\Delta t_{pair}$, which gives for each pair of photons in our sample their difference of time of observation. Thus, each pair of photons (from the same GRB) gives us an an estimated value of $\eta_\gamma$

$$\eta_\gamma^{[pair]} \equiv \frac{M_P \Delta t_{pair}}{D(1) E^*_{pair}}\,, \tag{3}$$

where $E^*_{pair}$ is the difference in values of $E^*$ for the two photons in the pair. Of course the $\Delta t_{pair}$ for many pairs of photons in our sample could not possibly have anything to do with in-vacuo dispersion: if the two photons were produced from different phases of the GRB (different peaks) their $\Delta t_{pair}$ will be dominated by the intrinsic time-of-emission difference. Those values of $\eta_\gamma^{[pair]}$ will be spurious, they will be "noise" for our analysis. However we also of course expect that some pairs of photons in our sample were emitted nearly simultaneously, and for those pairs the $\Delta t_{pair}$ could truly estimate $\eta_\gamma$. Form Fig. 1 one gets $\eta_\gamma = 30 \pm 6$, then we would expect that values of $\eta_\gamma^{[pair]}$ of about 30 are more frequent than expected without a relationship between arrival times and energy of the type produced by in-vacuo dispersion.

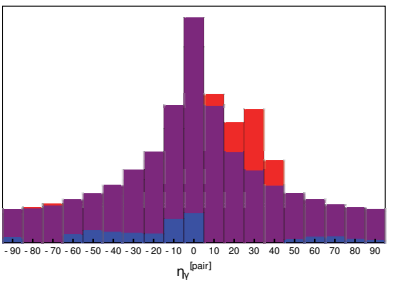

Fig. 2. Normalized distribution of $\eta_\gamma^{[pair]}$ for all pairs of photons (from the same GRB) within our data set. For bins where the observed population is higher than expected we color the bar in purple up to the level expected, showing then the excess in red. For bins where the observed population is lower than expected the bar height gives the expected population, while the blue portion of the bar quantifies the amount by which the observed population is lower than expected.

This is just what we find, as shown perhaps most vividly by the content of Fig. 2. The main point to be noticed in Fig. 2 is that we find in our sample a frequency of occurrence of values of $\eta_\gamma^{[pair]}$ between 25 and 35 which is tangibly higher than one would have expected in absence of a correlation between $\Delta t_{pair}$ and $E^*_{pair}$. Following a standard strategy of analysis (see, *e.g.*, Ref. 17) we estimate how frequently $25 \leq \eta_\gamma^{[pair]} \leq 35$ should occur in absence of correlation between $\Delta t_{pair}$ and $E^*_{pair}$ by producing $10^5$ sets of simulated data, each obtained by reshuffling randomly the times of observation of the photons in our sample. We also performed some variants of our analysis, first by dividing our data sample in three different energy ranges and considering only those pairs made of photons belonging to different groups (or excluding the photons with energy at the emission greater then 40 GeV, i.e. the only ones contributing to Fig. 1). Following a different procedure, we also estimated $\eta_\gamma$ with a best-fit technique performed for every triplet of photons from the same GRB. Remarkably, the excess of results for $\eta_\gamma^{[pair]}$ between 25 and 35 shows up in all these analyses with an overall significance of about 0.5%.

## 3. Discussion and Outlook

In summary we found rather striking indications in favor of values of $\eta_\gamma$ of about 30 in GRB data for all photons with energy at emission greater than 5 GeV. On the basis of our exploration, on future similar-size GRB data samples one should find again at least some partial manifestation of the same feature. We are of course much further from establishing whether this feature truly is connected with QG-induced in-vacuo dispersion, rather than being some intrinsic property of GRB signals. The imprint of in-vacuo dispersion is coded in the $D(z)$ for the distance dependence and, while that does give a good match to the data, one should keep in mind that only a few redshifts (a few GRBs) were relevant for our analysis. Moreover, given the very tight constraints on systematic QG delays[18], in-vacuo dispersion should most likely be of statistical ("fuzzy") nature.

The first detection of gravitational waves a binary neutron star merger GW170817 by the LIGO-Virgo Collaboration has provided fundamental new insights into the astrophysical site for r-process nucleosynthesis and on the nature of dense neutron-star matter. The detected gravitational wave signal depends upon the tidal distortion of the neutron stars as they approach merger. We examine how the detected chirp depends the adopted equation of state. This places new constrains on the properties of nuclear matter. The detected evidence of heavy-element nucleosynthesis also provides insight into the nature of the r-process and the fission properties of the heaviest nuclei. Parametrically, one can divide models for the r-process into three scenarios roughly characterized by the number of neutron captures per seed nucleus (n/s). In addition to neutron-star mergers, these include magneto-hydrodynamic jets from supernovae and the neutrino heated wind above the proto neutron star in core-collapse supernovae. Insight from GW170817 allows one to better quantify the relative contributions of each astrophysical site and the fission termination of the r-process recycling.

*Keywords*: Binary neutron stars - Gamma-ray bursts: Kilonova - Gravitational Waves - Nucleosynthesis - Stars: neutron.

## 1. Introduction

On August 17, 2017, Nature revealed herself in a most spectacular way, both from the gravitational waves detected by the LIGO and VIRGO collaborations [1], and by the multitude of follow up observations [2] of the GRB170817A kilonova, along with IR and optical ground-based observations. In this work we consider two aspects of what may have been learned from this event. On the one hand, the GW chirp implies a possible dilemma regarding the Nuclear EOS deduced from the Post-Newtonian tidal-polarizability vs. observed neutron star properties. Here we discuss our analysis of the chirp in numerical general relativity [3] as a means to better constrain the EoS and clarify the current dilemma. The second aspect considered here is that the kilonova EM spectrum indicates evidence of r-process nucleosynthesis that has implications for the fission barriers and termination of fission recycling during the r-process.

In the LIGO analysis [1] and in follow up analysis [4,5] the tidal polarizability was deduced from post-Newtonian expansion. The tidal polarizability (or deformability) $\Lambda$ is an intrinsic neutron-star property highly sensitive to the compactness parameter $[\Lambda \sim (M/R)^5]$ that describes the tendency of a neutron star to develop a mass quadrupole as a response to the tidal field induced by its companion. [6,7] Based upon the most recent analysis by LIGO [5] it has been deduced that the reduced tidal

polarizability is $\tilde{\Lambda} = 190^{+390}_{120}$ implying that the radius of the stars of 1.4 $M_\odot$ is in the range 10.5 km $\leq R \leq$ 13.3 km.

However, in this work we consider the possibility that as the stars approach merger during the chirp they are neither well described by post-Newtonian physics, not as a simple quadrupole deformation. Indeed, one desires to trace the evolution of the binary from when they first enter the LIGO window until some 30 sec later when the stars merge. For an orbit period of $\sim 100$ ms, this would require evolving the system for $\sim 3000$ orbits. This is indeed an daunting task from the standpoint of numerical relativity for which it is difficult to follow more than a few orbits due to limitations of computational resource.

In this work, however, we report on the first analysis of a general relativistic hydrodynamic simulation [3,8] that is capable of stably numerically integrating thousands of orbits. The solution of the field equations and hydrodynamic equations of motion is summarized in Refs. 9, 10. One starts with the slicing of spacetime into the usual one-parameter family of hypersurfaces separated by differential displacements in a time-like coordinate as defined in the (3+1) ADM formalism [11,12].

In Cartesian $x, y, z$ isotropic coordinates, proper distance is expressed as

$$ds^2 = -(\alpha^2 - \beta_i\beta^i)dt^2 + 2\beta_i dx^i dt + \phi^4 \delta_{ij} dx^i dx^j, \tag{1}$$

where the lapse function $\alpha$ describes the differential lapse of proper time between two hypersurfaces. The quantity $\beta_i$ is the shift vector denoting the shift in space-like coordinates between hypersurfaces. The curvature of the metric of the 3-geometry is described by a position dependent conformal factor $\phi^4$ times a flat-space Kronecker delta ($\gamma_{ij} = \phi^4 \delta_{ij}$). This conformally flat condition on the metric provides a numerically valid initial solution to the Einstein equations. The vanishing of the Weyl tensor for a stationary system in three spatial dimensions guarantees that a conformally flat solution to the Einstein equations exists.

To solve for the fluid motion of the system in curved spacetime it is convenient to use an Eulerian fluid description [9]. By introducing the usual set of Lorentz contracted state variables it is possible to write the relativistic hydrodynamic equations in a form which is reminiscent of their Newtonian counterparts [9]. The hydrodynamic state variables are: the coordinate baryon mass density, $D$, the internal energy density $E$ and the covariant spatial momentum density, $S_i$;

$$D = W\rho; \quad E = W\rho\epsilon; \quad S_i = (D + E + PW)U_i. \tag{2}$$

Key to maintaining is to evolve the the spatial three velocity in the rotating frame,

$$V^i = \alpha \frac{U_i}{\phi^4 W} - \beta^i; \tag{3}$$

In terms of these state variables, the hydrodynamic equations in the CFA are as follows: The equation for the conservation of baryon number takes the form,

$$\frac{\partial D}{\partial t} = -6D\frac{\partial \log\phi}{\partial t} - \frac{1}{\phi^6}\frac{\partial}{\partial x^j}(\phi^6 D V^j). \tag{4}$$

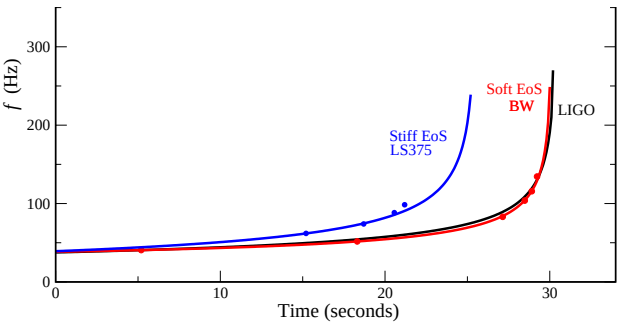

Fig. 1. Reconstructed LIGO gravitational wave chirp compared with the chirp calculated here based upon two equations of state for neutron stars.

The equation for internal energy evolution becomes,

$$\frac{\partial E}{\partial t} = -6(E+PW)\frac{\partial \log\phi}{\partial t} - \frac{1}{\phi^6}\frac{\partial}{\partial x^j}(\phi^6 E V^j) - P\left[\frac{\partial W}{\partial t} + \frac{1}{\phi^6}\frac{\partial}{\partial x^j}(\phi^6 W V^j)\right]. \tag{5}$$

Momentum conservation takes the form,

$$\frac{\partial S_i}{\partial t} = -6S_i\frac{\partial \log\phi}{\partial t} - \frac{1}{\phi^6}\frac{\partial}{\partial x^j}(\phi^6 S_i V^j) - \alpha\frac{\partial P}{\partial x^i} + 2\alpha(D+E+PW)\left(W - \frac{1}{W}\right)\frac{\partial \log\phi}{\partial x^i} + S_j\frac{\partial \beta^j}{\partial x^i} - W(D+E+PW)\frac{\partial \alpha}{\partial x^i} - \alpha W(D+\Gamma E)\frac{\partial \chi}{\partial x^i}. \tag{6}$$

where the last term in Eq. (6) is the contribution from the radiation reaction potential $\chi$ as defined in Refs. 3, 9, 8. Including this term allows for a calculation of the orbital evolution via gravitational wave emission in the CFA.

As a first test and calibration we have constructed quasi-stable orbits for which this term is set to zero. We then reconstruct the time sequence of orbits by fitting a modified form of the chirp,

$$\frac{96}{5}\pi^{8/3}\mathcal{M}^{5/3}t + \frac{3}{8}f^{5/3(at^2+bt+c)} + C = 0 \tag{7}$$

where $a$, $b$ and $c$ are deduced from fits to the numerical simulation and correspond to corrections due to the inclusion of higher moments in mass-energy and momentum in the chirp. This correction is motivated by the deviation of a logrithmic $f$ vs. $t$ plot from a straight line in numerical simulations.

An example of a reconstructed chirp is shown in figure 1 based upon orbits described in Refs. 3, 8. These show a stronger sensitivity to the nuclear EoS than that deduced from the PN analysis of tidal polarizability. [1,4]

## 2. Constraints on r-process nucleosynthesis and the termination of fission recycling

Observation of the multi-messenger followup[2] of the GRB170817A make a strong case for the existence newly synthesized $r$-process material in the ejecta from the binary neutron star merger. The light curve[16] and spectrum[17] are consistent with heating and opacity from $\sim 0.02 - 0.04$ $M_\odot$ of heavy-elements produced during $r$-process nucleosynthesis.

Ejecta from such neutron-star mergers can be characterized by extremely neutron neutron rich nucleosynthesis for which the r-process proceeds until beta- or neutron-induced fission occurs along the $r$-process path. Figure 2 from Ref. 13 highlights a key dilemma in nuclear physics. If the $r$-process path ends among light isotopes with $A \approx 285$ asymmetric fission occurs leading to a prominent peak around $A = 130$. On the other hand if the $r$-process proceeds until $A \approx 300$ as indicated by the fission barriers and yields from Refs. 14, 15, then a more unimodal

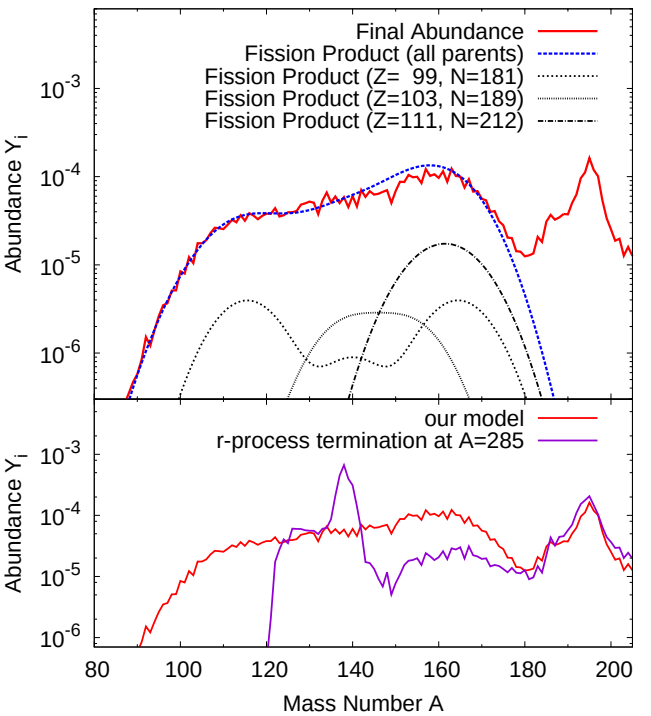

Fig. 2. Illustration from Ref. 13 of the impact of fission yields and fission recycling on the final r-process abundances. Upper panel shows the relative contributions for 3 representative nuclei compared with the final abundance distribution. The lower panel shows the same final r-process yields compared with the distribution that would result if fission recycling were only to occur from parent nuclei at the termination of the r-process path at $A = 285$.

fission distribution leads to the formation of the rare-earth peak, but little yield around the A=130 peak. Hence, identification of elements near the A=130 peak in the ejecta from the GRB170817A kilonova would answer a very important question regarding the fission barriers and yields of the heaviest elements formed in nature. Indeed, the tentative identification [16] of prominent absorption features due to neutral Te-I and Xe-I in the spectrum of the kilonova appears to have answered this question. However, this is controversial since it requires cool material and minimal line broadening, neither of which are expected in this environment. Obviously, confirmation of this detection is necessary in future observations.

*‡ E-mail: cesar.costa@inpe.br*

We discuss some aspects of de Araujo, Coelho and Costa[1,2] concerning the role of a time dependent magnetic ellipticity on the pulsars' braking indices and on the putative gravitational waves (GWs) these objects can emit. Since only nine of more than 2000 known pulsars have accurately measured braking indices, it is of interest to extend this study to all known pulsars, in particular as regards GW generation. In summary, our results show a pessimistic prospect for the detection of GWs generated by these pulsars, even for advanced detectors such as aLIGO and AdVirgo, and the planned Einstein Telescope, would not be able to detect these pulsar, if the ellipticity has magnetic origin.

*Keywords*: Pulsars; Gravitational Waves; braking index.

## 1. Ellipticity of Magnetic Origin and Gravitational Waves from Pulsars

If the magnetic field and (or) the angle between the axes of rotation and the magnetic dipole of the pulsars are independent of time, the combination of magnetic dipole and gravitational wave (GW) brakes could only explain braking index (n) in the interval $3 < n < 5$. The observations, however, show that only PSR J1640-4631 has braking index in this interval, as can be seen in Table 1. In particular, we consider this issue in the context of magnetic ellipticity[1]. It is worth stressing that the magnetic field and the angle between the axes of rotation and the magnetic dipole of the pulsars are dependent on time.

Recall that the equatorial ellipticity is given by

$$\epsilon = \frac{I_{xx} - I_{yy}}{I_{zz}}, \tag{1}$$

where $I_{xx}$, $I_{yy}$, $I_{zz}$ are the moment of inertia with respect to the rotation axis, $z$, and along directions perpendicular to it.

The pulsar is deformed by its own dipole magnetic field. Such deformation associated with the fact that the axes of rotation and of the magnetic dipole are

misaligned generates an ellipticity given by (see, e.g., Bonazzola and Gourgoulhon[3]; Konno et al.[4]; de Freitas Pacheco and Regimbau[5]):

$$\epsilon_B = \kappa \frac{B_0^2 R^4}{GM^2} \sin^2 \phi, \tag{2}$$

where $B_0$ is the dipole magnetic field, $R$ and $M$ are the radius and the mass of the star respectively, $\phi$ is the angle between the rotation and magnetic dipole axes, whereas $\kappa$ is the distortion parameter, which depends on both the star equation of state (EoS) and the magnetic field configuration[5]. We consider that $\kappa = 10 - 1000$, as suggested by numerical simulations[3,5].

Table 1. The periods ($P$) and their first derivatives ($\dot{P}$) for pulsars with known braking indices ($n$) (see also ATNF catalog[6,7]).

| Pulsar | $P$ (s) | $\dot{P}$ ($10^{-13}$ s/s) | $n^{\diamond}$ |
|---|---|---|---|
| PSR J1734-3333 | 1.17 | 22.8 | $0.9 \pm 0.2$[8] |
| PSR B0833-45 (Vela) | 0.089 | 1.25 | $1.4 \pm 0.2$[9] |
| PSR J1833-1034 | 0.062 | 2.02 | $1.8569 \pm 0.0006$[10] |
| PSR J0540-6919 | 0.050 | 4.79 | $2.140 \pm 0.009$[11] |
| PSR J1846-0258 | 0.324 | 71 | $2.19 \pm 0.03$[12] |
| PSR B0531+21 (Crab) | 0.033 | 4.21 | $2.51 \pm 0.01$[13] |
| PSR J1119-6127 | 0.408 | 40.2 | $2.684 \pm 0.002$[14] |
| PSR J1513-5908 | 0.151 | 15.3 | $2.839 \pm 0.001$[11] |
| PSR J1640-4631 | 0.207 | 9.72 | $3.15 \pm 0.03$[15] |

*Note*: $^{\diamond}$ $n \equiv f_{\rm rot}\, \ddot{f}_{\rm rot}/\dot{f}_{\rm rot}^2$, where $f_{\rm rot} = 1/P$ is the rotating frequency, $\dot{f}_{\rm rot}$ and $\ddot{f}_{\rm rot}$ are their time derivatives.

Recall that the power emitted by a rotating magnetic dipole is given by[16]

$$\dot{E}_{\rm d} = -\frac{16\pi^4}{3} \frac{B_0^2 R^6 \sin^2 \phi}{c^3} f_{\rm rot}^4, \tag{3}$$

and the power loss via GW emission reads[17]

$$\dot{E}_{\rm GW} = -\frac{2048\pi^6}{5} \frac{G}{c^5} I^2 \epsilon^2 f_{\rm rot}^6. \tag{4}$$

Also, the total energy of the pulsar is provided by its rotational energy, $E_{\rm rot} = 2\pi^2 I f_{\rm rot}^2$, and any change on it is given by $\dot{E}_{\rm d}$ and $\dot{E}_{\rm GW}$, namely

$$\dot{E}_{\rm rot} \equiv \dot{E}_{\rm GW} + \dot{E}_{\rm d}. \tag{5}$$

Now, from the definition of the braking index (see, e.g., the note in Table 1), one can easily obtain that[a]

$$n = 3 + 2\eta - 2\frac{P}{\dot{P}}(1+\eta) \left[ \frac{\dot{B}_0}{B_0} + \dot{\phi} \cot \phi \right], \tag{6}$$

[a]The detailed derivation of Eq. (6) can be found in de Araujo, Coelho and Costa[1].

where $\eta$ is defined in such a way that $\dot{E}_{\rm GW} = \eta \dot{E}_{\rm rot}$, which is interpreted as the efficiency of GW generation. In de Araujo, Coelho and Costa[1] it is also shown that with Eq. (6) one can explain, in principle, the braking indices of the pulsars of Table 1.

Recall that the GW amplitude generated by a pulsar reads

$$h^2 = \frac{5}{2}\frac{G}{c^3}\frac{I}{r^2}\frac{\mid \dot{f}_{\rm rot} \mid}{f_{\rm rot}}. \tag{7}$$

This equation considers that the spindown is due to gravitational waves only, i.e., $n = 5$ (spindown limit - SD).

From the definition of $\eta$ one obtains that $\dot{\bar{f}}_{\rm rot} = \eta \dot{f}_{\rm rot}$, i.e., the part of the spindown related to the GW emission brake. Thus, one can obtain an equation for the GW amplitude that holds for n $< 5$, namely

$$\bar{h}^2 = \frac{5}{2}\frac{G}{c^3}\frac{I}{r^2}\frac{\mid \dot{\bar{f}}_{rot} \mid}{f_{rot}} = \frac{5}{2}\frac{G}{c^3}\frac{I}{r^2}\frac{\mid \dot{f}_{\rm rot} \mid}{f_{\rm rot}}\,\eta. \tag{8}$$

Recall that the GW amplitude also reads

$$h = \frac{16\pi^2 G}{c^4}\frac{I\epsilon f_{\rm rot}^2}{r}, \tag{9}$$

(see, e.g, Shapiro and Teukolsky[17]). Combining both equations for the GW amplitude one obtains

$$\epsilon = \sqrt{\frac{5}{512\pi^4}\frac{c^5}{G}\frac{\dot{P}P^3}{I}\eta}. \tag{10}$$

Now, for a purely magnetic brake we have

$$\bar{B}_0 \sin^2\phi = \frac{3Ic^3}{4\pi^2 R^6} P\dot{P}, \tag{11}$$

where $\bar{B}_0$ would be the magnetic field whether the break were purely magnetic. If there is also a GW brake contribution we have that $B_0 < \bar{B}_0$. Combining the definition of $\eta$ and Eq. (10) one obtains after some algebraic manipulation the following equation for the efficiency $\eta$

$$\eta = 1 - \left(\frac{B_0}{\bar{B}_0}\right)^2, \tag{12}$$

which is obviously lower than one, as it should be. Substituting this last equation into Eq. (2) we obtain

$$\epsilon = \frac{3Ic^3}{4\pi^2 GM^2R^2} P\dot{P}\,(1-\eta)\,\kappa. \tag{13}$$

Finally, substituting this last equation into Eq. (10), we obtain

$$\eta = \frac{288}{5}\frac{I^3 c}{GM^4R^4}\frac{\dot{P}}{P}\,(1-\eta)^2\,\kappa^2. \tag{14}$$

Notice that with Eqs. (13) and (14) we obtain $\epsilon$ and $\eta$ in terms of $M$, $R$, $I$, $P$ and $\dot{P}$ for a given value of $\kappa$. Since in practice $\eta \ll 1$, the following useful equations are obtained

$$\epsilon \simeq \frac{3Ic^3}{4\pi^2 GM^2R^2} P\dot{P}\kappa \tag{15}$$

and

$$\eta \simeq \frac{288}{5}\frac{I^3c}{GM^4R^4}\frac{\dot{P}}{P}\kappa^2. \tag{16}$$

We now calculate $\epsilon_B$ and $\eta$ for the pulsars of Table 1. We then adopt fiducial values for M, R and I. We adopt $\kappa = 10$ and 1000, which have the same orders of magnitude of the values considered by, e.g., Regimbau and de Freitas Pacheco[5].

In Table 2 we present the result of these calculations. Even for the extremely optimistic case, the value of the ellipticity is at best $\epsilon_B \sim 10^{-5}$ (for PSR J1846-0258) and the corresponding efficiency $\eta \sim 10^{-8}$. Therefore, the amplitude of the GW in this case would be four orders of magnitude lower than the spindown limit ($\eta = 1$). Thus, even advanced detectors such as aLIGO and AdVirgo, and the planned Einstein Telescope, would not be able to detect these pulsars.

Table 2. $\epsilon$ and $\eta$ for $\kappa = 10$ (1000) for the Pulsars of Table 1.

| Pulsar | $\epsilon$ | $\eta$ |
|---|---|---|
| PSR J1734-3333 | $1.2 \times 10^{-7(-5)}$ | $1.1 \times 10^{-13(-9)}$ |
| PSR B0833-45 (Vela) | $4.9 \times 10^{-10(-8)}$ | $8.3 \times 10^{-14(-10)}$ |
| PSR J1833-1034 | $5.5 \times 10^{-10(-8)}$ | $1.9 \times 10^{-13(-9)}$ |
| PSR J0540-6919 | $1.1 \times 10^{-9(-7)}$ | $5.7 \times 10^{-13(-9)}$ |
| PSR J1846-0258 | $1.0 \times 10^{-7(-5)}$ | $1.3 \times 10^{-12(-8)}$ |
| PSR B0531+21 (Crab) | $6.1 \times 10^{-10(-8)}$ | $7.5 \times 10^{-13(-9)}$ |
| PSR J1119-6127 | $7.2 \times 10^{-8(-6)}$ | $5.8 \times 10^{-13(-9)}$ |
| PSR J1513-5908 | $1.0 \times 10^{-8(-6)}$ | $6.0 \times 10^{-13(-9)}$ |
| PSR J1640-4631 | $8.9 \times 10^{-9(-7)}$ | $2.8 \times 10^{-13(-9)}$ |

Notice that Eqs. (15) and (16) do not depend on the braking index n. Consequently, we can calculate such quantities for the pulsars of the ATNF Pulsar Catalog. We refer the reader to the paper by de Araujo, Coelho and Costa[2] for details. In Fig. 1 we show an interesting histogram with the data of the ATNF Catalog, namely, the number of pulsars for $\log \epsilon_B$ bin. Note the high number of pulsars concentrated around $\sim 10^{-10}$ ($10^{-8}$) for $k = 10$ (1000). The values of $\eta$ are also extremely small, a histogram can be found in de Araujo, Coelho and Costa[2], where can be seen a peak at $10^{-16} - 10^{-15}$.

These extremely small values of $\epsilon_B$ and $\eta$ imply that the GW amplitudes are at best seven orders of magnitude smaller than those obtained by assuming the spindown limit (SD), being therefore hardly detected (see Fig. 2).

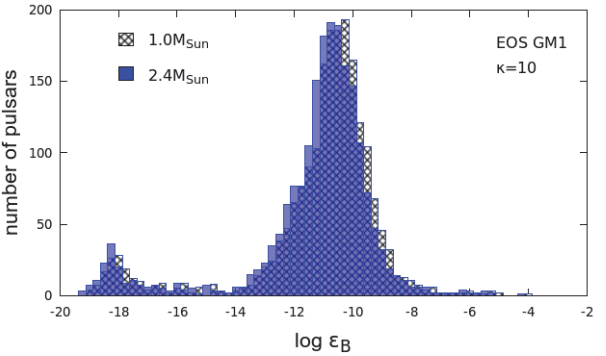

Fig. 1. Ellipticity histogram for the pulsars of ATNF Catalog for $\kappa = 10$.

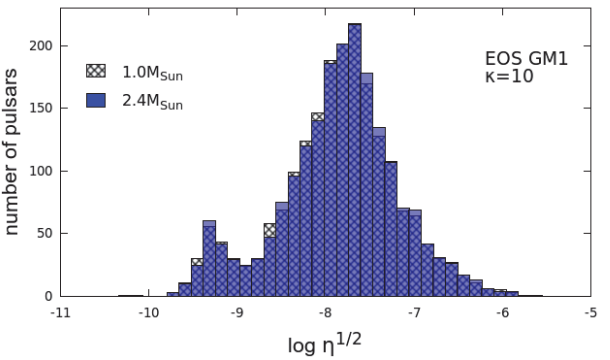

Fig. 2. Histogram of $\eta^{1/2} = h/h^{SD}$ (spin-down ratio) for the pulsars of ATNF Catalog for $\kappa = 10$.

## 2. Final Remarks

We present an expression for the braking index considering that the ellipticity is of magnetic dipole origin and time dependent. In this context, we model the braking indices of the 9 pulsars that have such measured quantities accurately. Then we calculate the amplitudes of the GWs generated by these 9 pulsars. Summing up, we conclude that these amplitudes are too small to be detected. For example, the pulsar PSR J1846-0258 would need to be observed for over 1000 years to be detected by the Einstein Telescope.

Since the equations for $\eta$, $\epsilon_B$ and $h$ are independent of n, we extend our study for most of the pulsars of the "ATNF Pulsar Catalog". Regarding detectability, the prospects remain pessimistic, since the ellipticity generated by the magnetic dipole is extremely small, the corresponding amplitude of GWs is much smaller than the amplitude obtained via the spindown limit.

# A strategy for detecting non-gaussianity of stochastic gravitational waves

Makoto Tsuneto[1], Asuka Ito[2], Toshifumi Noumi[2,3] and Jiro Soda[2]

[1] *SUNY Stony Brook Department of Physics and Astronomy, Stony Brook 11794-3800, USA*

[3] *Department of Physics, University of Wisconsin-Madison, Madison, WI 53706, USA*

We study how to probe non-gaussianity of stochastic gravitational waves with pulsar timing arrays. The non-gaussianity is a key to probe the origin of stochastic gravitational waves. In particular, the shape of the bispectrum which characterize the non-gaussianity carries valuable information of inflation models. We show that an appropriate filter function for three point correlations enables us to extract a specific configuration of momentum triangles in bispectra.

## 1. Introduction

Stochastic gravitational waves (GWs), the GW analog for the cosmic microwave background, are going through us from all directions. They contain primordial GWs[1,2] produced during inflation[3–6] in addition to GWs of cosmological/astrophysical origin[7]. As the name suggests, stochastic GWs are characterized by statistics such as the power spectrum, bispectrum and higher order correlation functions.

The detection of the power spectrum of stochastic GWs is a clue to probe the early universe. Moreover, the bispectrum of stochastic GWs, which represents the non-gaussianity, is a powerful tool to discriminate astrophysical and primordial origin since the former has a gaussian distribution as long as event rates are high enough to create continuous GWs[7,8].[a] Therefore, the bispectrum of stochastic GWs enables us to probe the early universe. Indeed, the bispectrum of primordial GWs contains the detail of inflation models like nonlinear interactions of the graviton. The shape of bispectra, which depends on inflation models[15–18], allows us to discriminate inflation models.[b] Furthermore, the imprint of new particles with the mass comparable to the Hubble scale during inflation can potentially appear in the squeezed limit of momentum triangles[20–26]. Therefore, the bispectrum is a powerful probe of the early universe and beyond the standard model.

Now, GW detectors are in operation to probe stochastic GWs, although no signal of stochastic GWs has been detected yet. The sensitive frequency band of interferometers like LIGO[27] and Virgo[28] is around $10^2$ Hz, while pulsar timing

[a] Alternatively, if the event rate is too low to produce continuous GWs, the distribution is not gaussian. Detectability of such feature is explored in Refs. 9–14.
[b] Recently, it was shown that the detection of power spectrum of primordial GWs is not enough to exclude bouncing universe models[19]. Therefore, the bispectrum is also important to distinguish inflation and bouncing universe models.

arrays such as EPTA[29] and NANOGrav[30] are searching for stochastic GWs with a frequency range $10^{-9}$-$10^{-7}$ Hz. The constraints on the energy density of stochastic GWs are $\Omega_{GW} < 1.2 \times 10^{-9}$ (EPTA), $\Omega_{GW} < 3.4 \times 10^{-10}$ (NANOGrav), and $\Omega_{GW} < 1.1 \times 10^{-11}$ (PPTA), respectively. In future, the space interferometers, LISA[31] and DECIGO[32], will be launched in a few decades. The pulsar timing array project SKA[33] will start in 2020 and significantly improve the current sensitivity. Its possible upper limit is $\Omega_{GW} < 1.0 \times 10^{-13}$.[34] Therefore, it is worth exploring a new theoretical research area for forthcoming observations.

In this paper, we investigate a method for detecting the bispectrum of stochastic GWs with pulsar timing arrays[35]. In particular, we explain how to utilize a filter function not only to maximize the signal to noise ratio (SNR), but also to extract a specific configuration of momentum triangles in the bispectrum.

## 2. GW signal in pulsar timing arrays

In the Minkowski spacetime, GWs as tensor perturbations of the metric can be expanded with plane waves:

$$h_{ij}(t,\vec{x}) = \sum_A \int_{-\infty}^{\infty} \mathrm{d}f \int \mathrm{d}\hat{\Omega}\, e^{2\pi \mathrm{i}\left(ft - |f|\hat{\Omega}\cdot\vec{x}\right)}\, \tilde{h}_A(f,\hat{\Omega}) e^A_{ij}(\hat{\Omega})\,, \tag{1}$$

where $\hat{\Omega}$ is the direction of propagation of GWs. Polarization tensors, which satisfy $e^A_{ij}(\hat{\Omega}) e^{A'}_{ij}(\hat{\Omega}) = 2\delta^{AA'}$, can be defined by

$$e^+_{ij}(\hat{\Omega}) = \hat{m}_i\hat{m}_j - \hat{n}_i\hat{n}_j\ , \quad e^\times_{ij}(\hat{\Omega}) = \hat{m}_i\hat{n}_j + \hat{n}_i\hat{m}_j\ . \tag{2}$$

Here, $\hat{m}$ and $\hat{n}$ are unit vectors perpendicular to $\hat{\Omega}$ and one another.

GW detectors have their specific response to GWs. For instance, pulsars can be utilized as a detector. A pulsar is a neutron star which emits periodic electromagnetic fields very accurately. If gravitational waves $h_A(f,\hat{\Omega})$ exist continuously between the Earth and a pulsar (the direction $\hat{p}$), we observe the redshift of an emitted pulse as[36]

$$\tilde{Z}(f,\hat{\Omega}) = \left(e^{-2\pi \mathrm{i} L\left(f + |f|\hat{\Omega}\cdot\hat{p}\right)} - 1\right) \sum_A \tilde{h}_A(f,\hat{\Omega}) F^A(\hat{\Omega},\hat{p})\ , \tag{3}$$

where

$$F^A(\hat{\Omega},\hat{p}) \equiv e^A_{ij}\,\frac{1}{2}\,\frac{\hat{p}^i\hat{p}^j}{1+\hat{\Omega}\cdot\hat{p}} \tag{4}$$

is the pattern function. It represents a geometrical factor, namely, dependence of the sensitivity on the configuration of the detector and GWs. Furthermore, we integrate Eq. (3)

$$\tilde{z}(f) = \int \mathrm{d}\hat{\Omega}\, \tilde{Z}(f,\hat{\Omega})\ , \tag{5}$$

because stochastic GWs propagate toward all directions. The quantity that is actually measured is the residual defined by

$$R(t) \equiv \int_0^t \mathrm{d}t' \int_{-\infty}^{\infty} \mathrm{d}f\, e^{2\pi \mathrm{i} f t'}\, \tilde{z}(f) \tag{6}$$

$$= \int_0^t \mathrm{d}t' \int_{-\infty}^{\infty} \mathrm{d}f \int \mathrm{d}\hat{\Omega}\, e^{2\pi \mathrm{i} f t'} \left( e^{-2\pi \mathrm{i} L\left(f + |f| \hat{\Omega}\cdot\hat{p}\right)} - 1 \right) \sum_A \tilde{h}_A(f, \hat{\Omega}) F^A(\hat{\Omega}, \hat{p}). \tag{7}$$

Since, for pulsar timing measurement, the minimum frequency is about $0.1\,\mathrm{yr}^{-1}$ and the shortest distance between the Earth and a pulsar is $\sim 100\,\mathrm{ly}$, we have $fL \gtrsim 10$. In this range, the exponential term in the parenthesis of Eq. (7) can be approximated to zero because it oscillates rapidly. Hence, Eq. (5) can be approximated as

$$\tilde{z}(f) \simeq -\sum_A \int \mathrm{d}\hat{\Omega} \tilde{h}_A(f, \hat{\Omega}) F^A(\hat{\Omega}, \hat{p})\ . \tag{8}$$

We find that the correlation of residuals is directly related with that of stochastic GWs. Therefore, observing appropriate correlation function of the signals, we can probe the statistic of stochastic GWs.

## 3. Probing bispectrum with pulsar timing arrays

Let us define the bispectrum as

$$\langle \tilde{h}_A(f_1, \hat{\Omega}_1) \tilde{h}_{A'}(f_2, \hat{\Omega}_2) \tilde{h}_{A''}(f_3, \hat{\Omega}_3) \rangle = B_{AA'A''}(|f_1|, |f_2|, |f_3|) \delta(f_1 + f_2 + f_3) \times \delta^{(3)}(|f_1|\hat{\Omega}_1 + |f_2|\hat{\Omega}_2 + |f_3|\hat{\Omega}_3)\ . \tag{9}$$

The first delta function denotes that correlations of stochastic GWs are time-independent. The second delta function shows that the momenta form a closed triangle due to homogeneity of the Minkowski spacetime. The bispectral shape varies depending on the inflation model, so that its measurement is a key to probe the early universe.

We define a correlation function of signals in three detectors with a filter function as follows:

$$S_{123} = \iiint_{-T/2}^{T/2} \mathrm{d}t_1 \mathrm{d}t_2 \mathrm{d}t_3\ s_1(t_1) s_2(t_2) s_3(t_3) Q(t_1, t_2, t_3)\,, \tag{10}$$

where the signal $s_i(t_i)$ in each detector contains the GW signal $z_i(t_i)$ and noises $n_i(t_i)$. We introduce a filter function in a form $Q(t_1, t_2, t_3) = Q(at_1 + bt_2 + ct_3)$, where $a, b$ and $c$ are positive constants. It will turn out that the filter function enables us to extract a specific configuration of the momentum triangle determined by these constants. Moving on to Fourier space, we have

$$S_{123} = \iiint_{-T/2}^{T/2} \mathrm{d}t_1 \mathrm{d}t_2 \mathrm{d}t_3 \iiiint_{-\infty}^{\infty} \mathrm{d}f_1 \mathrm{d}f_2 \mathrm{d}f_3 \mathrm{d}f\ \tilde{s}_1(f_1) \tilde{s}_2(f_2) \tilde{s}_3(f_3) \tilde{Q}(f) \times e^{2\pi \mathrm{i} f_1 t_1}\, e^{2\pi \mathrm{i} f_2 t_2}\, e^{2\pi \mathrm{i} f_3 t_3}\, e^{-2\pi \mathrm{i} f (a t_1 + b t_2 + c t_3)}\ , \tag{11}$$

where we have assumed $\tilde{Q}(-f) = \tilde{Q}(f)$. As in the case of the power spectrum, taking $T \to \infty$, one can carry out the integration:

$$S_{123} = \iiint_{-\infty}^{\infty} \mathrm{d}f_1 \mathrm{d}f_2 \mathrm{d}f_3 \mathrm{d}f\, \tilde{s}_1(f_1)\tilde{s}_2(f_2)\tilde{s}_3(f_3)\tilde{Q}(f)\delta(f_1 - af)\delta(f_2 - bf)\delta(f_3 - cf)$$
$$= \int_{-\infty}^{\infty} \mathrm{d}f\, \tilde{s}_1(af)\tilde{s}_2(bf)\tilde{s}_3(cf)\tilde{Q}(f)\,. \tag{12}$$

The ensemble average of $S_{123}$ becomes

$$\langle S_{123}\rangle = \int_{-\infty}^{\infty} \mathrm{d}f\, \langle \tilde{z}_1(af)\tilde{z}_2(bf)\tilde{z}_3(cf)\rangle \tilde{Q}(f)\ . \tag{13}$$

It should be noted that Eq. (13) is valid even for a single pulsar case as long as the noise is gaussian, namely, $\langle n_i(t)n_i(t)n_i(t)\rangle = 0$. From Eqs. (8), (9) and (13), one can deduce

$$\langle S_{123}\rangle = 2T \sum_{A,A',A''} \int_0^{\infty} \mathrm{d}f \frac{1}{f^3} B_{AA'A''}(af, bf, cf)\tilde{Q}(f) \frac{\sin\left(\pi(a+b+c)fT\right)}{\pi(a+b+c)fT}$$
$$\times \frac{(4\pi)^2}{abc}\Gamma^{AA'A''}(a, b, c; \hat{p}_1, \hat{p}_2, \hat{p}_3)\ , \tag{14}$$

where the ORF for the three point correlation is defined by [c]

$$\Gamma^{AA'A''}(a, b, c; \hat{p}_1, \hat{p}_2, \hat{p}_3) = -\frac{abc}{(4\pi)^2} \iiint \mathrm{d}\hat{\Omega}_1 \mathrm{d}\hat{\Omega}_2 \mathrm{d}\hat{\Omega}_3 \delta^{(3)}(a\hat{\Omega}_1 + b\hat{\Omega}_2 + c\hat{\Omega}_3)$$
$$\times F^{A}(\hat{\Omega}_1, \hat{p}_1)F^{A'}(\hat{\Omega}_2, \hat{p}_2)F^{A''}(\hat{\Omega}_3, \hat{p}_3)\ . \tag{15}$$

In Eq. (14), we see that the frequency and the angular integrals are separated due to the filter function, although there appears a suppression factor, $\int_{-T/2}^{T/2} e^{2\pi i(a+b+c)ft}\mathrm{d}t = \frac{\sin\left(\pi(a+b+c)fT\right)}{\pi(a+b+c)f}$, in the first line.[d] Eq. (15) shows that a specific configuration of the momentum triangle determined by $a, b$ and $c$ is extracted.[e] Therefore, we can probe the shape of the bispectrum with changing those parameters. For this purpose, we need to carry out the angular integration to evaluate the ORF. Although we do not study it in this paper, a full discussion is found in the paper[35].

## 4. Conclusion

In this paper, we investigate a method for detecting the bispectrum of stochastic GWs with pulsar timing arrays[35]. We showed that an appropriate filter function in

[c] Note that we have defined the ORF to be scale invariant with respect to $a$,$b$ and $c$.
[d] Allowing $a, b$ and $c$ to be negative, one can remove the suppression factor when $a + b + c = 0$, i.e., in the collinear limit. It implies that pulsar timing arrays is more sensitive to collinear limits of the bispectrum. However, we only focus on positive constants case to probe general momentum triangles in this paper.
[e] In an equal-time three point correlation function, all momentum triangles are integrated. Such case is well studied in the context of LISA[37–39].

three point correlations enables us to extract a specific configuration of momentum triangles in the bispectrum of stochastic GWs. Therefore, one can probe the bispectral shape, which carries important information of the early universe, by adjusting the filter function. Although we did not evaluate the ORF in this paper, a full discussion is found in the paper[35].

We present results from general-relativistic (GR) three-dimensional (3D) core-collapse simulations with approximate neutrino transport for three non-rotating progenitors (11.2, 15, and 40 $M_{\odot}$) using different nuclear equations of state (EOSs). We find that the combination of progenitor's higher compactness at bounce, that is a consequence of the use of softer EOS, leads to stronger activity of the standing accretion shock instability (SASI). We confirm previous predication that the SASI produces characteristic time modulations both in neutrino and gravitational-wave (GW) signals. Our results indicate that the correlation of the neutrino and GW signals, if detected, would provide a new signature of the vigorous SASI activity in the supernova core.

*Keywords*: Supernovae; hydrodynamics; gravitational waves; neutrinos.

## 1. Introduction

Core-collapse supernovae (CCSNe) have been attracting attentions of theoretical and observational astrophysicists for many decades. From multi-wavelength electromagnetic (EM) wave signals, a wide variety of observational evidence have been reported so far, which have all pointed toward CCSNe being generally aspherical. However the EM signals could only provide an indirect probe of the explosion mechanism of CCSNe, because they snapshot images of optically thin regions far away from the central engine. On the contrary, neutrinos and gravitational waves (GWs) are expected to provide direct probes of the inner-workings of CCSNe[1] as they propagate from the inner-core almost without interacting stellar mantle.

From a theoretical point of view, neutrino radiation-hydrodynamics simulations of CCSNe are converging to a point that multi-dimensional (multi-D) hydrodynamics instabilities including neutrino-driven convection and the Standing-Accretion-Shock-Instability (SASI[2]) play a crucial key role in facilitating the neutrino mechanism of CCSNe. Conventionally the GW and neutrino signatures reflecting such CCSNe mechanisms have been studied rather separately. For the neutrino signals, Ref. 3 was the first to find the SASI-induced modulations in the neutrino signals. They found that the SASI-induced modulation is clearly visible for two high-mass progenitors where high SASI activity was observed. Regarding the GW emissions from CCSNe, there are several emission processes in the postbounce phase. Among them, the most distinct GW emission process generically seen in recent self-consistent CCSN models is the one from the PNS surface oscillation[4,5].

The characteristic GW frequency increases monotonically with time due to an accumulating accretion to the PNS, which ranges from $\sim 100$ Hz to $\sim 1000$ Hz. As for another recent finding from self-consistent 3D models, it becomes clear that the SASI also produces a characteristic signature in the GW emission[5–7]. In this emission process, the GW frequency appears in relatively low frequency range of $\sim 100$ to 250 Hz, that is consistent with the SASI frequency, and persists when the SASI dominates over neutrino-driven convection[5,6].

These findings may raise a simple question whether there is some correlation between the SASI-induced neutrino and GW signals. Spotted by the neutrino and GW astronomy in the advanced era, the time is ripe to study in detail what we can learn about the explosion mechanism from the future *simulatenous* detection of neutrinos and GWs using outcomes of multi-D CCSN models. We will estimate neutrino event rates in both Hyper-K and IceCube from our 3D-GR models. We perform a correlation analysis between the GW and neutrino signals.

## 2. Numerical Methods

The numerical schemes for our 3D-GR models are essentially the same as those in Ref. 5. For the metric evolution, we employ the standard BSSN variables ($\tilde{\gamma}_{ij}$, $\phi$, $\tilde{A}_{ij}$, $K$, and $\tilde{\Gamma}^i$)[8,9]. Solving the evolution equations of metric, hydrodynamics, and neutrino radiation in an operator-splitting manner, the system evolves self-consistently as a whole satisfying the Hamiltonian and momentum constraints. The total stress-energy tensor is $T^{\alpha\beta}_{(\mathrm{total})} = T^{\alpha\beta}_{(\mathrm{fluid})} + \sum_\nu T^{\alpha\beta}_{(\nu)}$, where $T^{\alpha\beta}_{(\mathrm{fluid})}$ and $T^{\alpha\beta}_{(\nu)}$ are the stress-energy tensor of fluid and the neutrino radiation field, respectively. We consider three flavors of neutrinos ($\nu \in \nu_e, \bar{\nu}_e, \nu_x$) with no energy dependence. Here $\nu_x$ represents heavy-lepton neutrinos (i.e. $\nu_\mu, \nu_\tau$ and their anti-particles).

We use three EOSs based on the relativistic-mean-field theory with different nuclear interaction treatments, which are DD2 and TM1 of Ref. 10 and SFHx of Ref. 11. SFHx is the softest EOS followed in order by DD2, and TM1. We study frequently used solar-metallicity models of a 15 $M_\odot$ star[12], 11.2, and 40 $M_\odot$ star[13]. The 3D computational domain is a cubic box with 15000 km width and nested boxes with 8 refinement levels are embedded. Each box contains $128^3$ cells and the minimum grid size near the origin is $\Delta x = 458$m. Our 3D-GR models are named by the progenitor mass with the EOS in parenthesis like S15.0(SFHx) which represents the progenitor mass of 15.0 $M_\odot$ and the EOS SFHx are used. GWs are extracted from our simulations using the conventional quadrupole formula.

## 3. Results

We first present a short overview of hydrodynamics features in Fig. 1 (see Ref. 14 for more details). In S15.0(SFHx), the SASI activity was observed in the non-linear phase with global scale hot entropy structures. While in a lighter progenitor model

S11.2(SFHx), convection is observed by formation of small-scale convective bubbles behind the roundish stalled shock and dominates over the SASI motion.

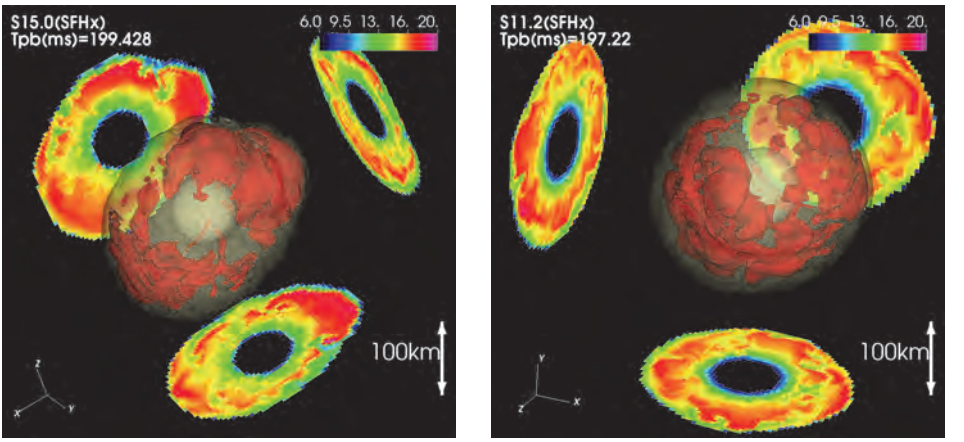

Fig. 1. Snapshots showing hydrodynamics features of represented models. Shown are the isentropic surfaces for $s = 7\ k_{\rm B}$ baryon$^{-1}$ (transparent shell) and for $s = 17\ k_{\rm B}$ baryon$^{-1}$ (red bubbles). The left and right panels are for S15.0(SFHx) and S11.2(SFHx), respectively. $T_{\rm pb}$ denotes the postbounce time. The contours on the cross sections in the $x = 0$, $y = 0$, and $z = 0$ planes are projected on the sidewalls. The left panel shows a typical (sloshing-)SASI structure, while the right one does many small scale convection bubbles.

To see how the SASI, that is more pronounced in S15.0(SFHx) than in S11.2(SFHx), makes a correlation between GW and neutrino signals, we show in Fig. 2 the GW amplitude $A_+$ [cm] and the neutrino event rate $N_\nu$ [ms$^{-1}$] in the top panel and their spectrum in the bottom. Here $N_\nu$ [ms$^{-1}$] is for Hyper-K (fiducial mass 440 kton[15]) and we show two extreme cases where the detector measures the original $\bar{\nu}_e$ (red line) or $\nu_x$ (green line) flux. The latter case corresponds to the complete flavor conversion through the Mikheyev-Smirnov-Wolfenstein (MSW) effect. In the bottom panel, the contours (red curves) correspond to the Fourier-decomposed anti-electron type neutrino event rates (two arbitrary chosen values of $dN_\nu/dF = 0.4$ (thin red line) and 0.8 (thick red line)). The left and right columns are for S15.0(SFHx) and S11.2(SFHx), respectively.

The bottom left panel (S15.0(SFHx)) shows a clear overlap between the neutrino modulation (see red contours in the spectrogram) and the GW modulation at $T_{\rm pb} \gtrsim$ 150 ms in the frequency range of $F \sim$ 100-150 Hz. Since the GW emission in the frequency range of $F \sim$ 100-150 Hz seen at $T_{\rm pb} \gtrsim 150$ ms is considered to be originated from strong SASI motion[5–7], the overlap naturally indicates that the SASI motion disturbs both the neutrino spheres and PNS core surface. The latter is the main emission region of the low frequency GWs[5,6]. On the other hand, in the smaller mass progenitor of S11.2(SFHx), we do not find any remarkable simultaneous oscillation of the neutrino and GW signals.

When the complete flavor conversion between $\bar{\nu}_e$ and $\nu_x$ is assumed (green line at $T_{\rm pb} \geq 150$ ms of model S15.0(SFHx) in Fig. 2), the time modulation is significantly suppressed as already reported in Ref. 3. This is because that the neutrino spheres of heavy-lepton neutrinos are located much deeper inside compared to those of anti-electron neutrinos. Consequently they are less affected by the SASI activity and the correlation between the GW and the neutrino event rate are expected to become weaker in the case of the complete flavor swap.

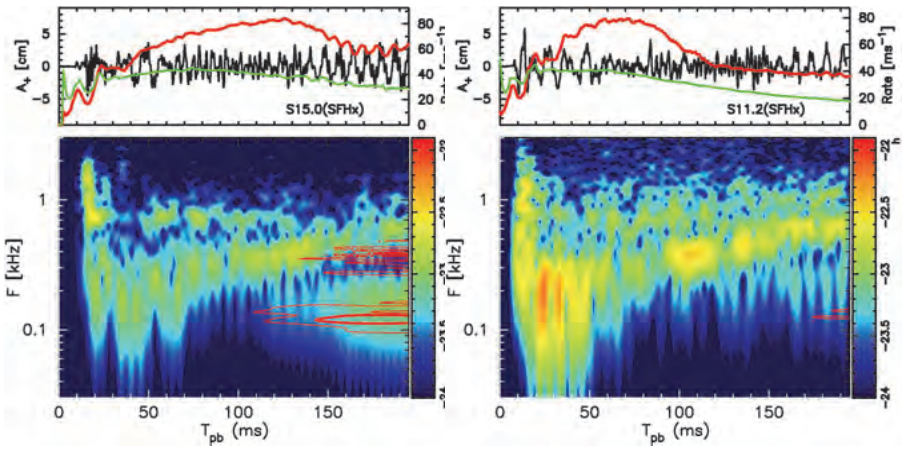

Fig. 2. For models S15.0(SFHx) (left) and S11.2(SFHx) (right), the top panel shows the neutrino event rate $N_\nu$ [ms$^{-1}$] (red and green lines are for $\bar{\nu}_e$ and $\nu_x$, respectively) for Hyper-K and the GW amplitude $A_+ = Dh_+$ [cm] (black line), whereas in the bottom panel we plot contours (red curves, only for $T_{\rm pb} \geq 100$ ms) of the anti-electron type neutrino spectra that are superimposed on the color-coded GW spectrum. Here $D$ and $h_+$ are the source distance of $D = 10$ kpc and the GW strain with plus mode, respectively. The observer's direction is fixed along the $z$-axis.

## 4. Summary and Discussion

We have presented results from our 3D-GR core-collapse simulations with approximate neutrino transport for two representative non-rotating progenitors (11.2 and 15 $M_\odot$). The SASI activity was seen for $15M_\odot$ star, while the entropy driven convection dominates over the SASI in $11.2M_\odot$ star. The combination of progenitor's higher compactness at bounce leads to the stronger SASI activity, that is consistent with previous studies, e.g., Ref. 16. Our 3D-GR models have confirmed previous predications that the SASI produces characteristic time modulations both in the neutrino and GW signals. Among the computed models, a 15.0 $M_\odot$ model exhibited more violent SASI motion, where the SASI-induced modulation in both GWs and neutrinos were clearly observed. The typical modulation frequency is in the range of ∼100-200 Hz, which is consistent with the oscillation period of the SASI motion.

Our results suggest that the correlation of the neutrino and GW signals, if detected, could provide a new signature of the vigorous SASI activity in the supernova core, which can be barely seen (like for the 11.2 $M_\odot$ model) if neutrino-convection dominates over the SASI.

In order to clarify whether we can or cannot detect the SASI-induced modulation in the GW and neutrino signals, we primarily need to perform a GW signal reconstruction study (e.g., Ref. 17). This is the most urgent task that we have to investigate as a sequel of this work. For a Galactic event, we apparently need third-generation detectors for observing the SASI-modulated GW signals[5–7], whereas the neutrino signals could be surely detected by IceCube and Super-K[3]. The neutrino burst can be used to determine the core bounce time, which raises significantly the detection efficiency of the GWs[18]. Our current study extends the horizon of previous prediction such as, when we would succeed the simultaneous detection of neutrino and GW signals from future nearby CCSN event, we could infer the supernova triggering dynamics (e.g., the SASI) from the following specific features (1) the low frequency ($F \sim 100$ Hz) modulation in both GW and neutrino signal and (2)[14] a few 10 ms time delay of the SASI-modulated GW signal from the SASI-modulated neutrino event rate.

## Acknowledgments

This research was supported by the European Research Council (ERC; FP7) under ERC Advanced Grant FISH-321263 (TK), ERC Starting Grant EUROPIUM-677912 (TK), JSPS KAKENHI Grant Number (JP15KK0173 (KK), JP17H05206, JP17K14306, JP15H00789, JP15H01039 (TK), and JP17H01130, JP17H06364 (KK and TT)), and JICFuS as a priority issue to be tackled by using the Post 'K' Computer. Numerical computations were carried out on Cray XC30 at CfCA, NAOJ.

The first-order electroweak phase transition in the early universe could occur in multiple steps leading to specific multi-peaked signatures in the primordial gravitational wave (GW) spectrum. We argue that these signatures are generic phenomena in multi-scalar extensions of the Standard Model. In a simple example of such an extension, we have studied the emergence of reoccurring and nested vacuum bubble configurations and their role in the formation of multiple peaks in the GW spectrum.

Despite of the great success of measurements at the Large Hadron Collider (LHC), the persistent absence of new physics evidence is driving an increasing discomfort among the particle physics community. The current void of new phenomena either indicates that new physics can only be manifest at a larger energy scale than previously thought, or results from a lack of sensitivity of the current experiments measuring rare events. In fact, the weaker the interaction strength between the SM and new physics, the greater the challenge to probe it.

On the other hand, the recent discovery of a binary neutron star merger, firstly observed by the gravitational waves (GW) interferometers of the LIGO-Virgo collaboration[1], a new era of multi-messenger astronomy has begun. Furthermore, the reach of GW observatories is by no means exhausted and larger sensitivities are designed for future space-based interferometers such as those of the LISA[2], DECIGO[3] and BBO[4] collaborations. This opens up the door for a plethora of new studies including connections with both cosmology and particle physics (see e.g. Refs. 5, 6 and references therein). In particular, the potential observation of a stochastic GW background produced by violent processes in the early universe, e.g. by expanding vacuum bubbles associated with strong cosmological phase transitions, may well become a gravitational probe for beyond-the-SM (BSM) physics and a complement for collider measurements. In this contribution, we discuss the key implications of such successive transitions for GW signals.

In cosmology, thermal evolution of the EW-breaking vacuum as the universe cools down is determined by the temperature-dependent part of the one-loop effective potential. Given the field content and its quantum numbers of an underlying multi-scalar fundamental theory, the shape of the potential can be determined at any temperature $T$. In a configuration of two minima of the effective potential coexisting at the critical temperature $T_c$, by using CosmoTransitions[7] one computes numerically the Euclidean action $\hat{S}_3$ describing transitions between the corresponding phases. The temperature $T_n$, at which the nucleation of vacuum bubbles effectively occurs, is estimated by setting the probability to nucleate one bubble per horizon volume to unity, which translates into $\hat{S}_3/T_n \sim 140$. The sphaleron suppression criterion $v_c/T_c \gtrsim 1$, with $v_c = v(T_c)$ the Higgs vacuum expectation value (VEV), defines a strong first-order phase transition. This typically implies that the transition produces strong GW signals detectable by the next generation of interferometers and may be used for constraining BSM scenarios. Here we study successive strong first-order EWPTs which we refer to as multi-step transitions. As a result one has more than a single transition pattern for a particular point in the parameter space, which results in sequential nucleation of bubbles of different vacua.

A generic BSM scenario typically contains a large number of scalar degrees of freedom which can be advantageous e.g. for EW baryogenesis. Even reducing the scalar sector to a few fields, new unexplored possibilities of transition patterns arise, in particular, transitions in several successive first-order steps. Therefore, a non-trivial EWPT is expected and multi-step transitions may have occurred in the early universe[5]. The basic characteristics of such multi-peak spectra may also be affected by dynamics of other sectors, in particular, by the neutrino sector suggesting the use of primordial GW data for probing the neutrino mass generation mechanisms[6].

In order to illustrate the generic features of multi-step first-order EW transitions, consider for instance a minimal extension of the SM scalar sector inspired by the high-scale Grand-unified trinification theory[8]. Besides the SM Higgs field $\mathcal{H}_1$, it contains an additional EW doublet $\mathcal{H}_2$ and singlet $\varphi$ fields which are charged under a U(1) family symmetry. The resulting potential possesses an approximate descrete $\mathbb{Z}_2$ symmetry acting as $\mathcal{H}_j \to -\mathcal{H}_j$ $(j = 1, 2)$ and $\varphi \to -\varphi$ which significantly simplifies the vacuum structure of the model. An expansion of the scalar fields in terms of real components

$$\mathcal{H}_j = \frac{1}{\sqrt{2}} \begin{pmatrix} \chi_j + i\chi'_j \\ \phi_j + h_j + i\eta_j \end{pmatrix}, \qquad \varphi = \frac{1}{\sqrt{2}} \left(\phi_s + S_R + iS_I\right), \tag{1}$$

defines the quantum fluctuations $h_1$, $h_2$ and $S_R$ about the classical configurations $\phi_\alpha = \{\phi_1, \phi_2, \phi_s\}$, respectively. With this expansion, the classical potential reads

$$V_{\rm cl}(\phi_\alpha) = \tfrac{1}{2} m_\alpha^2 |\phi_\alpha|^2 + \tfrac{1}{8}\lambda_\alpha |\phi_\alpha|^4 + \tfrac{1}{4}\lambda_{\alpha\beta} |\phi_\alpha|^2 |\phi_\beta|^2 . \tag{2}$$

A comprehensive analysis of the tree-level vacuum structure was performed recently in Ref. 8. It was shown that the basic characteristics of EWPTs in this model, in

particular, sequential first-order transitions, are generic for multi-Higgs extensions of the SM. Thus, this model, due to the simplicity of its potential (2), could serve as a good benchmark scenario for further in-depth explorations of cosmological implications of multi-scalar BSM theories.

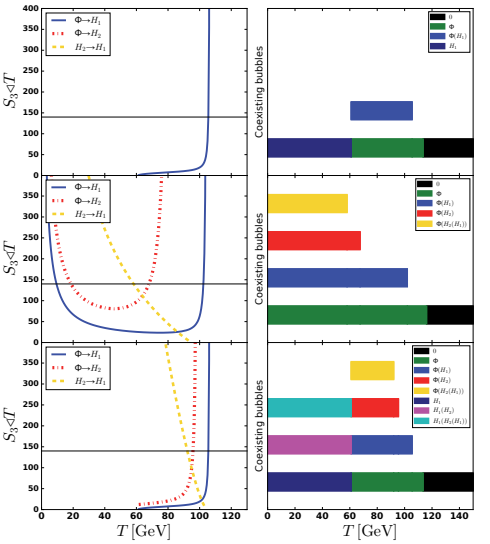

Fig. 2. Left column: evolution of $\hat{S}_3/T$ for all possible transitions. Right column: diagrams representing all types of bubbles (co)existing at a given temperature.

Since the scalar potential keeps evolving as the universe cools down below $T_n(H_2 \to H_1)$, the initial phase $\Phi$ becomes unstable also along the $H_1$ direction, so both transitions towards $H_1$ and $H_2$ can occur (coexisting bubbles scenario). In particular, if the potential barrier between the phases $\Phi$ and $H_1$ disappears, the new $H_1$-bubbles would nucleate in the parts of the universe that still remain in the $\Phi$-phase i.e. the direct $\Phi \to H_1$ transition quickly eliminates the $\Phi$-phase outside of the $H_2$-bubbles formed at an earlier time. Such a mixed situation with the coexistence of the ordinary $H_1$ and nested $H_2 \to H_1$ bubbles is depicted in Fig. 1 (middle panel). In the end of this process, one ends up with the $H_1$-bubbles inside the $H_2$-bubbles which exist in a universe filled with the $H_1$-phase. We denote these exotic cosmological objects as *reoccurring bubbles*. Since the $H_2$-bubbles cannot expand in a universe filled with the stable $H_1$-phase, they are pushed inwards and collapse while the $H_1$-bubbles nucleate inside them as illustrated in Fig. 1 (right panel).

In Fig. 2 we show three realistic cosmological scenarios where the objects discussed above are expected to occur. In the left column, we plot the evolution of the action $\hat{S}_3/T$ as a function of temperature for all possible transitions. Whenever a curve corresponding to a transition $i \to j$ crosses the horizontal line $\hat{S}_3/T = 140$, a bubble of phase $j$ is nucleated inside the phase $i$, which is denoted as $i(j)$ in what follows. In the right column, we show a diagrammatic representation displaying all types of bubbles (co)existing at a given temperature and corresponding to the plots in the left column. For example, the top panel describes a first-order phase transition $\Phi \to H_1$ when $H_1$-bubbles nucleate in a universe filled with the $\Phi$-phase (i.e. $\Phi(H_1)$). In particular, a universe in the symmetric phase [0] first collapses to

the Φ-phase through a second-order phase transition without generating any bubbles. Then, the $H_1$-bubbles are nucleated at $T \sim 105$ GeV and expand until the Φ-phase becomes unstable at around $T \sim 60$ GeV leaving a universe entirely filled by the true vacuum $H_1$.

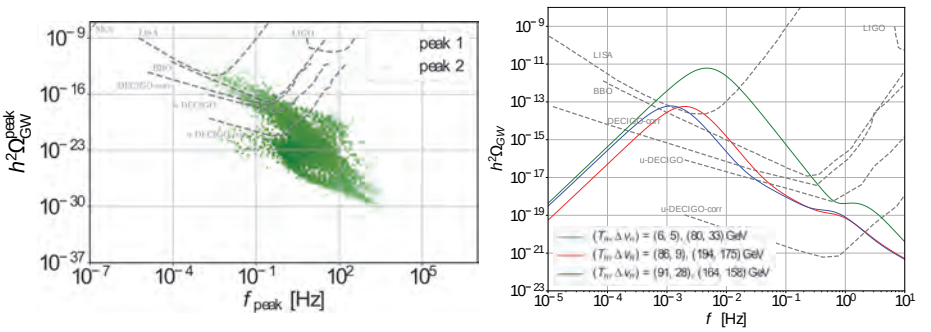

Fig. 3. **Left panel**: The results of the inclusive parameter scan in the considering 2HDSM where each point corresponds to a FOPT with the corresponding GW peak amplitude and frequency. Double-peak signatures are shown by red dots. **Right panel**: Benchmark double-peak GW spectra with the largest peaks entering the sensitivity domain of the LISA experiment with main characteristics specified in Table 1.

While the graphs on the second line of Fig. 2 represent a scenario where three successive steps lead to the nucleation of a nested bubbles $\Phi(H_2(H_1))$, those on the last line describe reoccurring bubbles that emerges from a nested ones. For instance, after nucleation of nested bubbles $\Phi(H_2(H_1))$, the potential barrier between the phases Φ and $H_1$ disappears (around $T \sim 60$ GeV), such that the parts of the universe in the Φ-phase collapse to the $H_1$-phase transforming the nested bubbles $\Phi(H_2(H_1))$ into the reoccurring ones $H_1(H_2(H_1))$. This type of cosmological objects is only possible if the nucleation temperatures of the corresponding steps are not too different (percolation typically occurs in the range of $\Delta T < 10$ GeV), and further likely to occur when symmetries in the potential enforces them to be identical.

We analyse the multi-peaked signatures in the power spectrum of GWs using the well known formalism of Ref. 9 which describes the energy density per logarithmic frequency of the GW radiation, $h^2\Omega_{\rm GW}$. The net GW signal is typically considered to be produced by three different sources due to bubble wall collisions, sound waves (SW) generated by the phase transitions, as well as magnetohydrodynamics (MHD) turbulences in the plasma. The bubble wall collisions typically do not contribute to the GWs production processes in the considering class of multi-scalar extensions of the SM (see also Ref. 5) so we account for the dominant SW and MHD contributions only.

The results of the inclusive parameter scan searching for FOPTs in the considering 2HDSM scenario are illustrated in Fig. 3 (left panel). Here, each point corresponds to a particular FOPT found in the scan, with calculated values of the

Table 1. Characteristics of selected benchmark double phase transitions whose GW signals emerge in the sensitivity domains of planned measurements and whose GW spectra are illustrated in Fig. 3 by green, red and blue lines, respectively. Here, the nucleation temperature, $T_n$, the scalar VEVs before $v_\alpha^i$ and after $v_\alpha^f$ the respective phase transition are given in units of GeV, while the peak-frequency, $f_{\rm peak}$, is given in Hz.

We show that gravitational wave radiative patterns from a point test particle falling radially into a Schwarzschild black hole, as derived by Davis, Ruffini, Press and Price[1], are present in the nonlinear regime of head-on mergers of black holes. We use the Bondi-Sachs characteristic formulation and express the gravitational wave luminosity and the radiated energy in terms of the *news* functions. Our treatment is made in the realm of Robinson-Trautman dynamics, with characteristic initial data corresponding to the head-on merger of two black holes. We consider mass ratios in the range $0.01 \leq \alpha \leq 1$. We obtain the exponential decay with $\ell$ of the total energy contributed by each multipole $\ell$. The total rescaled radiated energy $E_W^{\rm total}/m_0\alpha^2$ decreases linearly with decreasing $\alpha$, yielding for the point particle limit $\alpha \to 0$ the value $\simeq 0.0484$, about five times larger than the result of Davis et al.[1] We also analyze the mode decomposition of the net momentum flux and the associated impulse of the gravitational waves emitted, resulting in an adjacent-even-odd mode-mixing pattern with the dominant contribution coming from the mixed mode $(2, 3)$. We obtain the exponential decay with $\ell$ of the total gravitational wave impulse contributed by each $(\ell, \ell + 1)$ mixed mode.

*Keywords*: Black hole head-on mergers; Gravitational wave luminosity; Net momentum flux; Radiative patterns.

## 1. Introduction

The collision and merger of two black holes are among the astrophysical sources which produce gravitational waves in the strong field regime and are therefore of crucial interest for the present direct observations made by the LIGO/VIRGO consortium[2].

In the realm of general relativity the production and extraction of gravitational waves in processes involving black holes have been investigated basically within three complementary approaches, most of them connected to binary black hole inspirals: Post-Newtonian (PN) approximations[3], numerical relativity[4] and the close-limit-approximation (CLA) supplemented with PN calculations[5], as well as combinations of these approaches.

Our treatment[6] is based on the Bondi-Sachs (BS) energy-momentum conservation laws in the characteristic formulation[7], that regulate the gravitational wave radiative transfer processes of the system, in the realm of Robinson-Trautman (RT) spacetimes[8]. The characteristic initial data constructed for the RT dynamics already present a global apparent horizon so that the dynamics covers the post-merger phase of the system, which represents one of the most dynamic parts of the evolution, up to the final configuration of the remnant black hole[9].

The cornerstone of our approach is the dependence of the Bondi-Sachs net four-momentum wave flux[10] on the *news* functions – which are the basic quantities characterizing the gravitational wave degrees of freedom of the system and are, by definition, quantities of spin-weight[11] $s = -2$. This decomposition is exact in the nonlinear regime, leading to an accurate evaluation of the even parity signals and of their relative contribution to the physical quantities involved in the radiative processes of the system. All these features are discussed in the following sections.

Throughout the paper we use geometrical units $G = c = 1$.

## 2. Robinson-Trautman Spacetimes

Robinson-Trautman (RT) spacetimes[8] are asymptotically flat solutions of Einstein's vacuum equations that describe the exterior gravitational field of a bounded system radiating gravitational waves. The RT metric can expressed as

$$ds^2 = \left(\lambda(u,\theta,\phi) - \frac{2m_0}{r} - 2r\frac{P_{,u}}{P}\right)du^2 + 2dudr - \frac{r^2}{P^2(u,\theta,\phi)}d\Omega^2, \tag{1}$$

where $r$ is an affine parameter defined along the shearfree null geodesics determined by the vector field $\partial/\partial r$. Here $d\Omega^2 = d\theta^2 + \sin^2\theta d\phi^2$, where $\lambda(u,\theta,\phi)$ is the Gaussian curvature of the surfaces ($u$ =const, $r$ =const) defined by

$$\lambda(u,\theta,\phi) = P^2 + \frac{P^2}{\sin\theta}\left(\sin\theta\ \frac{P_{,\theta}}{P}\right)_{,\theta} + \frac{P^2}{\sin^2\theta}\left(\frac{P_{,\phi}}{P}\right)_{,\phi}. \tag{2}$$

$m_0$ is the only dimensional parameter of the spacetime and fixes the energy and length scales of the system. For the stationary case $m_0$ corresponds to the rest mass of the black hole with respect to an asymptotic Lorentz frame at the future null infinity. Einstein's equations yield

$$12m_0\ P_{,u} + P^3\left(\frac{(\lambda_{,\theta}\sin\theta)_{,\theta}}{\sin\theta} + \frac{\lambda_{,\phi\phi}}{\sin^2\theta}\right) = 0. \tag{3}$$

In the above, the subscripts $u$, $\theta$ and $\phi$ preceded by a comma denote derivatives with respect to $u$, $\theta$, $\phi$, respectively. Eq. (3), denoted RT equation, governs the dynamics of the gravitational field (which is totally contained in the metric function $P(u,\theta,\phi)$) and propagates the initial data $P(u_0,\theta,\phi)$ from a given initial characteristic surface $u = u_0$.

An important feature of RT spacetimes that establishes its radiative character arises from the expression of its curvature tensor that, in a suitable semi-null tetrad basis, assumes the form

$$R_{ABCD} = \frac{N_{ABCD}}{r} + \frac{III_{ABCD}}{r^2} + \frac{II_{ABCD}}{r^3}, \tag{4}$$

where the scalar quantities $N_{ABCD}$, $III_{ABCD}$ and $II_{ABCD}$ are of the algebraic type $N$, $III$ and $II$, respectively, in the Petrov classification of the curvature tensor[12].

Considering axial symmetry, the curvature tensor components in the above basis that contribute to $N_{ABCD}$ are $R_{0303} = -R_{0202} = -D(u,\theta)/r + \mathcal{O}(1/r^2)$ where

$$D(u,\theta,\phi) = -P^2\partial_u\left(\frac{c_{,u}}{P}\right), \quad \text{with} \quad c_{,u}(u,\theta) = \frac{1}{2}\left(\partial^2_{\theta\theta} - \cot\theta\partial_\theta\right)P(u,\theta). \tag{5}$$

The *news* function $c_{,u}$ is one of the fundamental objects in our analysis. Generally speaking, it informs the presence of gravitational waves being emitted from a given bounded source and observed at the wave zone (Petrov type $N$).

## 3. The Bondi-Sachs Conservation Laws: The Gravitational Wave Luminosity and the Net Gravitational Wave Impulse

From the supplementary vacuum Einstein equations in the BS integration scheme together with the outgoing radiation condition, the BS four-momentum conservation laws for axisymmetric RT spacetimes are given by [10]

$$\frac{dP^\mu(u)}{du} = -\frac{1}{4\pi}\int_0^{2\pi} d\phi \int_0^\pi \frac{1}{P}\, l^\mu (c_{,u})^2 \sin\theta \; d\theta, \tag{6}$$

where $P^\mu(u)$ is the BS four-momentum. In the above the four vector $l^\mu = (1,0,0,\cos\theta)$ defines the generators of the translations of the BMS group in the temporal and Cartesian $z$ axes of an asymptotic Lorentz frame at future null infinity [13]. The luminosity of the gravitational waves emitted is given by the right-hand side of (6).

The integration in $u$ of Eq. (6) results for $\mu = 0$ and $\mu = z$, respectively, in the total energy $E_W(u)$ and the net impulse $I^z_W(u)$ of the gravitational wave emission, given as

$$E_W(u) = \frac{1}{2}\int_{u_0}^u du \int_0^\pi \frac{(c_{,u})^2}{P}\sin\theta \; d\theta, \quad I^z_W(u) = \frac{1}{2}\int_{u_0}^u du \int_0^\pi \frac{(c_{,u})^2}{P}\cos\theta\sin\theta \; d\theta, \tag{7}$$

where $u_0$ is the initial time. Due to the axisymmetry, the components $I^x_W(u) = 0 = I^y_W(u)$ for all $u$.

## 4. Initial data and numerical evolution

The initial data to be used was derived in Aranha et al. [9] and that can be interpreted as representing two instantaneously Schwarzschild black holes in head-on merger along the $z$ axis, at $u = u_0$,

$$P(u_0,\theta) = \left(\frac{\alpha_1}{\sqrt{\cosh\gamma + \cos\theta\sinh\gamma}} + \frac{\alpha_2}{\sqrt{\cosh\gamma - \cos\theta\sinh\gamma}}\right)^{-2}. \tag{8}$$

In the derivation of (8) it turns out that $\alpha = \alpha_2/\alpha_1$ is the mass ratio of the Schwarzschild masses of the initial data, as seen by an asymptotic observer. In the remaining of the paper we will take $\alpha_1 = 1$ and denote $\alpha_2 = \alpha$, the mass ratio. This data already has a single apparent horizon so that the evolution covers the post-merger regime up to the final configuration, when the gravitational wave emission

ceases. For $\alpha$ sufficiently small the data may be considered as a perturbation of a Schwarzschild black hole in the RT dynamics.

The initial data (8) is evolved numerically via the RT equation (3), which is integrated using a Galerkin method with a Legendre polynomial projection basis space adapted to the axisymmetric RT dynamics. The implementation of the Galerkin method, as well as its accuracy and stability for long time runs, is described in details in Section V of Aranha et al.[14] Exhaustive numerical experiments show that after a sufficiently long time $u \sim u_f$ all the modal coefficients of the Galerkin expansion become constant up to 12 significant digits, corresponding to the final time of computation $u_f$. At $u_f$ the gravitational wave emission is considered to effectively cease and we obtain $P(u_f, \theta)$ that, in all cases, can be approximated as

$$P(u_f, \theta) = P_f(\cosh\gamma_f + \cos\theta \sinh\gamma_f). \tag{9}$$

This final configuration corresponds to a Schwarzschild black hole boosted along the $z$ axis, with a final boost parameter $\gamma_f$ and a final Bondi rest mass $m_0/P_f^3$. In all cases $\gamma_f < \gamma$ and $P_f < 1$.

## 5. The mode decomposition of the radiative content of the gravitational wave emission: Energy patterns

We are now led to examine the total energy $E_W^{\rm total}$ carried out of the system by the gravitational waves emitted, expressed as

$$E_W^{\rm total} = \sum_{\ell\geq 2} E_{W\ell} = \sum_{\ell\geq 2} \frac{1}{4\pi}\int_{u_0}^{u_f} N_{\ell 0}^2(u)du. \tag{10}$$

where

$$N_{\ell 0}(u) = 2\pi \int_0^\pi \left(\frac{c_{,u}(\theta,u)}{\sqrt{P}}\right) {}_{-2}\mathcal{Y}_{\ell 0}(\theta)\sin\theta\, d\theta. \tag{11}$$

Here, ${}_{-2}\mathcal{Y}_{\ell 0}(\theta)$ is the spin-weight spherical harmonics[11] with $s = -2$ for the axial case.

Differentiating Eq. (10) with respect to $u$ gives the mode decomposition of the luminosity, corresponding to the exact RT equivalent of the Moncrief-Zerilli formula[15] for the radiated luminosity of a particle falling radially into a Schwarzschild black hole. For the mass ratios examined in our numerical simulations, we obtain that the radiated energy per multipole $\ell$ decays exponentially with $\ell$, as illustrated in Fig. 1 (left) for three values of $\alpha$ where we display the log-linear plot the points $E_{W\ell}/m_0$ versus $\ell$ for $\ell = 2...6$. The best fit curve to these points corresponds to the simple exponential law

$$E_{W\ell}/m_0 = \mathcal{A}\, e^{-\mathcal{B}\ell}. \tag{12}$$

The normalized rms error between the best fit straight lines of the log-linear plots and the points is of the order of, or smaller than 0.25%. This behavior is maintained up to $\alpha = 0.7$; a complete survey is given in Aranha et al.[6]

Its is remarkable that the exponential pattern of the plots – first observed in the computation by Davis et al.[1] of the gravitational radiation from a point test particle falling radially into a Schwarzschild black hole – extends to the nonlinear regime of head-on mergers for mass ratios at least up to $\alpha = 0.7$. In this sense, for the mass ratios considered in Fig. 1 (left), the initial data (8) may be considered to actually correspond to a perturbed Schwarzschild black hole. A complete survey is given in Aranha et al.[6]

The total radiated energy $E_W^{\rm total}/m_0$, for several mass ratios up to $\alpha = 0.3$, exhibits a simple linear relation with $\alpha$,

$$E_W^{\rm total}/m_0\alpha^2 = 0.143275\ \alpha + 0.048462. \tag{13}$$

The values for $\alpha = 0.01$, not shown in Fig. 1 (left), correspond to $E_W^{\rm total}/(m_0\alpha^2) = 0.0500813$. The straight line is the best fit of the points with a normalized rms deviation $\simeq 0.35\%$. In the point particle limit ($\alpha \to 0$) we obtain $E_W^{\rm total}/m_0\alpha^2 = 0.048462$, about five times larger than the value $\sim 0.0104$ of Davis et al.[1]

## 6. The total impulse imparted to the system via emission of gravitational waves: The adjacent-even-odd mode mixing

In the same vein we now examine the net impulse applied to the system due to the emission of gravitational waves. Following the last section, it can be expressed by

$$I_W^z(u_f) \equiv \sum_{\ell\geq 2} I^z_{W(\ell,\ell+1)} = \sum_{\ell\geq 2} \frac{1}{2\pi}\sqrt{\frac{(\ell+3)\ (\ell-1)}{(2\ell+1)(2\ell+3)}}\int_{u_0}^{u_f} N_{\ell 0}(u)N_{\ell+1,0}(u)du \tag{14}$$

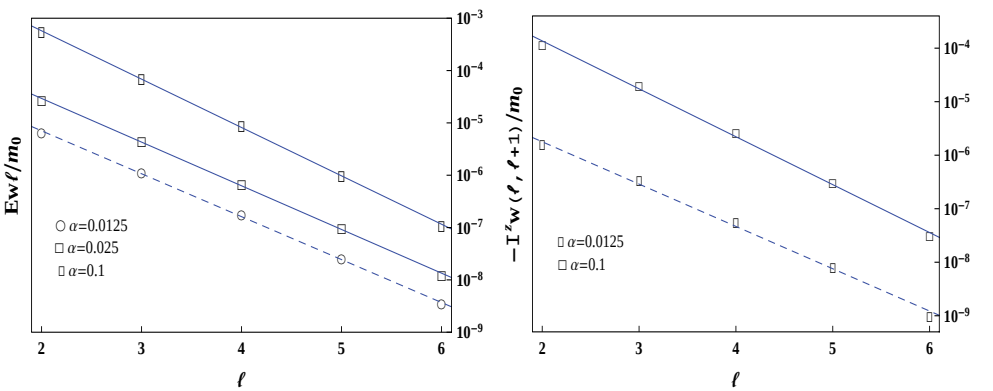

Fig. 1. *Left*: Plot of the points $E_{W\ell}/m_0$ versus $\ell$, for the several mass ratios $\alpha$ considered. This pattern – first observed by Davis et al.[1] in the gravitational radiation of a point test particle falling radially into a Schwarzschild black hole – is seen to be still maintained in the nonlinear regime of head-on merger of two black holes. *Right*: Log-linear plots of the mixed-mode impulses $-I^z_{W(\ell,\ell+1)}/m_0$ versus $\ell$, for the mass ratios $\alpha = 0.0125,\ 0.1$. The points are accurately fitted by straight lines, showing the exponential decay of the impulses with $\ell$.

that corresponds to the mode decomposition of the total net impulse into adjacent-even-odd mixed modes $I^z_{W(\ell,\ell+1)}$, which can be evaluated from the $N_{\ell 0}(u)$ given as in (11). We remark that the right-hand-side of (14) can be evaluated independently, so that we may obtain the impulse per mode $I^z_{W(\ell,\ell+1)}$ and the percentage of the contribution of each $(\ell, \ell+1)$ mixed-mode to the total net impulse imparted to the system. This can be seen in Fig. 1 (right).

This mode-mixing effect for the total momentum fluxes and the associated recoil velocities was first reported by Moncrief[15] for small odd-parity axisymmetric perturbations in the Oppenheimer-Snyder collapse models, and by Lousto and Price[16] for even-parity axisymmetric perturbations on a Schwarzschild black hole by a particle falling radially.

## Final Comments

The extension of this behavior for the whole mass ratio range $0 < \alpha \leq 1$ received a detailed examination in Ref. 6, both for the radiated energy per mode as well as for the mixed mode decomposition of the net momentum flux and impulse. In this reference we also examined the luminosity and the energy carried out by gravitational waves for increasing boost parameters $\gamma = [0.5, 0.6, 0.7, 0.8, 1.3]$. We obtain that the head-on mergers become more energetic as $\gamma$ increases, while the time duration of the GW bursts $\Delta u/m_0 \simeq 2$ remains approximately constant with increasing $\gamma$.

We focus on spacetime oscillations, the so-called $w$-modes, of gravitational waves emitted from a protoneutron star in the postbounce phase of core-collapse supernovae. By adopting numerical results from recent relativistic three-dimensional supernova models, we find that the $w_1$-mode frequency multiplied by the radius of the protoneutron star is expressed as a linear function with respect to the stellar compactness insensitively to the nuclear equation of state. Combining with another universal relation of the $f$-mode oscillations, it is shown that the time dependent mass-radius relation of the protoneutron star can be obtained by observing both the $f$- and $w_1$-mode gravitational waves simultaneously. That is, the simultaneous detection of the two modes could provide a new probe into finite-temperature nuclear equation of state that predominantly determines the protoneutron star evolution.

*Keywords*: Equation of state, protoneutron stars, gravitational waves.

## 1. Introduction

The gravitational waves from the mergers of binary black holes and a binary neutron star have been successfully detected[1,2], which leads to the beginning of a new age of the gravitational wave astronomy. In addition to the second-generation detecters, such as Advanced LIGO, Advanced VIRGO, and KAGRA, third-generation detecters like Einstein Telescope and Cosmic Explorer are already being proposed. Via observations with such detectors, one would obtain an imprint of open problems in compact objects. The most promising source for gravitational waves must be a merger of binary system of compact objects, while the core-collapse supernovae, which produce compact objects, could be a secondary candidate.

Up to now, in order to study the gravitational wave signals from core-collapse supernovae, extensive numerical simulations have been done. Through the results obtained by such simulations, it is considered that the $g$-mode oscillations excited around the protoneutron star surface are one of the most important gravitational wave emission in the postbounce phase[3–5]. In practice, the typical frequency of $g$-mode oscillations is expressed as $\sim M_{\rm PNS}/R_{\rm PNS}^2$ with the mass $M_{\rm PNS}$ and radius $R_{\rm PNS}$ of a protoneutron star. Thus, one may extract the information of protoneutron star properties by observing the $g$-mode gravitational waves from protoneutron stars.

On the other hand, as another approach, the gravitational-wave asteroseismology is a powerful technique for extracting interior information of compact objects. With such a technique one can constrain the equation of state (EOS), mass, and compactness of cold neutron stars (e.g., Refs. 6, 7, 8). With respect to the case of protoneutron stars, a few studies have been done[9–12]. In this study, by adopting

the results of numerical simulation of relativistic three-dimensional supernova models, we systematically examine the spacetime oscillations, the so-called $w$-modes, of gravitational waves from protoneutron stars. More details about this study can be seen in Ref. 10.

## 2. Protoneutron star models

To make a linear analysis, one has to prepare background protoneutron star models. In the present study, we adopt the numerical results of relativistic three-dimensional simulation[5] with the $15M_\odot$ progenitor models, adopting two different EOSs, i.e., SFHx and TM1. In particular, we consider very early phase up to $\sim$ 250 ms after core-bounce. In order to provide a static, spherically symmetric background model, the numerical data on each time step is averaged in the angular direction. Then, the protoneutron star's surface is determined at a fiducial rest-mass density of $10^{10}$ g/cm$^3$. In the left panel of Fig. 1, the evolution of protoneutron star models with two EOSs is shown in $M_{\rm PNS}$–$R_{\rm PNS}$ plane. With time after core-bounce, the mass increases due to the mass accretion, while the radius decreases due to the cooling. So, the mass and radius of protoneutron stars change with time from lower right to upper left in the left panel of Fig. 1. We remark that the sequence of mass and radius of protoneutron stars depends strongly on the adopted EOS.

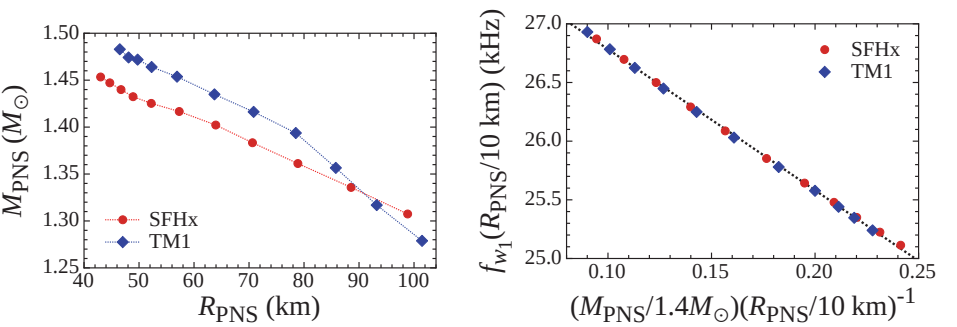

Fig. 1. Evolution of mass and radius of protoneutron stars in the left panel, and the $w_1$-mode multiplied by stellar radius as a function of stellar compactness in the right panel[10]. The circles and diamonds correspond to the results with SFHx and TM1 EOSs.

## 3. Asteroseismology in protoneutron stars

The perturbation equation derived from the linearized Einstein equations should be solved together with appropriate boundary conditions. First, we focus on the spacetime oscillations, the so-called $w$-modes, of gravitational waves from protoneutron star models. Since this mode is an oscillations of spacetime itself, the compactness, which is the ratio of $M_{\rm PNS}$ to $R_{\rm PNS}$, is an important parameter for describing

the frequencies[6]. In practice, we calculate the $w$-mode frequencies with the protoneutron star models at each time step and find that the evolution of frequencies depends on the adopted EOS. However, we also find that the frequencies multiplied with the radius can be expressed well as a linear function of the stellar compactness independently of the adopted EOS, as shown in the right panel of Fig. 1. In fact, we can derive the fitting formula of the $w_1$-mode frequencies as

$$f_{w_1}^{(\mathrm{PNS})}(\mathrm{kHz}) \approx \left[27.99 - 12.02 \left(\frac{M_{\mathrm{PNS}}}{1.4M_\odot}\right)\left(\frac{R_{\mathrm{PNS}}}{10\ \mathrm{km}}\right)^{-1}\right]\left(\frac{R_{\mathrm{PNS}}}{10\ \mathrm{km}}\right)^{-1}, \quad (1)$$

which is also plotted in the right panel of Fig. 1 with the dotted line.

On the other hand, we calculate the $f$-mode gravitational waves as in Ref. 9. Since the $f$-mode oscillations are a kind of acoustic oscillations, the frequencies can be characterized by the sound velocity or the stellar average density $M_{\mathrm{PNS}}/R_{\mathrm{PNS}}^3$[6]. In fact, we find that the time evolution of $f$-mode frequencies from protoneutron star depends on the adopted EOS, but the frequencies can be expressed as a linear function of the square root of the stellar average density independently of the adopted EOS as

$$f_f^{\mathrm{PNS}}(\mathrm{Hz}) \approx 14.48 + 4859 \left(\frac{M_{\mathrm{PNS}}}{1.4M_\odot}\right)^{1/2}\left(\frac{R_{\mathrm{PNS}}}{10\ \mathrm{km}}\right)^{-3/2}. \quad (2)$$

Now, we have two formulae for describing the $f$- and $w_1$-mode gravitational waves from protoneutron stars, which are independent of the adopted EOS for dense matter. So, by simultaneously observing the time evolution of two modes in the gravitational waves, one can obtain the time evolution of the stellar average density and compactness separately. That is, one can determine the mass and radius of protoneutron star at each time step after core-bounce as shown in the left panel of Fig. 1, which provides a new probe into the finite-temperature nuclear EOS.

## 4. Conclusion

The gravitational waves from supernovae are one of the most promising source. In the present analysis, we systematically examine the $w_1$- and $f$-mode gravitational waves after core-bounce, using the data of numerical simulations of relativistic three-dimensional supernova as a background model, and successfully derive universal formulae of $w_1$- and $f$-mode oscillations as a function of stellar compactness and average density independently of the adopted EOS. Thus, with the direct observations of gravitational waves from core-collapse supernovae, if one can identify the time evolution of $f$- and $w_1$-mode oscillations, one can in turn see the evolution of stellar average density and compactness, which tells us the evolution of mass and radius of a protoneutron star. As a result, one can in principle determine the finite-temperature nuclear EOS even through one event of gravitational waves from the core-collapse supernova.

The relation between the physics and the difference geometry had been discussed many years, we think gravitoelectromagnetism is a way of Linking gravitational potential to the curvature in the theory and the experiments. We discuss the relation between Lense-Thirring Precession and Gravitomagnetic clock. And we report the new result of gravitational mass defect though still can not find gravitomagnetic mass. In the last, we discuss gravitomagnetic experiments in binary pulsars and near earth spacetime.

*Keywords*: General relativity experiments; gravitational potential; curvature; Gravitoelectromagnetism; difference geometry.

## 1. The Introduction

As we known that gravitoelectromagnetism's (GEM) tool that include Fermi-Walker transported and Lorenz group in the proper reference frame[1] had successful applied in the Thomas precession of quantum physics[2]. Considered the complex of difference geometry between an observer and the reference frame[3] the relation between Post-Newtonian approximation and gravitoelectromagnetism[4], and gravitoelectromagnetic analogy based on tidal tensors[5] just been discussed recently.

In the experiments, there are only three which inlcude Lense-Thirring Precession from X-ray astrophysics, Gravity probe B from gyroscope, and LARES from laser ranging that provide the blurry evidence. Here we think gravitoelectromagnetism can linking gravitational potential to the curvature in the theory and the experiments. After introducing and reviewing gravitoelectromagnetism in Sec. 2, we discuss gravitomagnetic experiments in binary pulsars and near earth spacetime in Sec. 3, in especial, we give the experiment plan to check Kerr character of Terrae spacetime in Sec. 3.1 and the reason that gravitoelectromagnetism can linking gravitational potential to the curvature from the field theory in Sec. 3.2.

## 2. Gravitoelectromagnetism

After Einstein had general relativity[6], the relation between the physics and the difference geometry had been discussed many years. Even if Einstein had field equation from difference geometry, he also doubt wherher it can describe the more physics for he believed in the experiments and equivalence principles. Whatever, gereral relativity had strong impact on compact physics[7], and many researcher want to merge it into other forces of interaction[8].

Gravitoelectromagnetism, refers to a set of formal analogies between the equations for electromagnetism and relativistic gravitation; specifically: between Maxwell's field equations and an approximation, valid under certain conditions, to the Einstein field equations for general relativity. The analogy and equations differing only by some small factors were first published in 1893, before general relativity, by Oliver Heaviside as a separate theory expanding Newton's law. Gravitomagnetism is a widely used term referring specifically to the kinetic effects of gravity, in analogy to the magnetic effects of moving electric charge. The most common version of GEM is valid only far from isolated sources, and for slowly moving test particles[9]. And from the classical theory of fields[10], we known the field of gravity and electromagnetism in the model of the particle in the central body field both could be divide to the field with source plus the vortex field. Therefor, we think GEM could describe the weak field of spacetime.

### 2.1. *Lense-Thirring Precession, and Gravitomagnetic clock*

In 1687, Newton publish his book[11], which include the famous discusson of inertial forces on a fiuid contained in a rotating vessel. This discussion was critically reexamined by Mach[12] in an attempt to understand better how inertial forces arise. He suggested that the shape of the water-surface may depend on the rotation of the vessel "if the sides of the vessel increased in thickness and mass till they were ultimately several leagues thick". A calculation of such effects became possible afetr Einstein formulated his general theory of relativity[6]. Lense and Thirring proposes the precession on the vertical direction of the motion[13].Lense-Thirring (LT) Precession (i.e. Frame dragging) aways was find in the astrophysical context and in Physics as gravitomagnetism effect.

Mashoon give the gravitomagnetic clock effect for the circular orbits[14]. Recently, generalized gravitomagnetic clock effect was calculated for the GPS near the earth[15].

As the above mentioned, if gravitational potential can be divided into gravitoelectric potential and gravitomagnetic potential by GEM field, When the potential difference of gravitoelectric potential is proportional to the gravitational frequency shift, gravitomagnetic potential also can naturally be reflected in time measurement by some form. If the precision of clock is enough to measure gravitomagnetic potential, that means we had the chance to explore gravitomagnetic clock effect.

### 2.2. *Gravitomagnetic mass and Gravitational mass defect*

In math-physics, after the work from Minkowski, Levi-Civita, Synge, Bondi, Pirani, Hawking, and Wald et al., general differential geometry becomes the mathematical foundations of relativity. Komar mass[16] and ADM mass[17] become the basis concept of general relativity, the early study show gravitomagnetic mass could be exist in the theory[18].

Here we report we think gravitational mass defect can be find in PSR B1913+16[19] though still can not find gravitomagnetic mass now.

## 3. Gravitomagnetic experiments in binary pulsars and near earth spacetime

In classical mechanics, the LaplaceRungeLenz vector (i.e. LRL vector) is a vector used chiefly to describe the shape and orientation of the orbit of one astronomical body around another, such as a planet revolving around a stellar. For two bodies interacting by Newtonian gravity, the LRL vector is a constant of motion, meaning that it is the same no matter where it is calculated on the orbit; equivalently, the LRL vector is said to be conserved. More generally, the LRL vector is conserved in all problems in which two bodies interact by a central force that varies as the inverse square of the distance between them; such problems are called Kepler problems.Therefor, the light bending and perihelion precession can have a unified approach which described by the LRL vector[20] as the evolution under the perturbed potentials for the conservation of the LRL vector origin from the inverse-square central force. For it, the model of two spin particle and the LRL vector[21] is well in most of binary pulsar for almost of it is the classical Kepler problems in the frame of classical Newtonian gravity.

For two neutron star system that is two compact sources system. In a *Gedanken-experiment*, to the extreme elliptic binary MSP system, we can have a hypothesis that the space-time of the orbit is flat in the apoapsis, BUT there is a new Curved space-time when two compact stars is in the periapsis for the masses of binary and the distance is very close. The Birth and death of this Curved space-time have related with Gravitational radiation. In this state, we can think it is the new Schwarzschild spacetime or Kerr spacetime in the periapsis. Therefore, LRL vector is not conservation and symmetry for it is not the inverse-square central force now. And the angular momentum vector of two stars is not conservation and symmetry for gravitional wave will bring the part of it. Therefor, we have the chance to mersure orbital symmetry violations in LT Precession of binary pulsar although it predicted by the particle in one body system[22,23]. and have the Angular Momentum of the Curved space-time in the periapsis by gravitomagnetic measurement[24]. Compared with Dr Wex, we think the frame of the particle in one body system is well in the periapsis. Whatever, $P_b$ and $\dot{P}_b$ are the directly measurement parameters to LT Precession of binary pulsar. But we still less the reasonable frame to estimate LT Precession and gravitomagnetic clock in the same time to pulsar - a natural clock and gyroscope.

Recently, the influence of the Coriolis Force in atom interferometry was find[25] in the earth spacetime, in fact, it was detect by torsion balance in 1919[26], and aways been study by geophysical and inertial navigation. In the frame of GEM, Semerk provide the way of spacetime dividing by five term[27,28] which include Coriolis term (one early reference that mentioned the apparent Coriolis force (Lense-Thirring

effect) and "induced Coriolis force", or "Lense-Thirring effect" by Pugh[29]). Here we think the Coriolis force can be seen the Coriolis term of spacetime in the order of gravitational potential for GEM field should extend to the Schwarzschild spacetime naturally. Then many relativistic phenomena are predicted and many Newtonian physics phenomenon are refresh in the viewpoint of spacetime geometry[19].

### 3.1. *Near earth spacetime as Kerr Spacetime*

Another interesting probelem is whether we can make a distinction between Schwarzschild and Kerr spacetime in the Terrae spacetime. To Kerr spacetime[30], it is the statinary spacetime which different with Schwarzschild spacetime that had the Static Observer[31]. In the procession of study the analogy between general relativity and electromagnetism for slowly moving particles in weak gravitational fields, some researcher think time variable term take place is the boundary of gravitoelectromagnetism application[9], here we think time variable term means that non-Static Observer take place which from Kerr spacetime. As the lunar tidal have impact on the free fall objects[2], and from Coriolis effect[25] and tidal effect was measured by the clock and the different type gyroscope (Optical, mechanical, vibration etc.), we think use two (or more) Full (or partly) Tensor Gradiometry (FTG) to interference in the large distance of the earth, if we can measure the time variable of the clock rate, that is enough to show that Kerr spacetime is existence for NO static observer in that scale spacetime. And the FTG Interferometer (Array) will help us in understand the large scale structure of spacetime, the partly tensor gradiometry only can find the time variable term. About the interferometric method of full tensor gravitational gradiometer array in measurement of gravitational theory and cosmology, we are applying the patent in China and in PCT[32].

### 3.2. *From the curvature to potential in the Gravitoelectromagnetism*

For the complex of definition about momentum (potential) of gravitational field, the local spread about the momentum of gravitational field, the momentum of gravitational wave, and the boundary between the local and non-local, all is the frontier of math-physics and theoretical physics. About gravitational wave, the objects just is in the state of fast than $C^{-5}$ which can provide Non-Local spread in the field theory[10]. Consider gravitational wave was find, we can think the $C^{-5}$ is the boundary between the local momentum interacting of gravitational field and non-local gravitational wave momentum spread. Consiered gravitomagnetic concept (potential and mass) cross the weak field and the drastic changes of the curvature, we think gravitoelectromagnetism as a way of linking gravitational potential to the curvature in the theory and the experiments is reasonable.

## 4. The Summary

We discuss gravitomagnetic experiments in binary pulsars and near earth spacetime, in particular, we give the experiment plan to check Kerr character of the earth spacetime and the reason that gravitoelectromagnetism can linking gravitational potential to the curvature after reviewed the theory of gravitoelectromagnetism.

# Developing tools for multimessenger gravitational wave astronomy

Maria C. Babiuc Hamilton*

*Department of Physics, Marshall University, Huntington, WV 25755, US*
**E-mail: babiuc@marshall.edu*

The Marcel Grossmann triennial meetings are focused on reviewing developments in gravitation and general relativity, aimed at understanding and testing Einstein's theory of gravitation. The $15^{th}$ meeting (Rome, 2018) celebrated the $50^{th}$ anniversary of the first neutron star discovery (1967), and the birth of relativistic astrophysics. Another discovery of the same caliber is the detection of the binary neutron star GW170817 in 2017 – almost as if to celebrate the same jubilee – marking the beginning of multi-messenger gravitational wave astronomy. We present work in progress to craft open-sourced numerical tools that will enable the calculation of electromagnetic counterparts to gravitational waveforms: the `GiRaFFE` (General Relativistic Force-Free Electrodynamics) code. `GiRaFFE` numerically solves the general relativistic magnetohydrodynamics system of equations in the force-free limit, to model the magnetospheres surrounding compact binaries, in order (1) to characterize the nonlinear interaction between the source and its surrounding magnetosphere, and (2) to evaluate the electromagnetic counterparts of gravitational waves, including the production of collimated jets. We apply this code to various configurations of spinning black holes immersed in an external magnetic field, in order both to test our implementation and to explore the effects of (1) strong gravitational field, (2) high spins, and (3) tilt between the magnetic field lines and black hole spin, all on the amplification and collimation of Poynting jets. We will extend our work to collisions of black holes immersed in external magnetic field, which are prime candidates for coincident detection in both gravitational and electromagnetic spectra.

*Keywords*: Numerical relativity; black holes; gravitational waves, magnetosphere, jets.

## 1. Introduction

The 2017 detection of both gravitational waves (Ref. 1) and electromagnetic radiation (Ref. 2) from two colliding neutron stars is a very important event, akin to the discovery of neutron stars in 1967 by J. Bell and A. Hewish. This event – the rightfully-named Golden Binary – started the gold rush of multi-messenger gravitational wave astronomy. Observations from neutron star mergers provide deep insights into the highly-nonlinear interaction between strong gravity and the surrounding magnetosphere, which could explain the mechanism behind the emission of short gamma ray bursts and relativistic jets. Sources of strongly collimated astrophysical jets come at all scales, from pulsars to quasars, but they have in common one fact: they are compact objects rotating within their magnetospheres. Spinning neutron stars have a dipolar magnetic field and emit electromagnetic radiation due to the tilt between the spin axis and the magnetic field lines. Black holes don't have magnetic poles, and therefore their magnetic fields are external, being generated by the accretion disc. Although black holes tend to align their spin with the angular momentum of the accretion disc, the spin and orientation of the accretion disks usually change as the holes grow through mergers and gas accretion.[3]

Initially, merging supermassive black holes don't rotate in the same direction, and misalignment between the accretion disc and the black hole spin is expected.

Recent magnetohydrodynamic simulations show that for short timescales, jets are only partially aligned with the black hole spin.[4] The influence of the tilt between the black hole spin and the rotation axis of the accretion disc, and therefore the role the orientation of the magnetic field plays in the formation and quenching of jets, is not yet fully understood.[5] Another process that is not completely understood is what is under the hood of the main engine that powers the jet. Are high black hole spins essential in triggering jet production, or is the most important role played by the dynamics of the accretion disc?[6] Theoretical models show that relativistic jets can be generated from the rotational energy of a rapidly spinning black hole in strong magnetic fields through the Blandford-Znajek (BZ) mechanism.[7] The vacuum around a rotating black hole is electromagnetically active, and gives rise to strong electric fields when the black hole is surrounded by a magnetic field. Those gravito-rotationally induced electric fields cause a toroidal magnetic field, which plays an important role in collimating astrophysical jets. Astronomical observations report that the transition from radio-quiet to radio-loud quasars occurs for black hole spins around 0.7 to 0.9 times the speed of light.[8] If black hole spin is at the root of this transition, one should see a sharp delimitation in the value of the black hole spins necessary for the onset and quenching of the jet.[9] Another problem arises when two merging black holes, embedded in an external magnetic field, spiral towards each other. The gravitational waves produced in this astrophysical scenario are expected to exert a direct effect on the magnetic fields. This coupling between the magnetic field and the surrounding dynamical spacetime induces electromagnetic waves, coincidental with the production of gravitational waves, which provides a detection avenue for multimessenger gravitational wave astronomy.[10]

We engage in numerical explorations to study the interplay between black holes and the surrounding magnetosphere, in order to understand how spinning black holes drag the space-time around them, causing the collimation and amplification of jets. This is a problem not yet completely elucidated, although great strides have been made towards it's resolution.[11,12] We use the recently-released open-source `GiRaFFE` code (Ref. 13) to perform numerical simulation of single Kerr black holes evolving in external magnetosphere and to look at the effect of black hole spin on the output of electromagnetic luminosity in order to discern if there is a threshold spin for the production or extinction of collimated jets. Next we study the effect of tilted magnetospheres around a black hole with a fixed spin of 0.8 times the speed of light, in order to discern if the tilt angle plays any role in the amplification or reduction of the jet power.

## 2. Methods

*Theoretical Approach*: In order to explore the coupling between highly energetic gravitational and electromagnetic fields we use the General Relativistic Force-Free

Electrodynamics (`GRFFE` ) ansatz. `GRFFE` is a limiting case of General Relativistic MagnetoHydroDynamics (GRMHD), consisting on ideal plasma coupled to strong electromagnetic and gravitational fields, when the magnetic field energy dominates and the fluid pressure can be ignored. This theoretical model combines the assumption of perfect electric conductivity of the plasma with the fact that the Lorentz force in the comoving frame is immediately neutralized by induced electric currents, and it is commonly implemented in numerical codes to analyze the magnetized environment around pulsars or accreting black holes.[14] This `GRFFE` approach is implemented in our open-source `GiRaFFE` code (Ref. 15) designed to model the magnetosphere of highly-relativistic objects, such as neutron stars and black holes. The spacetime is evolved with the Einstein field equations, while the dynamics of the magnetized fluid are modeled using the conservation law $\Delta_\nu T^{\nu\mu}_{EM} = 0$ for the energy-momentum tensor $T^{\nu\mu}_{EM}$, and the Maxwell's equations $\Delta^*_\nu F^{\nu\mu} = 0$ for the electromagnetic tensor $F^{\nu\mu}$ in the force-free limit, $F^{\nu\mu} J_\nu = 0$. The updated variables are the magnetic field $B^i$ and the Poynting vector $S_i = -\gamma_{i\nu} n_\mu T^{\nu\mu}_{EM}$.[15] Here, $J_\nu$ is the 4-current, $\gamma_{i\nu}$ is spatial three-metric, and $n_\mu$ the timeline unit vector.

*Numerical Techniques*: The code evolves the vector potential $A_\mu = (\Phi, A_i)$ and Poynting vector $S_i$ one-forms, supplemented with an electromagnetic gauge evolution equation on a staggered grid, in order to keep the magnetic field divergenceless.[15] The evolution variables are linearly extrapolated to the outer boundary domain, which is causally disconnected from the interior by Adaptive Mesh Refinement (AMR). In order to prevent the force-free condition from breaking down during the evolution due to accumulation of numerical error, two supplementary conditions are imposed on $S_i$ during evolution to limit the direction and magnitude of the electric field so that it stays perpendicular to and smaller than the magnetic field: $E_i B^i = 0$ and $B^2 > E^2$. However, this condition does not account for the current sheet (CS), which inherently forms in magnetized plasmas and it's a critical component of the magnetospheres of rapidly spinning black holes.[11] We introduce a thin CS spatially localized at the equator by setting to zero the velocity perpendicular to the $z = 0$ plane.

*Initial Specifications*: We start with the magnetospheric Wald ansatz $A_t = 0, A_i = \frac{B_0}{2}(g_{i\theta} + 2a g_{it})$ in terms of the Kerr metric in spherical coordinates.[16] This vector potential creates a purely azimuthal magnetic field in Boyer-Lindquists coordinates, but in the horizon-penetrating Kerr-Schild coordinates there is an extra toroidal component $B_\phi$, due to the rotation of the geometry. The CS develops in the equatorial plane, forcing the anchored magnetic field lines to rotate with the black hole. There is no known exact solution for this magnetosphere, which is known as the "ultimate Rosetta Stone" for its close connection to the BZ process.[11,12]

The second initial configuration is a uniform azimuthal magnetic field created by a toroidal vector potential $A_\phi = \frac{B_0}{2} r^2 \sin^2\theta$, which in cartesian coordinates becomes $A_i = \frac{B_0}{2}(y, -x, 0)$ and produces a vertical magnetic field of magnitude $B_0$. With the CS in the equatorial plane, we tilt the magnetic field off the $z$-axis with an angle $\chi$ by a rotation $A_i \to \frac{B_0}{2}(y, -x\cos\chi, x\sin\chi)$ around the $x$-axis.

## 3. Results

The metric is described by the Kerr geometry in cartesian Kerr-Schild coordinates, radially shifted with $r_0 = \sqrt{1-a^2}$ such that $r \to 1 + r_0$, and the black hole inner horizon is at $r_- = 1$. We vary the spin from $a = 0.5c$ to $a = 0.95c$ and run a suite of 15 tests, with the constant $B_0 = 0.1M$ for the magnetic field. The numerical grid consists of $n = 5$ levels of refinement, with resolution scaling as $\Delta x_0/2^{n-1}$ where $\Delta x_0 = 2M$, and extends to $[-50M, +50M]^2$ in the $(x, y)$ plane and to $[-100M, 100M]$ in the $z$ direction. We visualize the EM luminosity: $L_{EM} = \int r^2 S d\Omega$, given by the Poynting flux across a sphere: $S = n^i \epsilon_{ijk} \sqrt{\gamma} E^j B^k$, $n^i = \frac{x^i}{r}$. In all the figures dark colors are low luminosity, bright colors are high luminosity.

*Magnetospheric Wald*: In Fig. 1 we show the time evolution of this testcase for $a = 0.95c$, at $r = 20M$. We distinguish two transient domains, between $t = \{0, 50\}M$ and $t = \{150, 200\}M$, when the electromagnetic field changes, and two stable phases: for $t = \{50, 150\}M$ with a collimated ring-like jet structure at the poles, and the second starting at $t = 200M$ when the jet broadens and precesses.

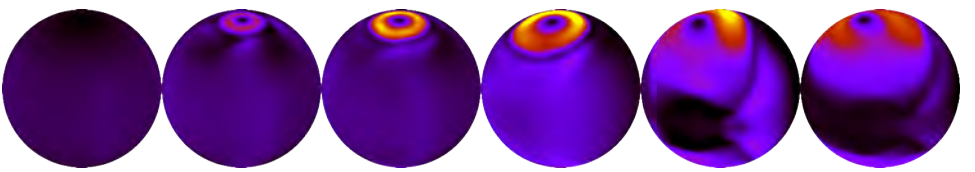

Fig. 1. Poynting luminosity of Wald magnetosphere with equatorial CS for Kerr black hole of spin $a = 0.95c$ and radius $r = 20M$. From left to right the time is $t = \{20, 60, 100, 140, 180, 200\}M$.

In Fig. 2 we plot the Poynting flux at $r = 20M$ and $t = 100M$ corresponding to the maximum amplitude and collimation of the jet. The intensity of the EM luminosity depends on the spin, as expected for the BZ process, however we discern the poloidal jet even at low spins, with no sign of spin threshold for jet production.

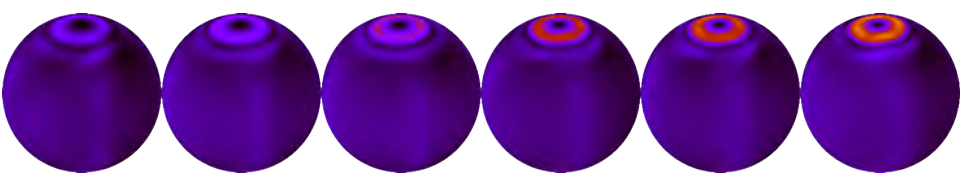

Fig. 2. Poynting luminosity of Wald magnetosphere with equatorial CS for Kerr black hole at $t = 100M$ and $r = 20M$. From left to right the spins are: $a = \{0.5, 0.6, 0.7, 0.8, 0.85, 0.9\}c$.

In Fig. 3 we plot the Poynting luminosity for a Kerr hole with spin $a = 0.95c$ for increasing radii $r = \{10, 20, 30, 40\}M$ at the time corresponding to the maximum

amplitude and collimation of the jet. We see that the power of the jet scale is inversely proportional to the radius, while the collimation is directly proportional.

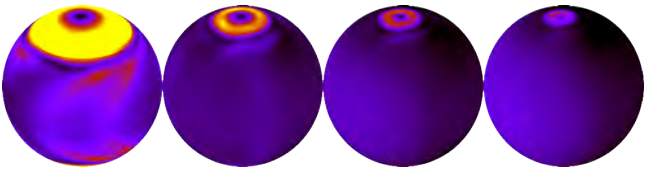

Fig. 3. Poynting luminosity of Wald magnetosphere with equatorial CS for Kerr black hole for $a = 0.95c$. From left to right $\{r, t\} = \{10M, 90M\}, \{20M, 100M\}, \{30M, 110M\}, \{40M, 120M\}$.

*Uniform Magnetosphere*: Fig. 4 shows that the time evolution of the luminosity for an initially vertical magnetosphere around a Kerr black hole is similar to the Wald magnetosphere. We compare the luminosity for four tilt angles at $t = 100M$ in Fig. 5 and at $t = 300M$ in Fig. 6, and we see that it increases with the tilt angle.

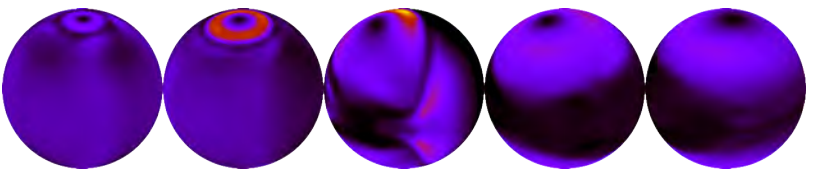

Fig. 4. Poynting luminosity of vertical magnetosphere with equatorial CS for Kerr black hole with $a = 0.8c$ and $r = 20M$. From left to right the time is $t = \{60, 120, 180, 240, 300\}M$.

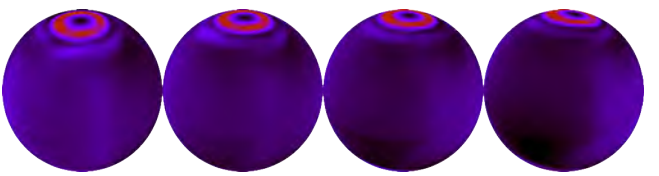

Fig. 5. Poynting luminosity of tilted magnetosphere with equatorial CS for Kerr black hole with $a = 0.8c$, $r = 20M$ and $t = 100M$. From left to right the angle is $\chi = \{0°, 15°, 30°, 45°\}$.

## 4. Discussion

We find that the geometry brings the black hole magnetosphere to a stability domain with a poloidal, precessing jet. We see two stable phases: early on, the jet forms a collimated, ring-like structure at the poles, while at late times, the jet broadens and precesses. Both the spin and the tilt angle affect the amplitude but not the shape of

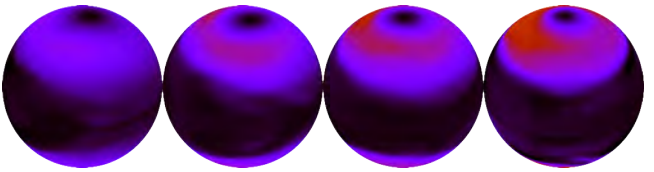

Fig. 6. Poynting luminosity of tilted magnetosphere with equatorial CS for Kerr black hole with $a = 0.8c$, $r = 20M$ and $t = 300M$. From left to right the angle is $\chi = \{0°, 15°, 30°, 45°\}$.

the jet, with no indication of high spin threshold for jet formation. Visualizations are available at `https://github.com/mbabiuc/KerrMagnetosphere`.

DECIGO (DECi-hertz Interferometer Gravitational wave Observatory) is a planned space mission targeting the detection of gravitational waves from very beginning of the universe, which no one has ever seen. As DECIGO utilizes freely flying Fabry-Perot cavities in orbit, a feasibility study of complex of its control systems including laser interferometer, which is tightly connected to drag-free control system together with formation-flying system, is a critical issue to realize DECIGO. As a first step to realize drag-free control required for DECIGO, we started from two experiments: the first one is a demonstration of position control using a thrust system, and the other is the development of a thrust stand to characterize the thrusters with $\mu$N-level force noise. In this paper, our progress and prospects for the next of these experiments are summarized.

*Keywords*: Gravitational wave; DECIGO; Drag-free control; Formation flying.

## 1. Introduction

The idea of DECIGO [1] is to build a laser interferometer having Fabry-Perot (FP) cavities in its arms with baseline of 1000 km, forming a triangular shape like LISA [2] in orbit. As test masses (TM), which work as mirrors for FP cavities also, probe for gravitational waves in spacetime, they are housed in spacecraft (S/C) and should be kept freely floating inside S/C using drag-free control. In addition to the control of three FP cavities, a drag-free control system tightly connected to formation-flying control to keep the three S/Cs in a triangular shape is essential to establish the control complex required for DECIGO. Using the FP cavity, instead of an optical transponder, for a laser link between S/Cs is a significant and also essential difference between DECIGO and LISA. To make these techniques feasible, sequential development of basic technologies are indispensable.

## 2. Demonstration of position control using thrust system

Drag-free control is a control system that S/C follow freely floating TMs inside S/C. The separation and the relative attitude between TMs and S/C are measured by local sensors, then by feeding these error signals back to the thrusters the S/C will ideally follow the TMs. Actually, as each S/C holds a couple of TM, common displacements and angle deviation of TMs relative to S/C are involved in drag-free control. On the other hand, error signals for differential degrees of freedom are fed back to the local actuators to provide forces on the TMs to maintain relative position and attitude between the TMs and the S/C. Therefore, the bandwidth of drag-free control should be below 10 Hz, in order not to degrade the signals in the observation band of the laser interferometer.

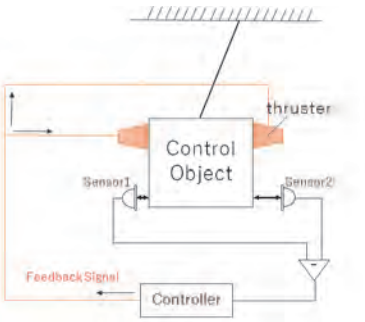

Fig. 1. The schematic diagram of position control experiment using thrust system.

The first step to demonstrate these complex systems is an experiment of position control using thruster-like propulsion as actuators, because one of most significant difference between terrestrial detectors and space missions is that S/C is to use thrusters as actuators instead of traditional electro-magnetic actuators. The object to be position-controlled, which is supposed to be a S/C thruster on board, is suspended with a single pendulum with one degrees of freedom for translation (Fig. 1). The position of the object is sensed using a photo sensor fixed on the optical table to give a differential displacement between the optical table and the object. We used a FPGA-based computer, cRIO (National Instruments), to provide digital filtering as a controller. A simple lag-lead filter was implemented on FPGA using LabVIEW software to stabilize the feedback control loop. We have composed a thruster-like propulsion system using a small $CO_2$ gas cartridge together with regulators and flow controller using piezo valves. Therefore, the error signals from the photo sensors were fed back to the input of piezo-controlled flow controller through the FPGA controller. The photo sensor and cRIO was located on the table top, so the signals from FPGA to the piezo valves were sent via a pair of very thin wires.

The behavior of error and feedback signals in the time domain is plotted in Fig. 2, which shows that the eigen mode of the pendulum at about 0.7Hz was certainly suppressed by engaging the control loop. The corresponding transfer function of the control loop is plotted in Fig. 2. The signals around this peak structure had been effectively fed back and suppressed as it was expected form time domain signals in Fig. 2. One of the next steps is to characterize and improve the current system to performance as well as DECIGO requires. The second is to extend the system to a demonstration of drag-free control for all degrees of freedom.

## 3. Development of thrust stand to measure $\mu$N-level force noise

The TMs are to be housed and freely floating inside S/C in an ideal situation. But in reality, TMs could be affected by external accelerations caused by many sources, including gravity, electro-magnetic interaction, cosmic rays, and so on. Especially,

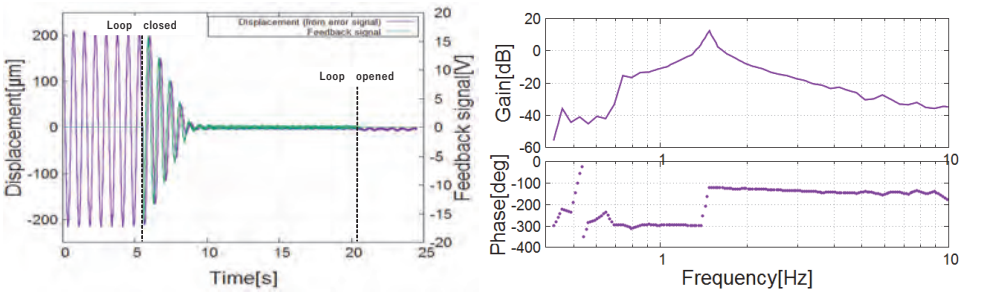

Fig. 2. The behavior of the error and the feedback signals in time domain (left) and the open-loop transfer function of control loop (right).

the displacement of S/C itself, which can act as a source of external acceleration on the TM through some coupling between TM and S/C, is thought to be one of most significant force noise sources. The force noise of the thrusters is an inevitable source for the displacement on S/C. Thus, in this sense, low force noise is an indispensable characteristic required for DECIGO. So far, the requirement for the force noise of the thruster is set to be $10^{-7}\mathrm{N}/\sqrt{\mathrm{Hz}}$ at 0.1 Hz, assuming some coupling between S/C displacements and external acceleration on the TM.

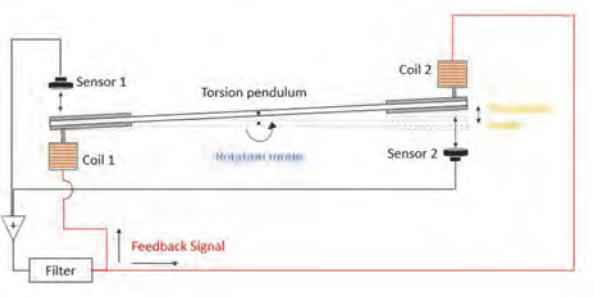

Fig. 3. The schematic diagram of the setup for the thrust stand system experiment.

We have started to develop a so-called thruster stand to measure the force noise spectrum of the thruster system. In order to extend measurement band width below 0.1 Hz, it is well-known, and also a beneficial idea to use a torsion pendulum for lowering resonant frequency, instead of single pendulum (Fig. 3). The measurement method of tiny force is based on a mechanism of a servo-type accelerometer, in which the error signals of position-controlled TM gives information on the external acceleration. Current thruster stands have no thrust systems on board, so the main objective of this setup is to evaluate the system noise of the measurement systems (Phase-1). The rotation of the torsion pendulum was sensed with a couple of photo

sensors located at opposite sides of the each end of the torsion bar. Adding these signals from photosensors can eliminate the common displacement signals from the translation mode of the pendulum, and thus gives an error signal for rotation degrees of freedom. This error signal was fed back to the coil-magnet actuator to maintain the rotation angle of the torsion bar.

The measured system noise of the thruster stand is plotted in Fig. 4 together with identified noise sources. The floor noise level below several Hz is already below our requirement except at around pendulum resonant frequency. We have also tried to modify our current system to have a thruster-like propulsion system on board (Phase-2). The concept of the measurement system is the same but the weight of the stand was increased to 2.4 kg due to the thrusters and a Michelson type laser interferometer was used as a displacement sensor instead of photo sensor. The floor noise level and the noise structure in the frequency range of our interest was changed according mainly to the change in the mechanical structure, as is shown in Fig. 4. The force measurement system using a torsion pendulum seems to work below our requirement noise level in terms of system noise. Thus, the next step is to actually measure the propulsion noise of the thrusters.

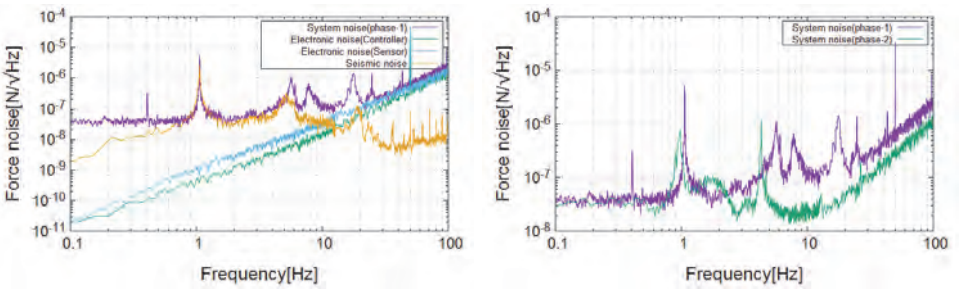

Fig. 4. The noise-equivalent sensitivity curve for the thruster stand system with identified noise sources (left) and the sensitivity curve for the thruster stand of phase-2 compared with phase-1 (right).

## 4. Conclusions

We have developed control and measurement systems closely related to a drag-free control of space gravitational wave antenna mission, DECIGO. The position control using a thrust system succeeded in showing the feasibility of the system for one degree of freedom of translation, and the thrust stand showed acceptable noise levels against requirement in terms of system noise.

DECIGO and B-DECIGO is space gravitational wave detecter project which aims decihertz band. In (B-)DECIGO, dual-pass differential Fabry-Pérot interferometer (DPDFPI) is planed to be used. Also, to reduce the noise from the space craft displacement, drag-free control is implemented. It is needed to demonstrate DPDFPI with drag-free control with a test bench. In the test bench, DPDFPI is constructed with softly suspended benches and cavities to mimic the motion in the space. In this article, the design of the optical and mechanical part in the test bench is reviewed. First, the optical design is shown. Second, mechanical suspension design is explained. All resonance modes of the important degree of freedom is designed to be less than $\sim 1$ Hz.

*Keywords*: Gravitational wave; laser interferometer; DECIGO; B-DECIGO.

## 1. Introduction

DECIGO and B-DECIGO is a proposed space-borne gravitational wave detector in decihertz frequency range.[1] (B-)DECIGO have many objectives, such as, observation of compact binary coalescences such as black holes and neutron stars, measurement of Hubble constant from long duration signal of neutron star inspirals, and, especially in DECIGO, characterization of inflation. The sensitivity of DECIGO will reach $\sim 10^{-24}\ 1/\sqrt{\mathrm{Hz}}$ since DECIGO has a Fabry-Pérot cavity in its arms which interact gravitational waves.

In DECIGO and B-DECIGO, the dual-pass differential Fabry-Pérot interferometer (DPDFPI) as shown in Fig. 1 is planed to be used. In DPDFPI, the laser lights from two satellites co-stand in one arm cavity and its length can be measured by two ways. This leads to the redundancy which is important in space mission. In addition, the number of test mass for one interferometer is reduced in DPDFPI.

Laser interferometers are operated in ground-based gravitational wave detectors, such as Advanced LIGO, Advanced Virgo, KAGRA.[2–5] However, specific control scheme of DPDFPI in (B-)DECIGO is still under consideration. In order to decide the control scheme of DPDFPI, some special techniques to space-borne detecters should be demonstrated, such as drag-free control with interferometer control. Drag-free control is a scheme where the distance and angle between the spacecraft and the test mass which is contained in the spacecraft are measured and controlled. This is necessary to reduce a noise coupled with spacecraft motion.

Before launch of (B-)DECIGO, DPDFPI with drag-free control has to be demonstrated on the ground. For the demonstration, construction of the test bench started. In this article, we reviewed the design of the test bench.

## 2. Design of the interferometer test bench

### 2.1. *Overview of the test bench*

The overview schematic of the test bench is shown in Fig. 1. The test bench is designed to have essential parts of (B-)DECIGO; DPDFPI and drag-free controlled spacecrafts. All main cavities and almost all input and output optics except laser sources and electro-optic modulators are placed in a vacuum chamber. The laser sources and its modulation systems for taking a length and angular signal of the cavity are placed outside of the chamber. The light is introduced though optical fibers into the chamber. The interferometer scale is about 1 m. This is limited by the size of the vacuum chamber. The detailed optical design is explained later. The mechanical system is divided into two components; test masses, i.e. cavity mirrors, and optical benches where the input and output optics are placed. The optical bench emulates the spacecraft in the space. To mimic low-gravity environment in space, the test masses and optical benches are softly suspended as explained later. As the demonstration of the drag free control, the relative motion and angle between the suspended optical bench and mirrors is measured and controlled with local sensors and actuators.

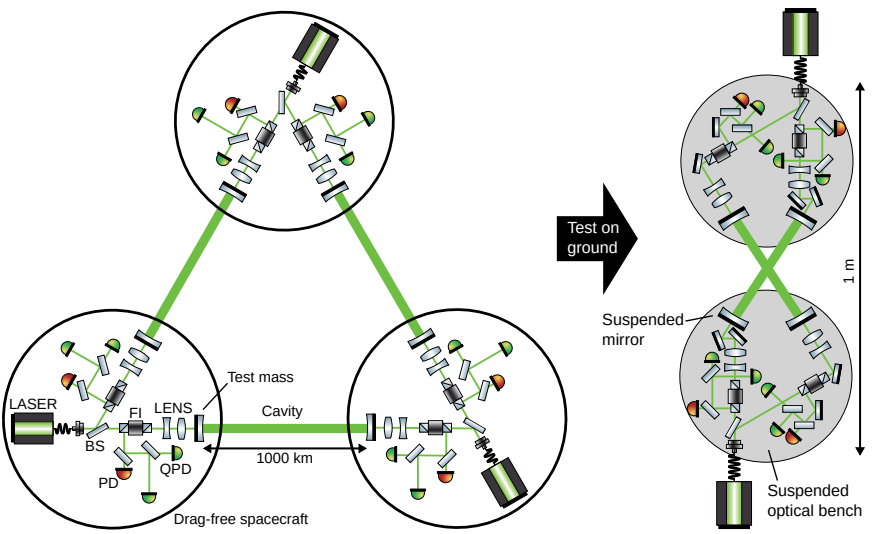

Fig. 1. Overview schematic of DECIGO and its the test bench on ground. BS, beam splitter; FI, Faraday isolator; PD, photodetector; QPD, quadrant photodetector.

### 2.2. *Optical design of the test bench*

The schematic of the optical design is shown in Fig. 2. The optical design of the test bench is made miniaturized and simplified compared with (B-)DECIGO design. The length of the cavity is 0.63 m and the radius of curvature of each mirror is 2 m. The cavity is critically coupled with finesse of 3100. The laser with wavelength of 1550 nm is introduced with fiber from the outside of the chamber. During the transfer, the laser is phase-modulated by electro-optic modulator for Pound-Drever-Hall technique and so-called wave front sensing technique for cavity length and alignment measurement.[6–8] The fiber output collimator is place on the suspended optical bench. The output light is splitted to two ways for two cavities. The light is isolated by Faraday isolators. The Faraday isolators can separate the reflected and transmitted light since the lights input from each side of the cavity have orthogonal linear polarization. The reflected light is received by radio-frequency photodetectors and quadrant photodetectors which are used to sensing cavity length and alignment measurement. The transmitted light is monitored with the photodetectors. In the test bench, the frequency and intensity stabilizing system is not implemented.

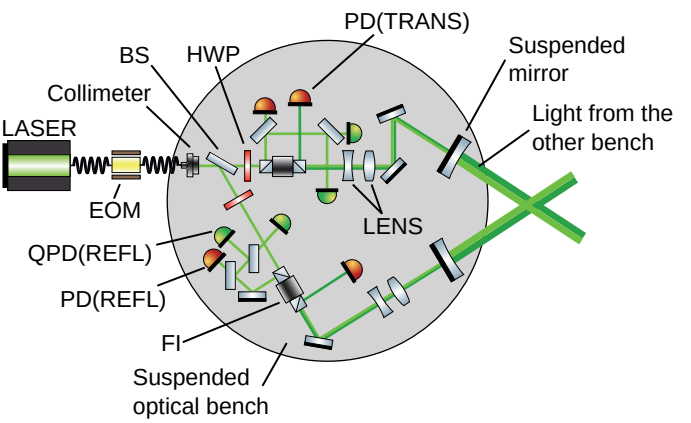

Fig. 2. Optical design of the test bench. EOM, electro-static modulator; HWP, half wave plate.

### 2.3. *Mechanical design of the test bench*

The schematic of the suspension system is shown in Fig. 3. In the test bench, there two types of suspension system: optical bench and cavity mirror suspension system. They are designed to have resonant frequency less than $\sim 1$ Hz for all considered mode.

The cavity mirrors are suspended with a double pendulum system. The first stainless beam is $10 \times 2 \times 2$ cm$^3$ and mass of 360 g. It is suspended by single tungsten wire with 10-cm long and 120-$\mu$m diameter. The mirror holder which contains the cavity mirror is suspended from one edge of the beam by two tungsten

wires with 40-$\mu$m diameter. The mirror holder is made of aluminum and its mass is about 220 g. The mirror holder has plus shape to increase moment of inertia for yaw and pitch motion. To compensate the mass of the mirror holder, a the counter weight is attached on the other edge of the beam.

The optical bench is suspended with a single piano wire whose diameter is 150 $\mu$m and length is 25 cm via a coil spring with spring constant of $\sim 10^3$ N/m. The optical bench is an aluminum plate with thick of 1.5 cm and diameter of 30 cm. The total mass of the optical bench including optic on it is estimated to be about 15 kg.

The estimated resonant frequencies of the mirror and the optical bench suspension for each impotant mode calculated with a toolkit of 3D rigid-body modeling coded in Mathematica® in Refs. 9, 10 are shown in Table 1. For the mirror and the optical bench suspension, the mode in terms of the center of the mirror and aluminum plate are considered, respectively. Table 1 shows that the requirement is almost achieved.

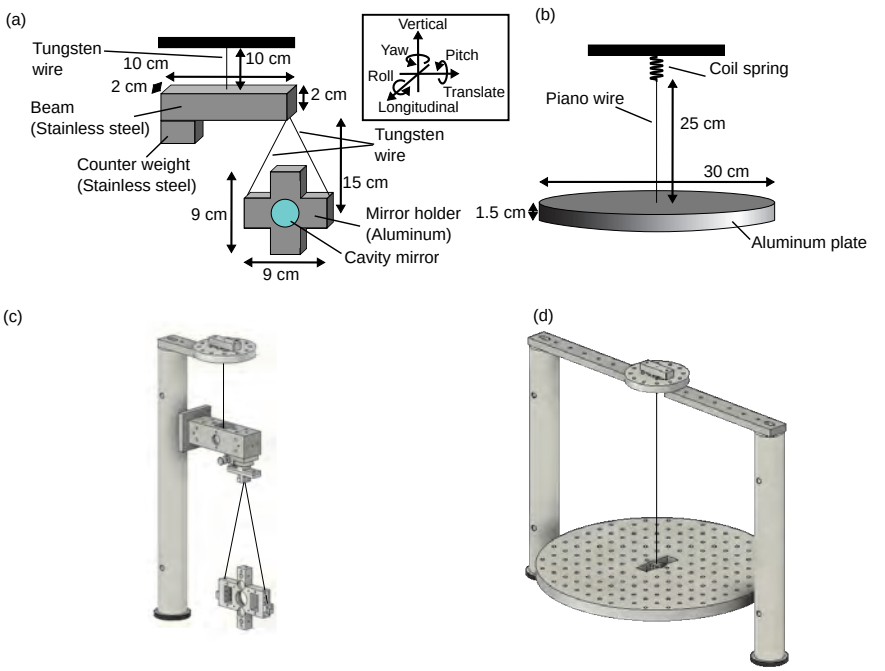

Fig. 3. Schematic (upper panel) and CAD image (lower panel) of the suspension system of the test bench. Left and right panels show the mirror and optical bench suspension system, respectively. In the CAD image of the optical bench (d), the coil spring is not shown. For the mirror and the optical bench suspension, the mode in terms of the center of the mirror and aluminum plate are considered, respectively.

Table 1. Resonant frequencies for each mode of two suspension types. Mode name: L, longitudinal; T, translation; V, vertical; Y, Yaw; P, pitch; R, roll. Since the roll mode of the mirror does not matter due to the symmetry of the mirror, its resonant frequency is shown just for reference.

| Suspension type | L | T | V | Y | P | R |
|---|---|---|---|---|---|---|
| Mirror | 0.02 Hz | 1 Hz | 0.5 Hz | 0.1 Hz | 0.05 Hz | (30 Hz) |
| Optical Bench | 1 Hz | 1 Hz | 1.4 Hz | 0.01 Hz | 0.09 Hz | 0.09 Hz |

### 2.4. *Local sensors and actuators*

To measure the relative motion and angle between the cavity mirrors and optical bench, reflective photosensors and optical levers are used. The motion and angle of the optical bench in the inertial system of a ground is also measured with photosensor and optical levers. As actuators, conventional coil-magnet actuators are used. They are used to apply force between mirror suspension and optical bench and apply force to the optical bench from the ground. The latter simulates thrusters of space craft, such as cold gas or field-emission electric propulsion thrusters. Note that these sensors and actuators are not ones which will be used in (B-)DECIGO. However, they can be replaced by the real ones for the integration test of the whole (B-)DECIGO system in future.

## 3. Summary and outlook

In this article, we reviewed the experimental design of the test bench for DECIGO and B-DECIGO. Optical and mechanical systems which is essential part of the test bench has been designed. Construction of the test bench is on going and will be followed by demonstration of the DPDFPI with drag-free control.

KAGRA is a new gravitational wave detector which aims to begin joint observation with Advanced LIGO and Advanced Virgo from late 2019. Here, we present KAGRA's possible upgrade plans to improve the sensitivity in the decade ahead. Unlike other state-of-the-art detectors, KAGRA requires different investigations for the upgrade since it is the only detector which employs cryogenic cooling of the test mass mirrors. In this paper, investigations on the upgrade plans which can be realized by changing the input laser power, increasing the mirror mass, and injecting frequency dependent squeezed vacuum are presented. We show how each upgrade affects to the detector frequency bands and also discuss impacts on gravitational-wave science. We then propose an effective progression of upgrades based on technical feasibility and scientific scenarios.

*Keywords*: Gravitational waves; Cryogenics; Underground; Laser interferometer; Optimization.

## 1. Introduction

The era of gravitational wave astronomy began with the first direct detections of gravitational waves from binary black holes and binary neutron star systems by Advanced LIGO and Advanced Virgo[1,2]. Improving the sensitivity of these detectors enables more frequent detections and more precise source parameter estimation. To this end, there have been extensive studies to improve the sensitivity beyond the detector's original design sensitivity.

Within LIGO Scientific Collaboration and Virgo Collaboration, there are ongoing effort to upgrade Advanced LIGO and Advanced Virgo detectors to $A+$[3] and $AdV+$[4], respectively, by around 2024[5]. The designed sensitivities of A+ and AdV+ are improved over that of Advanced LIGO and Advanced Virgo by roughly a factor of two. The improvement is in part realized by the coating thermal noise reduction either from the mechanical loss reduction of the coating material or from larger beam size. Also, broadband quantum noise reduction is expected by using a 300-m filter cavity to generate frequency dependent squeezed vacuum[6,7]. Twofold broadband sensitivity improvement leads to eightfold increase in the detection rate, and halves the parameter estimation error.

KAGRA is another laser interferometric gravitational wave detector which is being built in Japan[8,9] and plans to start observation jointly with Advanced LIGO and Advanced Virgo from late 2019. Compared with the other detectors, KAGRA has two technologically unique features: it is constructed at a seismically quiet underground site, and it uses sapphire mirrors at cryogenic temperatures to reduce thermal noise. Therefore, KAGRA has a unique potential to further improve its sensitivity, and upgrading KAGRA will require different approach compared with the other detectors.

In this paper, we discuss the prospects for the upgrade of the KAGRA detector. We start by describing possible technologies that can be applied for upgrading KAGRA and show that different technologies will improve the sensitivity in different frequency bands. We then discuss impacts on gravitational wave detections for each upgrade, and show possible strategy for the KAGRA upgrade in this decade.

## 2. Technologies for the KAGRA upgrade

The current design sensitivity of KAGRA is shown in Fig. 1. At low frequencies, the sensitivity is limited by the suspension thermal noise and the quantum radiation pressure noise. At high frequencies, the sensitivity is limited by the quantum shot noise. At the most sensitive band in the mid-frequencies, the sensitivity is limited by the mirror thermal noise, which manly comes from the coating Brownian noise. Thanks to cryogenic cooling of the sapphire test masses to 22 K, the mirror thermal noise is smaller than Advanced LIGO and Advanced Virgo although the size of the test mass is smaller. However, the suspension thermal noise is higher since the heat extraction is done by the sapphire fibers suspending the test mass and it requires thick and short fiber (1.6 mm diameter, 35 cm long) for efficient heat extraction. The

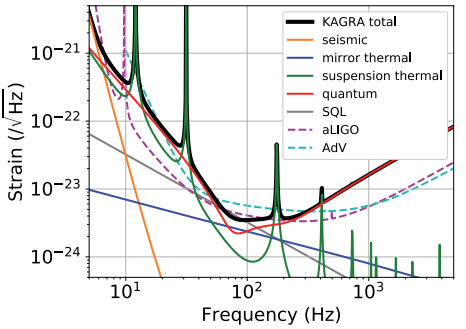

Fig. 1. The design sensitivity of KAGRA. The seismic noise shown includes the estimated Newtonian noise from the surface and bulk motion of the mountain containing KAGRA. The mirror thermal noise shown is the sum of the thermal noise from the test mass substrates and the coatings. Sensitivity curves for Advanced LIGO (aLIGO)[12] and Advanced Virgo (AdV)[5] are also shown for comparison.

quantum shot noise is also higher due to input laser power limitation for cryogenic cooling. Because of these features, KAGRA plans to use quantum non-demolition techniques such as the detuing of the signal recycling cavity and homodyne readout to reduce quantum noise in the most sensitive band at the cost of narrowing the detector bandwidth. Detailed discussion on the sensitivity optimization of KAGRA is given in Refs. 10, 11

To improve the sensitivity of KAGRA, retuning of laser power and suspension parameters will help at certain frequency bands. Increasing the mirror mass and injection of frequency dependent squeezed vacuum are also promising ways to improve the sensitivity. In the following subsections, we will discuss the effect of each technology for the upgrade of KAGRA. We will then discuss longer term prospects for the upgrade which can be realized by combining multiple technologies in this decade. Example sensitivity curves of KAGRA upgraded with different technologies discussed below are shown in Fig. 2 (Left). The interferometer parameters and the dimensions of the suspension fibers to calculate these sensitivity curves are optimized with particle swarm optimization method described in Ref. 11. The sensitivity curve data are available at Ref. 14.

### 2.1. *Laser power and heat extraction*

The input laser power and suspension thermal noise is closely related in KAGRA since heat extraction is done by the suspension fibers. To improve the sensitivity at low frequencies, reduction of suspension thermal noise is necessary. This can be done by changing the suspension fibers to thinner and longer ones since suspension thermal noise scales with $d_{\rm f}^2/l_{\rm f}$, where $d_{\rm f}$ and $l_{\rm f}$ are the diameter and the length of the fiber, respectively. However, this will result in larger shot noise because the heat extraction efficiency will be less and maximum input laser power allowed will be

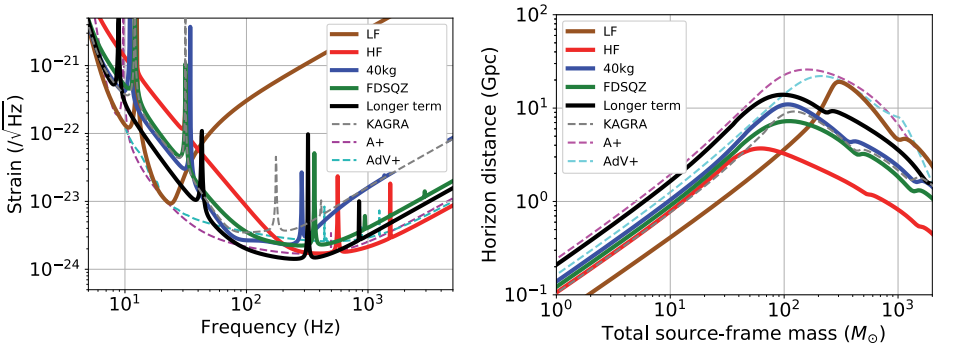

Fig. 2. (Left) Example sensitivity curves for the upgrade of KAGRA using different technologies. LF: Lower input power plan to focus on low frequency. HF: Higher power plan with frequency independent squeezed vacuum to focus on high frequency. 40kg: Sensitivity with increased mass of the test masses from 22.8 kg to 40 kg. FDSQZ: Sensitivity with the injection of frequency dependent squeezed vacuum generated with a 30-m filter cavity. Longer term: Example of longer term upgrade plan combining multiple technologies. Sensitivity curves for A+[13] and AdV+[5] are also shown for comparison. (Right) The horizon distance of example KAGRA upgrades for equal-mass, nonspinning binaries. The horizon distance shows the maximum distance at which gravitational waves can be detected with signal-to-noise ratio of more than 8.

less. Similarly, higher laser power to reduce shot noise at high frequencies require thicker and shorter suspension fibers, which will result in larger suspension thermal noise.

The *LF* curve shown in Fig. 2 is an example curve which the sensitivity at low frequencies is improved by lowering the laser power at the beam splitter from 673 W to 5 W. This plan requires higher detuning of the signal recycling cavity to reduce quantum noise at around 20-30 Hz. The suspension thermal noise peak at 31 Hz in the original KAGRA design sensitivity comes from the vertical motion of the intermediate mass suspension. Therefore, to remove this peak from the low frequency band, the *LF* plan also requires heavier intermediate mass with thinner and longer suspension wires. The interferometer parameters are optimized to maximize the inspiral range of 100 $M_\odot$-100 $M_\odot$ binary in the detector frame.

The *HF* curve shown in Fig. 2 on the other hand focuses on the high frequencies by increasing the laser power at the beam splitter to 3400 W. It also assumes the injection of frequency independent squeezed vacuum to further reduce the shot noise. Here, 6 dB of detected squeezing at high frequencies is assumed. The interferometer parameters are optimized to minimize the sky localization error of GW170814-like binary neutron stars[11].

### 2.2. *Increasing the mirror mass*

Increasing the mass of the test mass generally improves the sensitivity since the suspension thermal noise and quantum radiation pressure noise scales with $m^{-3/2}$ and $m^{-1}$, respectively. The coating thermal noise also can be reduced since larger

mirror allows larger beam size on the mirror. Assuming both the aspect ratio of the mirror and the ratio of the beam diameter to the mirror diameter to be the same, the coating thermal noise scales with $m^{-1/3}$.

The *40kg* curve shown in Fig. 2 is an example sensitivity with the mirror mass increased from 22.8 kg to 40 kg. Considering the design inside the current KAGRA cryostat, 40 kg would be the size limit without changing the cryostat drastically. The interferometer parameters are optimized to maximize the inspiral range of 1.4 $M_\odot$-1.4 $M_\odot$ binary. We note here that coating thermal noise reduction by larger beam size is assumed but smaller mechanical loss of the coating material is not assumed in the sensitivity calculation to show a feasible plan.

Interestingly, increasing the mirror mass result in the sensitivity improvement only at mid-frequencies where coating thermal noise dominates. This is because heavier mass requires higher laser power to keep the frequency $f_{\rm SQL}$ where quantum noise reaches the standard quantum limit to be the same. In case of KAGRA, $f_{\rm SQL}$ should be as high as possible until the quantum noise reaches the coating thermal noise, if we want to maximize the inspiral range. This is because the frequency dependence of the standard quantum limit ($f^{-1}$) is larger than that of the inspiral signal ($f^{-2/3}$). Therefore, the laser power scales with more than $m$. Higher laser power requires thicker suspension fibers and in the end the suspension thermal noise is not much dependent on the mirror mass.

### 2.3. *Frequency dependent squeezing*

Injection of frequency dependent squeezed vacuum is a promising way to reduce both radiation pressure noise and shot noise, which can be done without increasing the mirror mass or the laser power. The *FDSQZ* curve shown in Fig. 2 is an example curve which can be realized with 30-m filter cavity and 5 dB of detected squeezing at high frequencies. 30-m filter cavity can be constructed along the vacuum tubes of the signal recycling cavity. The interferometer parameters are optimized to maximize the inspiral range of 1.4 $M_\odot$-1.4 $M_\odot$ binary.

As discussed previously, the input laser power should be increased for higher $f_{\rm SQL}$ and this result in slightly worse suspension thermal noise. Also, injection of squeezed vacuum prefers no detuning of the signal recycling cavity. Therefore, injection of frequency dependent squeezed vacuum result in a sensitivity improvement at high frequencies.

### 2.4. *Longer term prospects*

As we have shown, applying only one of these technologies give sensitivity improvement at certain frequency bands. Combination of multiple technologies is necessary for broadband sensitivity improvement. The *Longer term* curve shown in Fig. 2 is an example sensitivity for 5 to 10-year upgrade plan which can be realized with 100 kg mirrors, 30-m filter cavity and 3500 W of the laser power at the beam splitter.

The interferometer parameters are optimized to maximize the inspiral range of 1.4 $M_\odot$-1.4 $M_\odot$ binary.

The situation is similar to *FDSQZ* plan, but because of larger test mass, suspension thermal noise and coating thermal noise are also reduced. In total, twofold broadband sensitivity improvement will be realized.

## 3. Science case study and disussion on strategic upgrade

Although combination of multiple upgrade components is necessary for the broadband sensitivity improvement, upgrades to the detector should be done in an incremental way. Which to be implemented at earlier stages depend on the technological feasibility and impact on gravitational-wave science.

Figure 2 (Right) shows the horizon distance of each example upgrade for compact binary coalescences. *LF* plan has the largest horizon distance above $\sim 200 M_\odot$ in total mass, whereas *40kg* plan has the largest horizon distance for smaller masses. We can say that *LF* has the highest probability of detecting the intermediate mass black holes (IMBHs).

Although the horizon distance is not great, *HF* plan gives the smallest sky localization error for binary neutron stars. The median of the sky localization error for GW170817-like binaries calculated with the same method described in Ref. 11 for *LF*, *HF*, *40kg* and *FDSQZ* are 0.507 deg$^2$, 0.105 deg$^2$, 0.156 deg$^2$ and 0.119 deg$^2$, respectively. For the sky localization of 30 $M_\odot$-30 $M_\odot$ binary black holes, *40kg* gives the smallest error. For constraining neutron star equation of state and for search for continuous waves from pulsars, *HF* and *FDSQZ* will be the best choices since the sensitivity from 500 Hz to 4 kHz is important for these studies. For the test of general relativity through inspiral-merger-ringdown waveform, broadband configuration such as *FDSQZ* and *40kg* would be preferred.

From the technical feasibility point of view, *LF* has the largest uncertainty since there are many kinds of low frequency excess noises other than the fundamental noises discussed above, such as scattered light noise, vibration noise from cryocoolers, interferometer controls noise etc. 40 kg test mass would be feasible in next few years, but even larger mirror is required for longer term upgrade. Considering that higher power laser source and squeezed vacuum source are required also for longer term upgrade, implementing these as a first step to focus on high frequency sensitivity improvement would be a strategy for the upgrade. *HF* plan is also attractive in that it might be able to do original science because *HF* has better sensitivity at high frequencies than A+ and AdV+.

## 4. Summary

Upgrading KAGRA requires simultaneous tuning of the parameters related to thermal noise and those related to quantum noise since the heat extraction is done through the fibers suspending the test mass mirrors. We showed that shifting the

detector frequency band of KAGRA is possible by changing the input laser power. We also showed that increasing the mirror mass and injection of frequency dependent squeezed vacuum will improve the sensitivity at mid-frequencies and high frequencies, respectively. Considering the technical feasibility and impact on the detection of gravitational waves, possible strategy for upgrading KAGRA would be to focus on high frequency improvement with higher laser power and squeezed vacuum injection for near term. In a longer term, broadband twofold improvement with frequency dependent squeezed vacuum injection and heavier mirror would be realized.

In this study, improvements in the coating, increased heat conductivity of the suspension sapphire fibers and reduced heat absorption of the sapphire mirror are not considered. More detailed investigations and other possibilities of the upgrade will be reported elsewhere.

# Status of a cryogenic mirror suspension for KAGRA gravitational wave detector

Takafumi Ushiba* on behalf of the KAGRA Collaboration

*Institute for Cosmic Ray Research, The University of Tokyo*
*Kashiwa, 277-8582 Chiba, Japan*
**E-mail: ushiba@icrr.u-tokyo.ac.jp*

We demonstrated a cryogenic mirror suspension for a gravitational detector, KAGRA, and evaluated several performances such as cooling time and damping control. Cooling mirrors is promising technique for reducing the mirror thermal noise that fundamentally limits sensitivity of current ground-base gravitational-wave detectors around 100 Hz region. Cryogenic technology for mirror suspensions is therefore essential for further improvement of detector sensitivity beyond the 2nd generation detectors such as aLIGO, aVIRGO, and KAGRA. In this paper, current status of KAGRA cryopayloads is discussed.

*Keywords*: KAGRA, gravitational waves, laser interferometric gravitational-wave detector, cryogenics.

## 1. Introduction

The first direct detection of gravitational waves (GW) were achieved in 2015,[1] and more than 10 GWs are detected during LIGO-VIRGO observation run 1 and 2 by LIGO Scientific Collaboration and Virgo Collaboration.[2] These discoveries yield fruitful knowledge on our universe and open a new window of GW astrophysics and astronomy. For promoting them, it is crucial to construct a grobal network of GW detectors with sufficient high sensitivity such as KAGRA[3] and LIGO-India[4].

KAGRA is an interferometric GW detector located at Kamioka-mine in Japan. Two key features of KAGRA are using underground site for reducing seismic noise and cooling mirrors for mitigating thermal noise. KAGRA experienced two test runs called i-KAGRA operation in 2016 and bKAGRA phase1 operation in 2018, which are the first underground km-scale interferometer operation and km-scale cryogenic interferometer operation, respectively.[5,6]

It is a promising method to use cooled mirrors in order to reduce thermal noise, which fundamentally limits sensitivity of laser interferometric gravitational-wave detectors at room temperature such as aLIGO and aVIRGO. So, it is quite important to apply cryogenic technique to GW detectors for developing the further sensitive GW detectors like LIGO Voyager and Einstein Telescope.[7,8]

## 2. KAGRA cryogenic payload

### 2.1. *Overview*

Sapphire test masses of KAGRA are suspended by 13.5-meter 9-stage suspensions (Type-A suspensions), which consist of 5-stage room-temperature suspension (Type-A tower) and 4-stage cryogenic suspension (cryogenic payload).[6] Stages of

the cryogenic payload are platform, marionette, intermediate mass, and mirror from the top and there are corresponding recoil masses except for the platform. The intermediate mass has four sapphire blade springs and the mirror is suspended from them with four sapphire fibers. Since the sapphire fiber is too thick to make a loop, sapphire fibers are hooked on sapphire ears bonded on the side of the mirror.

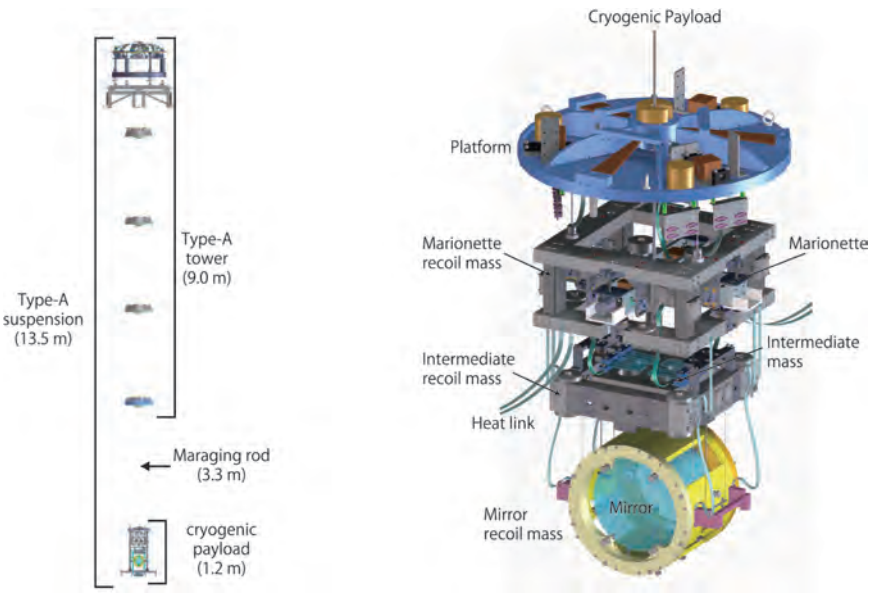

Fig. 1. Schematic view of the Type-A suspension and cryogenic payload.

To actuate angular and translational motions of mirrors, there are 6 coil-magnet actuators on both marionette stage and intermediate mass stage, and 4 on test mass stage[9]. To sense the local motion of the mirror, three kinds of local sensors are installed: optical levers(OLs) for mirror and marionette, length-sensing optical lever for mirror and reflective-type photosensors (PSs) for intermediate mass and marionette stages. These actuators and sensors are utilized for mirror alignment, local damping control, and interferometer operation.

### 2.2. *Sapphire mirror*

Hydroxide catalysis bonding (HCB) method is used for bonding the ear to the mirror because it is strong enough to support the mass at cryogenic temperature and not low-Q bonding to introduce additional thermal noise.[10,11] To mitigate a coupling between longitudinal and pitch motion, the position of the sapphire ears should be 48 mm below the center of gravity of sapphire mirrors.[12] It is also important to bond the ears to the center of the mirror along the optical axis to reduce coupling

between vertical and pitch motion. Coordinates of mirror shapes and ear position are shown in Fig. 2.

After bonding the sapphire ears to the mirrors, we measure the position of ears. Table 1 represents the measured result of the practical KAGRA mirrors.

After the confirmation of the ear positions, mirror stores for one month to promote chemical reaction of HCB. Then, tests of the ear strength are performed for one week. All the mirror for KAGRA were already passed these prcesses and deliverred at Kamioka-mine.

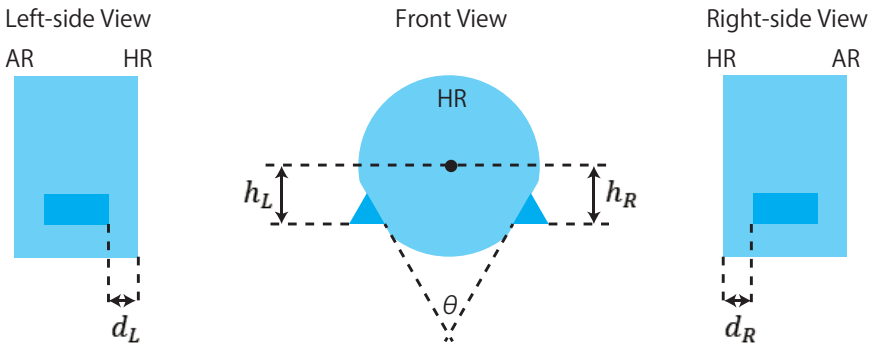

Fig. 2. Coordinates of mirror shapes and ear position.

Table 1. Summary of the mirror shapes and ear positions of KAGRA sapphire mirrors. Precision of the measurement is 50 $\mu$m for length and 0.1 degrees for angle.

| Mirror | Diameter (mm) | Thickness (mm) | $d_R$ (mm) | $d_L$ (mm) | $h_R$ (mm) | $h_L$ (mm) | $\theta$ (degrees) |
|---|---|---|---|---|---|---|---|
| ITMX | 220.34 | 150.12 | 35.03 | 35.02 | 48.27 | 48.38 | 36.0 |
| ITMY | 220.30 | 150.32 | 35.29 | 35.25 | 48.48 | 48.37 | 36.0 |
| ETMX | 220.28 | 149.96 | 35.09 | 35.05 | 48.03 | 48.08 | 36.0 |
| ETMY | 220.34 | 149.57 | 34.83 | 34.82 | 48.25 | 48.10 | 36.1 |

## 3. Installation of cryogenic payloads

Onece the mirrors are deliverred to the Kamioka-mine, they are suspended by cryogenic payloads and installed to KAGRA cryostats. Since the height of whole Type-A suspension is too large to install at onece, Type-A towers and cryogenic payloads are installed individually and connected with 3.3-meter maraging-steel rod after each installation (Fig. 3).

All the electrical cables on cryogenic payloads are connected from the top of Type-A tower and fixed along each stage of Type-A suspension to avoid vibration

injection through the cables. On the other hand, heat conductors for cooling is directly connected to a marionette recoil mass to cool the suspension effectively. Therefore, the material of the heat conductors is extremely pure aluminum that can balance high thermal conductivity with low stiffness to reduce vibration due to heat connection.

The first KAGRA cryogenic payload was suspended in November, 2017 and the last one was suspended in Feburary, 2019.

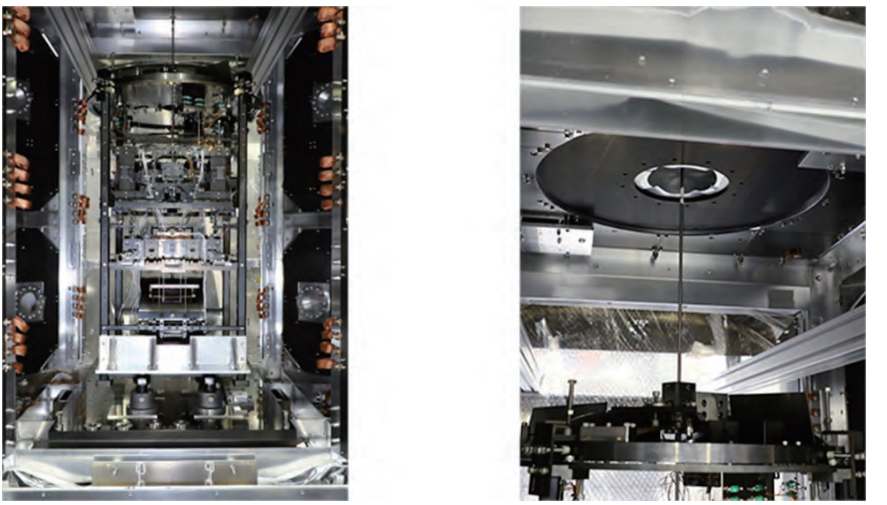

Fig. 3. Photos of a cryogenic payloads and its suspension rod from room temperature suspension. Left photo shows a cryigenic payloads installed inside a cryostat. Right photo shows a 3.3m maraging-steel rod.

## 4. Cooling

A cryogenic payload of the ETMY was cooled during the bKAGRA phase1 and the sapphire mirror reached 18 K. It takes almost one month to be a steady state, which is almost as we expected. Details are discussed in a paper.[6]

## 5. Angular motion

Mirror angular motion should be small sufficiently when we operate an interferometric gravitational wave detector. Active damping control is therefore implimented to the cryogenic payload during the bKAGRA phase1 operation. Figure 4 shows typical angular motion of the sapphire mirror with and without damping control of the cryogenic payload.

Yaw motion of the suspension could be reduced from the RMS of 4.4 $\mu$rad to that of 1.2 $\mu$rad. However, pitch motion of the suspension increased from the RMS

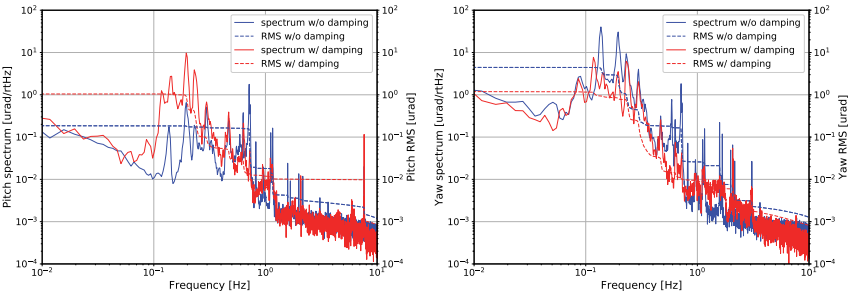

Fig. 4. Typical angular motion with and without damping control of cryogenic payload. Left figure shows pitch motion and right one shows yaw motion of the sapphire mirror. Red and blue lines in each graph show angular motion with and without damping, respectively. Dashed line represents RMS of mirror angular motion calculated by integration of the spectra from high frequency.

of 0.18 $\mu$rad to that of 1.0 $\mu$rad due to the actuator coupling between yaw and pitch motion. This large coupling is due to the rubbing of the electrical cables, such as actuators, thermometers, and sensors, between room temperature suspension and the platform.

Residual RMS of the angular motion is limited by several peaks around 0.2 Hz. These peaks are also due to the rubbing. This rubbing issue was solved after bKAGRA phase1 operation by tying cables to the suspension wires. So, our current suspension has no peak around there.

## 6. Summary and Future

All KAGRA sapphire mirrors were ready and already suspended by the Type-A suspension. Initial cryogenic suspension had some issures, especially on the angular motion of the mirror. However, these problems have been alredy solved and current cryogenic payload performance is quite stable.

All suspensions have been already installed, and all vacuum chambers were evacuated in April, 2019. At the begining of May, the final sapphire mirror started to be cooled, and the facility construction of KAGRA was completed. So, we are ready to start full-fledged commissioning. LIGO and VIRGO Observation run 3 has already started from April, 2019, and we are promoting interferometer comissioning to join the O3.

# Dynamical properties of binary stars hosting planets in the Galactic Center

Nazanin Davari* and Roberto Capuzzo-Dolcetta

*Department of Physics, University of Sapienza, Rome, Piazzale Aldo Moro 5/00185, Italy*
**E-mail: nazanin.davari@uniroma1.it*

We present some preliminary results of our work[1] about the close encounter of binary stars hosting planets on S-type orbits with the Sgr A* supermassive black hole in the center of our Galaxy.

*Keywords*: Galaxy: center; methods: numerical; planetary systems; stellar dynamics.

## 1. Introduction

Tidal breakup of binary stars passing close to a supermassive black hole (SMBH) in the center of galaxies may lead to the capture of one star around the SMBH (S-star) and the ejection of its companion as a hypervelocity star (HVS) (Hills mechanism).[2]

HVSs are fast-moving B-type main sequence stars observed in the Galactic halo at distances 50-120 kpc from the Galactic Center.[3] Some of them moving at extremely high velocities, i.e. they are not gravitationally bound to the Galaxy. The first observation of HVSs was in 2005,[17] a 3 $M_{\odot}$ main-sequence star, leaving the Galaxy with a heliocentric radial velocity of $853 \pm 12\ kms^{-1}$. HVSs that are originated from the Galactic Center can be used to constrain the Milky Way (MW) dark matter halo mass distribution since their orbits are completely determined by the MW potential.[6] A 3-4 $M_{\odot}$ star could be accelerated to such high velocities due to a close encounter with a relativistic gravitational potential.[4] So far, various mechanisms, as a result of close encounters with the relativistic potential well, have been proposed to study the ejection of HVSs. Yu & Tremaine[5] suggested a three-body interaction between a single star and a binary black hole (BBH). In this scenario, Sgr A* is assumed to be one component of a BBH. HVSs may also have been produced as a result of the interaction between stars within 0.1 pc of the Sgr A* black hole (BH) and a cluster of stellar-mass BHs that have segregated to that region.[7] Furthermore, the close interaction between a massive, orbitally decayed, globular cluster and the SMBH can give rise to ejection of some stars in the cluster as HVSs.[8]

Over the last decade monitoring the central arcsecond ($< 0.05$ pc) of the MW by two groups of researchers, [a] shows the presence of both population of early-type and late-type stars (about 40 bright stars),[14] the so-called S-stars[b] Unlike HVSs, S-stars are the most tightly bound stars which revolve around the SMBH residing in

[a] A group centered in the Max Planck Institute for Extraterrestrial Physics and a group at UCLA, California.
[b] "S" stands for "(infrared) source".[9]

the centre of the Galaxy (e.g. Schödel et al. 2002).[10] Refs. 11, 12, 13, 14 acquired orbital parameters of the S-stars using high-resolution near-infrared observations. Their results show that such stars would have semimajor axes in the range $\sim 0.005$ to $\sim 0.05$ pc, masses in the range 3-20 $M_{\odot}$. Similarly to HVSs, these are also classified as main-sequence stars, mostly of spectral type B. That is to say, they might be the former companion of the HVS in Hills mechanism.

On another side, it is known that stars borrow planets around them, also when they are in binaries. Therefore, it seems interesting to study the interaction of binary stars hosting planets with the SMBH in the MW center. In this work, we investigate the orbital properties of the plunging binary stars and their fate together with that of their planets after close interactions with the SMBH in the Galactic Center (GC).

## 2. Computational Method

We performed a huge set of simulations using a regularized $N$-body algorithm, the `AR-CHAIN` integrator,[15] which includes post-Newtonian corrections up to order 3.5 and properly modified (`ARGdf` code)[19] to account for an analytic external potential and its dynamical friction. Assuming spherical symmetry for the inner galactic region, we considered as mass distribution model the sum of a Dehnen's and a Plummer's distribution.

For our simulations, we considered both the case of a non-spinning (Schwarzschild) and a spinning (Kerr) with the dimensionless spin parameter $\chi = 0.76$ SMBH with mass $M_{\bullet} = 4 \times 10^6 M_{\odot}$ initially placed in the origin of the reference frame. We assumed binary stars of 3 $M_{\odot}$ each revolving around each other on initial circular orbit with (initial) separation in the range $a_* = 0.1 - 0.5$ AU.[16] The mass value chosen is comparable to the mass of the first HVS observed.[17] Each star has one planet initially at $a_p = 0.02$ AU from its host star with mass $m_p = 10^{-3} M\odot$ (Jupiter-like planet). The center of mass of the binary star is assumed initially at 2000 AU away from the SMBH. We give the system a transverse (respect to the line joining the binary and the SMBH) initial velocity of 66.5 km $s^{-1}$. We run simulations at varying the inclination of the binary orbital plane respect to that of the motion of its center of mass; 0°, 90° and 180°. We vary also the initial orbital phase angle values of the binary ($\phi$) in the $0° - 360°$ range at steps of 15°.[16]

Table 1. Set of initial conditions for our runs.

| inclination (degrees) | $a_\star$ (AU) | $a_P$ (AU) | $m_\star$ ($M_\odot$) | $m_P$ ($M_\odot$) | $\phi$ (degrees) |
|---|---|---|---|---|---|
| 0 | 0.1 – 0.5 | 0.02 | 3 | 0.001 | 0-360 |
| 90 | 0.1 – 0.5 | 0.02 | 3 | 0.001 | 0-360 |
| 180 | 0.1 – 0.5 | 0.02 | 3 | 0.001 | 0-360 |

## 3. Preliminary Results

When a binary star hosting planets, with our given parameters, is disrupted by the SMBH, stars and planets may eject as hypervelocity stars or hypervelocity planets (HVPs). In some cases, stars and/or planets may remain bound to the SMBH in highly eccentric orbits or are swallowed by it. In Figures 1 and 2 we sketch two possible examples for the fate of binary+planets system after a close interaction with a spinning SMBH.

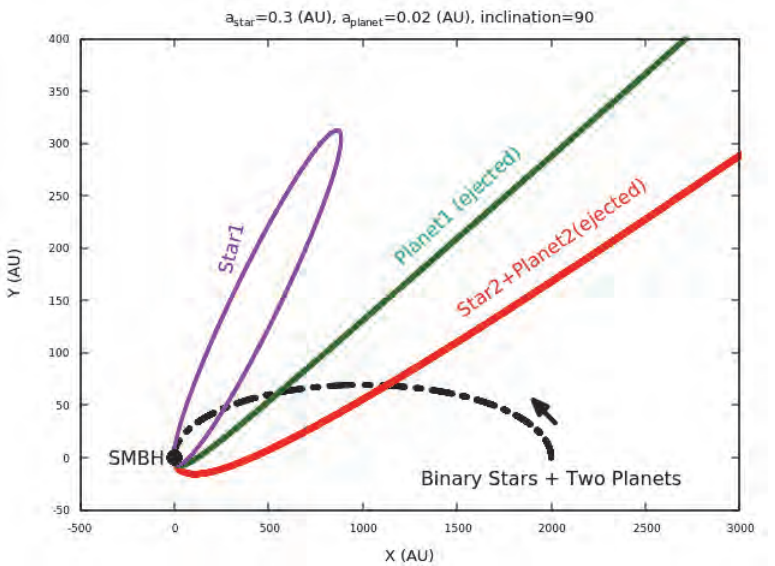

Fig. 1. HVS with planet.

The main aim of this work is to check conditions upon which binary stars borrowing planets around them can give rise to HVSs still keeping bound their planets even after the close interaction with the SMBH in the GC.

In Fig. 1, the initial semi-major axis of the binary star motion is 0.3 AU and the orbital plane inclination is 90°. After the first encounter, there is a break-up of the binary. One star is ejected keeping its planet bound (red line) and the former companion star starts revolving around the SMBH (magenta line) while its planet is ejected as HVP (green line). Fig. 2 refers to an initial separation of 0.1 AU for the two stars in the binary; again, the inclination of the plane is 90°. In this case, after the first encounter with the SMBH, the stars swap their planets, and one of the stars escapes the GC as HVS with the planet orbiting around it (green line). The companion star loses the planet after three passages around the SMBH (red line shows the three revolutions around the SMBH before they get separated); its planet ejects as HVP (blue line).

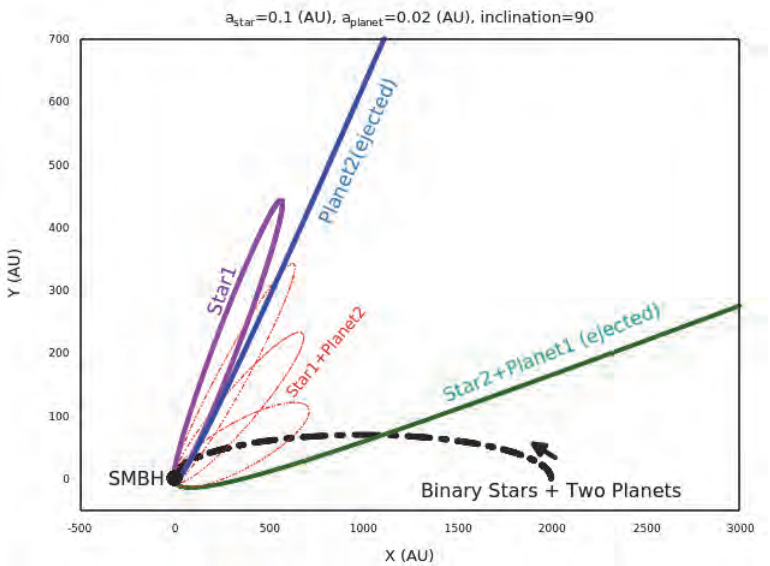

Fig. 2. Exchange of planets.

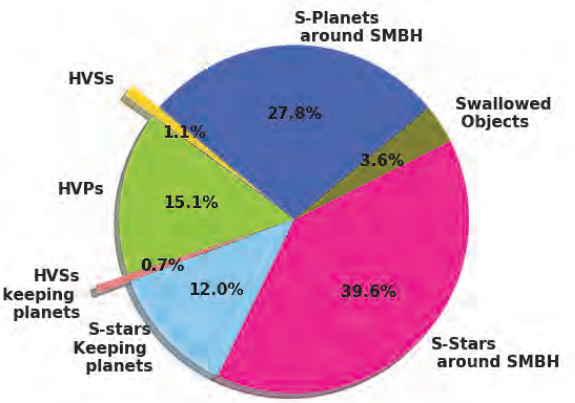

Fig. 3. Inclination 0°.

The following pie charts (Figs. 3 and 4) quantify the likelihood of different outcomes for the co-rotating and counter-rotating cases, after the binary star is broken up by the SMBH in our whole set of simulations. An intriguing aspect to examine, deepening the work by Fragione & Ginsburg,[18] will be checking the detection chance of such HVPs around their hosting stars, with transit techniques.

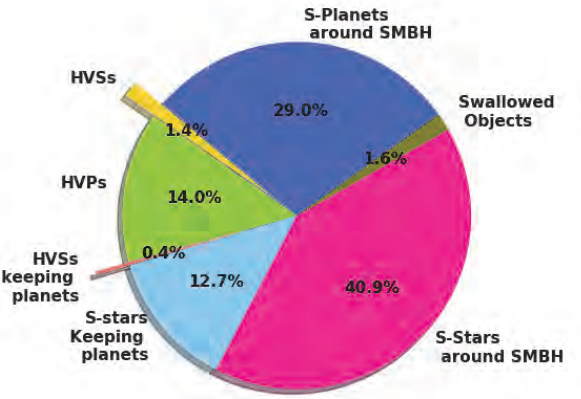

Fig. 4. Inclination 180°.

## 4. Forthcoming Research

An immediate and natural future development of this work is enlarging the study to binary and triple systems hosting multi-planet systems. This would allow an estimate of the number of high-velocity wandering planets, other than providing an estimate of the background contribution of multiple small bumps of gravitational wave emission.

We briefly describe and discuss the set-up of the project Mocca Survey Database I. The database contains more than 2000 Monte Carlo models of evolution of real star cluster performed with the Mocca code. Then, we very briefly discuss results of analysis of the database regarding the following projects: formation of intermediate mass black holes, abrupt cluster dissolution harboring black hole subsystems, retention fraction of black hole - black hole mergers, and tidal disruption events with intermediate mass black holes.

*Keywords*: Methods: numerical - globular clusters: general - stars: black holes.

## 1. Introduction

Recent high resolution observations of globular clusters (GC) provide a very detailed picture of their physical status and show complex phenomena connected with multiple stellar populations, binary evolution, black holes (BH) and the Galactic tidal field. Despite such great observational progress there are many theoretical uncertainties connected with the origins of GCs and their primordial properties. To bridge the gap between present-day observed star cluster properties and their properties at the time of cluster formation, we need to discriminate between different theories and models by means of numerical simulations of GC evolution. The best suited codes for such a task are N-body and Monte Carlo codes. In this paper we will describe results of Monte Carlo simulations done with the MOnte Carlo Cluster simulAtor - Mocca.[11,17] (and references therein) All those simulations were collected in a Mocca Survey Database I, which then was analyzed from the point of view of properties and evolution of different kinds of BH populations.

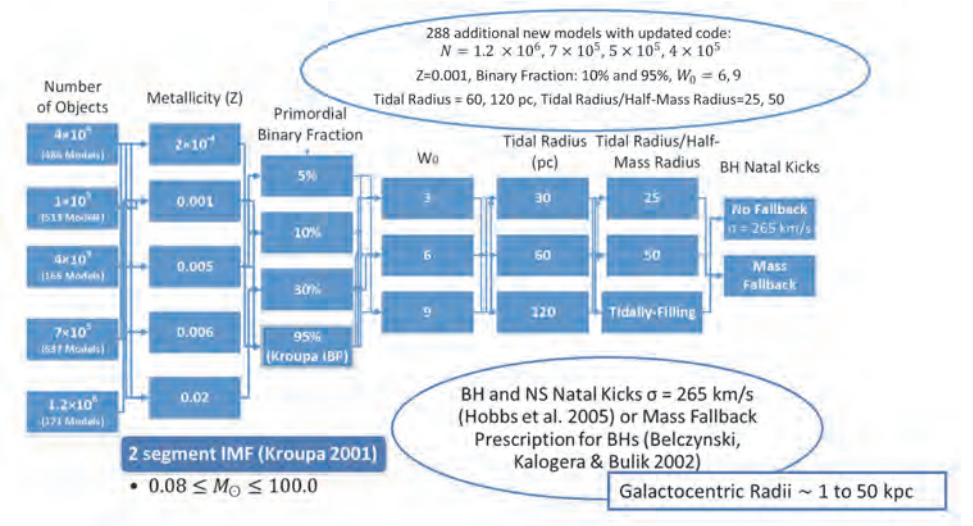

Fig. 1. The initial set-up of the MOCCA simulations of the real star clusters stored in the MOCCA-SURVEY DATABASE I. The model parameters and relevant references are listed in the Figure. In the models the pair-instability supernovae, pulsation pair-instability supernovae, electron capture supernovae and accretion induced supernovae were not taken into account. BHs formed in the simulations have masses smaller than about $15 - 20\ M_\odot$, depending on metallicity.

## 2. MOCCA and MOCCA Survey Database I

The MOCCA code is a version of the Monte Carlo codes and can be considered as so-called 'kitchen sink' code, which is able to follow most physical processes important during star cluster dynamical evolution. The MOCCA code treats the relaxation process using the method described by Henon,[13] that was significantly improved by Stodółkiewicz,[25,26] and more recently by Giersz and his collaborators.[10–12,17] (and reference therein). For stellar and binary evolution Jarrod Hurley's BSE code is used,[15,16] and for the scattering experiment John Fregeau's Fewbody code.[7] The realistic description of an escape process in a tidally limited cluster is done on the basis of the Fukushige & Heggie theory.[8] The MOCCA code provides as many details as N-BODY codes. It can follow evolution and movement of particular objects. The MOCCA code is extremely fast. It needs about a day to complete an evolution of a real size globular cluster. So, instead of just one N-body model, hundreds or thousands models can be computed with different initial conditions. The MOCCA code is ideal either for dynamical models of a particular cluster or for large surveys.

The MOCCA SURVEY DATABASE I[2] contains about 2000 models of GCs with different initial masses, structural and orbital parameters. The brief description can be found on Fig. 1 and more details is given in Askar et al., Table I.[2]

As it was pointed out by Askar et al.,[2] it can be assumed that the MOCCA SURVEY DATABASE I cluster models are more or less representative of the Milky Way GC population.

## 3. Intermediate Mass BH Formation in GCs

In the literature, so far, there were four possible groups of scenarios proposed for intermediate mass BH (IMBH) formation in GCs: Direct collapse of very massive Population III stars proposed by Madau and Rees,[20] runaway merging of very massive MS stars in dense young star clusters, first discussed by Portegies Zwart et al.,[23] accretion of the residual gas on stellar mass BHs formed from the first generation stars recently proposed by Leigh et al.[19] and the scenario based on results of Mocca simulations of evolution of dense stellar systems proposed by Giersz et al.[12] In this scenario an IMBH is formed because of buildup of BH mass solely due to mergers in dynamical interactions and mass transfers in binaries. This scenario is a much expanded and refined scenarios proposed ealier by Miller & Hamilton[21] and by Leigh et al.[19]

In the Mocca Survey Database I there were about 460 IMBHs formed out of 2000 models, and they formed even in very low N models, as small as consisting of 40000 objects. As it is described in detail in Ref. 12 there are generally two regimes of IMBH formation: 1) very fast an IMBH mass buildup (FAST) starting from the very beginning of the cluster evolution, which requires very large initial central densities. In a time of about one Gyr, an IMBH mass grows to up a few tens of thousands $M_{\odot}$, and 2) slow IMBH mass buildup (SLOW) starting later on in the cluster evolution, usually, around the core collapse. It requires rather moderate initial central densities, and masses of IMBHs are quite moderate, from a few hundred up to a few thousand $M_{\odot}$. The process of IMBH formation is highly stochastic. The larger the initial cluster concentration, the earlier, faster and with higher probability an IMBH will form.

Here is the detailed, slightly updated comparable to Ref. 12, description of the FAST and SLOW scenarios:

(1) SLOW and FAST formation scenarios;

   (a) SLOW scenario - either a single BH is left after the early phase of SN explosions (SNe), or a single BH is formed via mergers or collisions during dynamical interactions, usually around the core collapse time. The central density has to be greater than about $10^5\ M_{\odot}/pc^3$;
   (b) FAST scenario - several dozen/hundreds BHs remain in the system after the early phase of SNe, and form a dense central subsystem. The central density must be extremely high, greater than $10^8\ M_{\odot}/pc^3$, for an IMBH to form. Alternatively, all BHs are quickly and efficiently removed from the system via dynamical interactions. If at least one remains, then the SLOW scenario is followed;

(2) Initial mass buildup of IMBH progenitors:

   (a) If the cluster density is large enough, the collisions between main sequence (MS) stars lead to formation of very massive MS stars, hundreds of $M_{\odot}$. If

such a star collides with a BH then a very massive BH (already an IMBH) is formed.
   (b) If cluster density it is not large enough MS does not collide efficiently and stellar mass BH will be formed, because of stellar evolution and strong stellar winds.

(3) BHs are the most massive objects in GC, so they quickly form a binary via a three-body interaction;
(4) Further BH binary evolution is due to dynamical interactions with other binaries and stars, or because of gravitational wave radiation (GW);

   (a) orbit tightening leading to mass transfer from MS/Red Giant/Asymptotic Giant Branch companions;
   (b) exchanges and collisions, leaving the binary intact;
   (c) total collisions during dynamical interactions or GW mergers - in this case, the binary is destroyed and only a BH is left;

(5) Newly created single BH quickly forms a new binary via another three-body interaction, which is further free to undergo subsequent dynamical interactions with other single and binary stars, and the process repeats. In this way, the BH mass steadily increases.

Total collisions are the most important ingredient of an IMBH formation in the SLOW scenario. In this way BH mass can steadily increase and BH binaries are not kicked out from the system due to dynamical three- or four-body interactions. That is the reason why IMBH formation is so stochastic in the SLOW scenario.

As it can be seen in Fig 2, there are clearly visible two channels of dynamical interactions leading to formation IMBH seeds: runaway MS star mergers and BH formation because of collisions with a BH, and runaway mergers and BH formation because of pure stellar evolution. The larger the cluster density the larger the maximum mass of runaway merged MS star and consequently the larger the BH mass (collision product of stellar mass BH and very massive MS star). Less dense models form lower mass BHs, which later in the course of evolution will substantially grow. Very massive BHs are preferentially formed for very dense models at the very beginning of the cluster evolution. We should here caution readers, the above picture relies on very uncertain properties and evolution of extremely massive MS stars formed in runaway collisions and on the amount of accreted mass onto stellar mass BH during collision with extremely massive MS star. Such collision is more similar to the common envelope phase than to direct collision of similar mass BHs and a MS stars, in which probably only small amount of mass can be accreted onto BH. We checked, that in the case of only 10% of accreted mass an IMBH is still formed, so the FAST scenario seems to work in real physical systems.

We would like to stress that the presented scenarios for IMBH formation in GCs, in particular the SLOW scenario, do not require any specific conditions, unlike

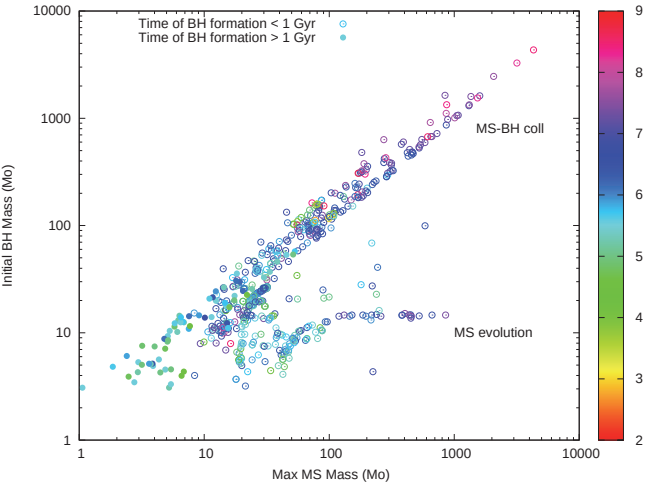

Fig. 2. Mass of just formed BH as a function of mass of MS star just before a supernova explosion. Open circles - formation of BH before 1 Gyr. Filled circles - formation of BH after 1 Gyr. The color bar on the right side shows the initial cluster central densities in $M_{\odot}/pc^3$.

other scenarios proposed in the literature. IMBH formation occurs solely via binary dynamical interactions and mass transfer in binaries. The FAST scenario is more probable to occur in galactic nuclei, or in extremely dense star clusters.

## 4. BH-BH Merger Gravitational Wave Radiation Kicks

We used Mocca Survey Database I to estimate GW kick retention fraction of BH-BH merger products. We found about 4500 such mergers. The amplitude of the GW recoil kick velocity depends on the spin magnitudes, degree of misalignment between BH spins and the binary angular momentum and on the BH mass ratio. The kick velocities were calculated according to Ref. 3 and final spins according to Ref. 24. We checked many different assumptions about the BH spins: random, constant equal to 0.5, or a function of metallicity and initial stellar mass.[6] There are two classes of mergers: mergers in 'primordial' binaries (binaries which keep the same stars during the whole evolution), which have only small spin misalignments, and 'dynamical' mergers in binaries which were involved in strong interactions, e.g. exchanges or disruptions, for which spin directions were distributed randomly. The evolution of each BH was tracked. Each product of BH-BH merger, also a BH, was assigned with a recoil kick velocity. Merger products with velocities greater than the cluster escape velocity were removed from any further interactions. Those merger products that remained in the cluster were assigned with a modified spin value, computed according to Ref. 24, and could contribute to next generations of

BH-BH mergers. 'Dynamical' mergers were mainly mergers with IMBHs and have small mass ratio, so nearly 0.7 of them were retained in the system. For 'primordial' binaries the retention fraction seems to saturate at about 0.2. This is connected with the fact that most 'primordial' BH-BH binaries consist of low mass BHs, which according to Belczynski et al.[6] have large spins. On average, we should expect that about 0.3 mergers will be retained in the system. This result does not strongly depend on the assumed initial BH spin distributions.

The retention fraction is a strong function of time. In the case of 'dynamical' mergers, it is changing from the initial values of 0.5-0.6, when the IMBH mass is still relatively small, and steadily increasing up to 0.9 in the later stages of the cluster evolution, when the mass ratios in IMBH-BH mergers drop down to 0.01 - 0.001 values. The retention fraction for 'primordial' binaries substantially increases after about 1 Gyr due to decrease of the mass ratio. It seems that first binaries with mass ratio close to 1 are merged and later on binaries with smaller and smaller mass ratios start to merge. The retention fraction for models with BH subsystems is very small and equal to about 0.1. This is because such models have relatively low concentration and low escape velocity. There is a clear correlation, the larger the cluster concentration the larger the retention fraction. Interested readers, we refer to the paper by Morawski et al.[22] where they can find all details connected with this work.

We would like to stress that our results confirm analytic and semi-analytic results obtained earlier by many authors, but for the first time real simulation data was used to obtain the BH merger retention fraction and its dependence on the different cluster evolutionary scenarios and global cluster parameters. This approach is not fully self consistent, but it is the first step to fully integrate BH merger kicks in dynamical evolution of GCs.

## 5. Tidal Disruption Events with IMBHs

Formation of IMBHs in the MOCCA models and their subsequent mass buildup have to be connected with tidal disruption of star intruders, so called tidal disruption events (TDEs). We analyzed the Mocca Survey Database I looking for disruptions of white dwarfs (WD), MS stars or other luminous stars. We found 344755 WD-IMBH type events, 750753 MS-IMBH type events and 42934 other-IMBH type events. The work is still in progress and we would like only to summarize briefly a very preliminary results. Most TDEs are formed in massive GCs with relatively small galactocentric distances. To form an IMBH in the FAST scenario a very large central density is needed. Such density can be achieved easily in massive GCs with small tidal radii (small galactocentric distances). Due to dynamical friction, some of such GCs will migrate towards to galactic center and merge with the nuclear cluster (NC). From that point, our models of GC evolution are no longer applicable. Interestingly, any TDE events associated with IMBHs hosted by those

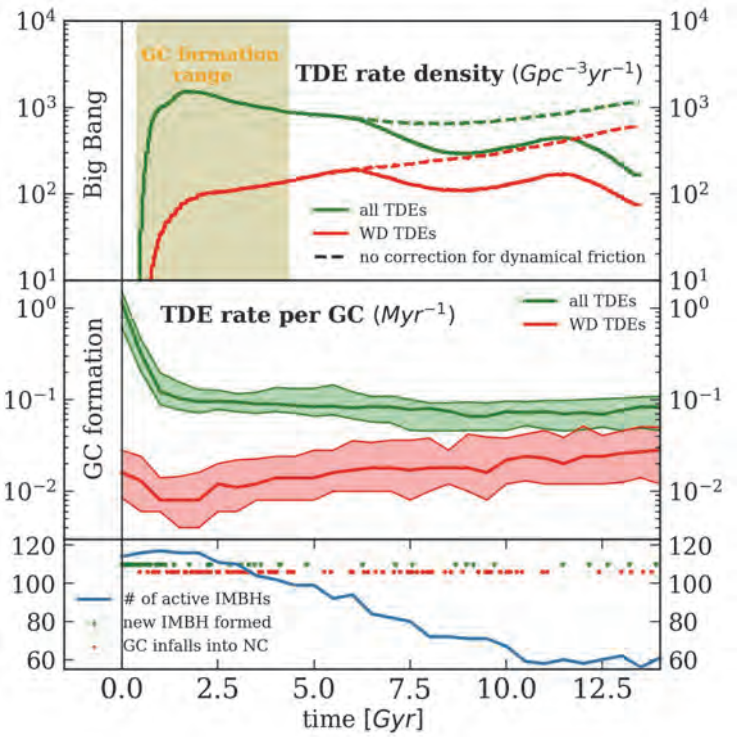

Fig. 3. The TDE rates as a function of the GC age. Red lines - rates for WDs. Green lines - rates for WDs and MS stars. Dashed line - for all models, solid line - only for models which do not migrate to the galactic center. Top panel - TDE density rate ($Gpc^{-3}yr^{-1}$). Middle panel - TDE rate per GC ($Myr^{-1}$). Bottom panel - number of active GCs. Red dots - time when GC merge with nuclear star cluster, green dots - time when new IMBH is formed.

GCs would be observable in the galactic nuclei. In any case, in order to calculate the IMBH TDE rate in actual GCs we exclude from our computations those GC models that have fallen into the NC. In the Fig. 3 we show the TDE rates computed assuming that all TDEs outside the galactic center can be observed. Present day TDE rate density is smaller by factor of about 3–4 when the evolution of GCs in the galactic environment (in a Milky-Way type galaxy) is taken into account. Also the number of "active" GCs in which TDEs are happening is much smaller now than was, showing strong influence of galactic environment on the observed TDEs. Interestingly, IMBHs formed in the SLOW scenario are responsible for only a small fraction of possible TDEs. The obtained TDE rates are comparable to other theoretical estimates.

In the future work we are planning to populate galaxies in the local universe with MOCCA GCs models and estimate the local TDE rates.

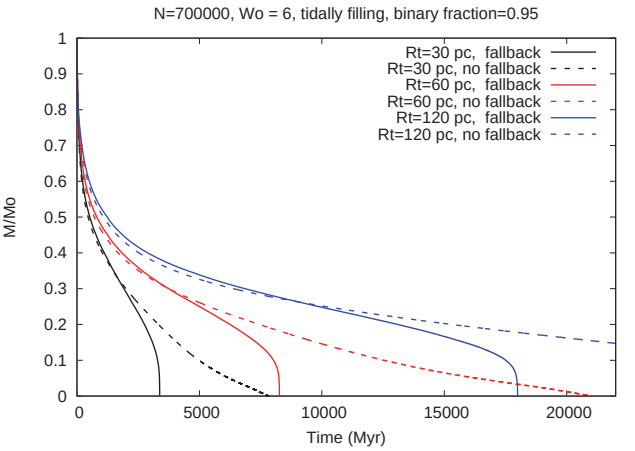

Fig. 4. Evolution of the fraction of cluster bound mass as a function of time for tidally filling Mocca cluster models with 700000 objects (stars and binaries), $W_0 = 6$ and binary fraction equal to 0.95, for different tidal radii and SNe natal kicks mass fallback set to ON or OFF.

## 6. BH Subsystem and a Third Cluster Dissolution Mechanism

We used the Mocca Survey Database I to investigate the dissolution process for dynamically evolving star clusters embedded in an external tidal field, with focus on the presence and evolution of a stellar-mass BH subsystem. We argue that the presence of a BH subsystem can lead to the dissolution of tidally filling star clusters and this can be regarded as a third type of cluster dissolution mechanism, in addition to well known mechanisms connected with strong mass loss due to stellar evolution and mass loss connected with the relaxation process. As it can be seen in Fig. 4 for models with mass fallback ON (high BH retention fraction), the third process is characterized by abrupt cluster dissolution connected with the loss of dynamical equilibrium. The abrupt dissolution is powered by the strong energy generation from a massive stellar-mass BH subsystem accompanied by tidal stripping. We argue that such a mechanism is universal and should also work for tidally under-filling clusters with top-heavy IMF. Observationally, star clusters which undergo dissolution powered by the third mechanism would look as 'dark clusters' i.e. composed of stellar mass BH surrounded by expanding halo of luminous stars,[4] and they should be different from 'dark clusters' harbouring an IMBH as discussed by Ref. 1. An additional observational consequence of an operation of the third dissolution mechanism should be larger than expected abundance of free floating BHs in the Galactic halo. Interested readers, we refer to the paper by Giersz et al.[9] where they can find all details connected with this work.

For the first time we detected microlensing events at zero latitude in the Galactic bulge using the VISTA Variables in the Vía Láctea Survey (VVV) data.[9] We have discovered a total sample of $N = 630$ events within an area covering 20.7 sq. deg.[11,12] Using the near-IR color magnitude diagram we selected $N = 291$ red clump sources, allowing us to analyse the longitude dependence of microlensing across the central region of the Galactic plane. We thoroughly accounted for the photometric and sampling efficiency. The spatial distribution is homogeneous, with the number of events smoothly increasing toward the Galactic center. We find a slight asymmetry, with a larger number of events toward negative longitudes than positive longitudes, that is possibly related with the inclination of the bar along the line of sight. We also examined the timescale distribution which shows a mean on $17.4 \pm 1.0$ days for the whole sample, and $20.7 \pm 1.0$ for the Red Clump subsample

*Keywords*: Gravitational lensing: microlensing — Galaxy: bulge — Galaxy: structure.

## 1. Introduction

Gravitational microlensing is a geometrical effect related to the apparent increase in the brightness of a background source by an object (lens) located sufficiently close to the line of sight.[13] This effect is useful to detect objects independently of their intrinsic brightness, with a wide range of masses from planets to black holes.

The main surveys dedicated to detect microlensing events in the galactic bulge are the Massive Astrophysical Compact Halo Objects (MACHO),[2] the Optical Gravitational Lensing Experiment (OGLE),[16] the Microlensing Observations in Astrophysics (MOA),[4] the Expérience pour la Recherche d'Objets Sombres (EROS),[3] the Disk Unseen Objects (DUO),[1] the Wise Observatory[14] and the Korean Microlensing Telescope Network (KMTNet).[7,8]

Although a large number of events have been discovered, it is not possible to study the plane of the Milky Way ($|b| < 2°$) with these optical surveys due to the

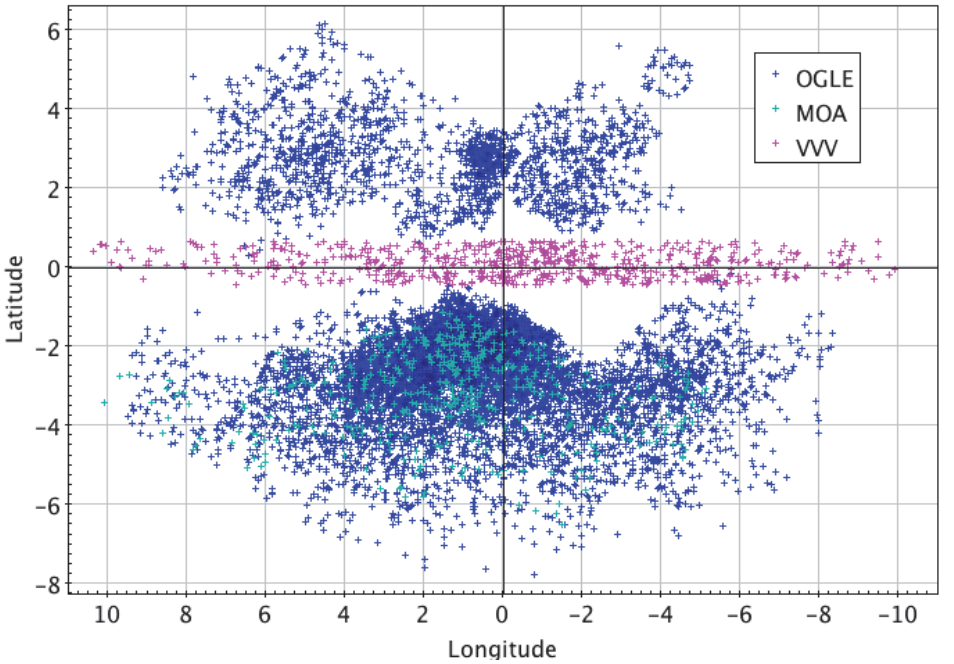

Fig. 1. Spatial distribution of the VVV microlensing events presented in this work (magenta crosses) around the Galactic center. The blue crosses are the microlensing events from the OGLE Early Warning System (EWS, http://ogle.astrouw.edu.pl) and the cyan crosses are the microlensing events discovered by MOA. All of the events happened between 2010 and 2015. Figure from Ref. 12 reproduced with permission.

high extinction and crowding. However, the Galactic plane is especially interesting because, as the density of stars increases, we expect to find microlensing events in large quantities.[19]

The only way to study the plane of the Galaxy is through observations in infrared bands. Motivated by this, we carried out the first systematic search of microlensing events at low latitudes using the *VISTA Variables in the Vía Láctea Survey* (VVV).[9] We analysed 14 VVV tiles (from b327 to b340) covering a large area within $-10.00° \leq l \leq 10.44°$ and $-0.46° \leq b \leq 0.65°$. The 3 innermost tiles (b332, b333 and b334) were published in Ref. 11. The other 11 tiles are presented in Ref. 12.

## 2. The VVV data

The *VISTA Variables in the Vía Láctea Survey* (VVV)[9] is an ESO public survey scanning the Milky Way bulge and adjacent section of the southern mid-plane in the near-infrared. Using the Visible and Infrared Survey Telescope for Astronomy (VISTA) 4-meter telescope located at ESO Cerro Paranal Observatory in Chile.

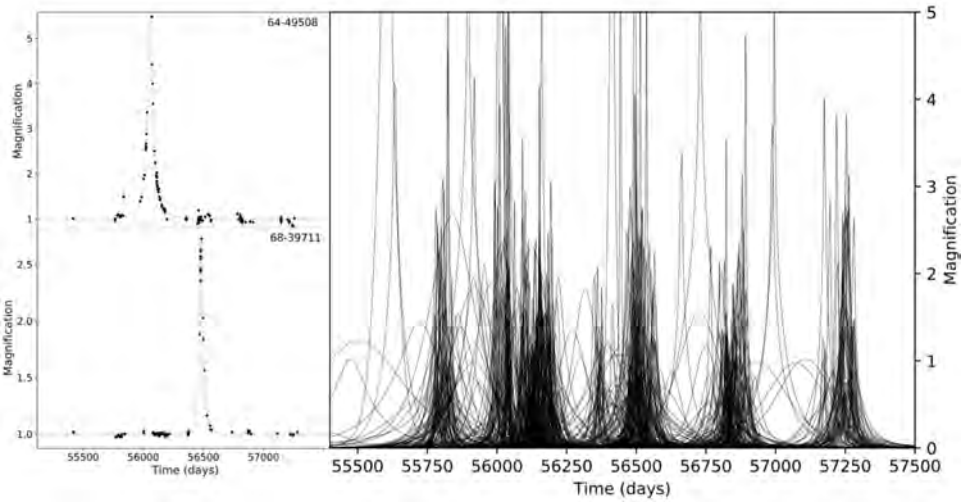

Fig. 2. Left: Examples of two typical microlensing event light curves. Right: Fits to all 630 microlensing events discovered between 2010 and 2015.

The area studied comprises $63 \times 10^6$ light curves for individual point sources and a multi-epoch campaign in the $K_s$-band ($K_s < 17.5$mag) with $\sim 90$ epochs spanning six seasons of observations (2010–2015). The PSF photometry was carried out using DAOPHOT II/ALLSTAR package.[5] The search procedure was done using the standard microlensing model, i.e., considering sources and lenses as point-like objects.

## 3. VVV Microlensing events

Initially we found 182 microlensing events in the three innermost tiles (b332, b333 and b334), with an excess in the number of events in the central tile and a relatively large number of long timescale events (with $t_E > 100$ days). We extended the sample in order to study in greater detail the behaviour along the Galactic longitude. The final sample consists of 630 microlensing events within $-10.00° \leq l \leq 10.44°$ and $-0.46° \leq b \leq 0.65°$. The complete sample is shown in Fig. 1 along with the OGLE and MOA events discovered during the same period. Fig. 2 shows all of the microlensing fits as well as two typical light curves. The animation that shows the microlensing events detected during the operation of the VVV survey is available online.[a] In the upper panel an image of the studied area is shown and the flash corresponding to each microlensing event detected in their respective positions. The intensity of the flash is associated with the amplitude. In the lower panel this figure

[a] https://www.youtube.com/watch?v=Uv08EAKVSQo

is reproduced as a function of time. The different colors correspond to the tile of each event and therefore are related to its position.

The events show a homogeneous distribution, smoothly increasing in numbers towards the Galactic centre, as predicted by different models due to the high stellar density. Considering that we expect to find a smaller amount of microlensing events due to the extreme extinction and crowding,[17] the increase in the number of events towards the center of the galaxy is expected to be even more peaked. Additionally we found an asymmetry in the density distribution with a higher number of events ($\sim 60\%$) at negative Galactic longitudes, this can be explained by the inclination of the bar along the line of sight.

Red Clump (RC) sources are low-mass stars that are burning Helium in the core. The study of the sources located in the RC is more reliable because they are more localised in the Color-Magnitude Diagram (CMD) and we can assume that they belong to the bulge. Consequently, using the near-IR Color-Magnitude Diagram we selected the Red Clump sources to analyze the longitude dependence of microlensing across the central region of the Galactic plane. Fig. 3 shows the CMD of the 14 VVV tiles along with the final sample of events. The red circles are the events located in the RC, corresponding to 46% of the sample ($N = 291$ events).

In order to study the timescale distribution it is crucial to implement an efficiency analysis. The photometric efficiency was performed using artificial star simulations for the RC stars.[17] The incompleteness is severe as we approach to the

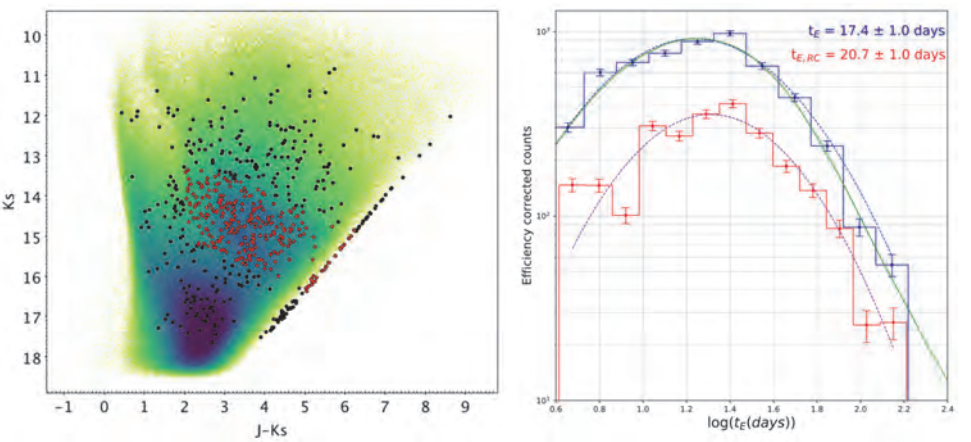

Fig. 3. Left: $K_s$ vs. $J$-$K_s$ color magnitude diagram for the 14 VVV tiles. The black circles are the microlensing sources, and the red circles are the red clump sources. Right: Efficiency corrected timescale distributions. The blue histogram is the distribution of the complete sample. The red histogram corresponds to the RC sources. Dashed lines show the best fit model of each histogram. The green shows the model proposed by Wegg et al.[18] normalised to the peak of our distribution. Figure from Ref. 12.

Galactic center, reaching values close to 40%. The sampling efficiency is cadence and timescale dependent, and was computed using Monte Carlo simulations for each fixed representative timescales with random impact parameters and times of maximum magnification. Due to the different cadence among the 14 tiles studied we performed the efficiency for each tile separately. With this analysis we conclude that the VVV Survey is limited by the sampling efficiency and is more efficient discovering long timescale events than short timescale events due to the large time coverage but low and irregular cadence.

The efficiency corrected timescale distribution is shown in Fig. 3 for the complete sample and for the RC sources. The mean timescale is $17.4 \pm 1.0$ days for the complete sample and $20.7 \pm 1.0$ days for the RC sources, in agreement with previous results. We also examined the timescale distribution for different longitudes, obtaining a clear decrease in the mean timescales as we approach to zero longitudes. A similar trend was previously reported by Wyrzykowski et al. 2015[19] but at higher latitudes using OGLE data.

## 4. Summary

We detected $N = 630$ microlensing events in the plane of the Galaxy using the VVV data. We performed for the first time a longitude analysis across the central Galactic plane at $b = 0$ deg. The spatial distribution shows a peak in the center as expected, although it is asymmetric, with more events towards negative longitudes.

The efficiency analysis demonstrates that the VVV survey is successful in detecting long/intermediate timescale events in highly reddened areas. Short timescale events are harder to find due to the low cadence of the survey (nightly at best). Our results can be complemented with other near-IR surveys to study the event rate, such as the UKIRT microlensing survey,[15] which is currently mapping the inner bulge with a higher cadence.

We computed the timescale distribution corrected by efficiency for the complete sample and RC sources. The distribution shows a peak consistent with previous measurements at higher latitudes in the bulge.

This study has many applications, from the study of the general behaviour of the complete microlensing population, to the study of specific events such as the events showing parallax effect, binary sources or lenses, as well as the very long timescale events which favor massive lenses (like black holes[10]). Furthermore, the analysis at very low latitudes is useful to optimise the observational campaign for the Wide Field Infrared Survey Telescope (WFIRST)[6] and to complement other recent near IR surveys.[15]

In this context, the study of a larger area is warranted to increase the statistics and in turn cover common areas with OGLE and MOA in order to complete a panoramic coverage of the event rates in the inner regions of the Milky Way.

We study the evolution of a massive primordial hard black hole binary (BHB) in small- and intermediate-size isolated star clusters, modelled as proxies of galactic open clusters (OCs), by means of direct $N$-body simulations. Some of our models show a significant hardening of the BHB in a relatively short time. Some of them merge within the cluster. The perturbation of stars around BHB systems is key to induce their coalescence. Under our assumptions, we estimate a BHB merger rate of $R_{\rm mrg} \sim 2$ yr$^{-1}$ Gpc$^{-3}$. In some cases the BHB triggers tidal disruption events which, however, are not linked to the GW emission.

*Keywords*: Galaxy: open clusters and associations: general – stars: black holes stars: kinematics and dynamics – gravitational waves.

## 1. Introduction

The Laser Interferometer Gravitational-Wave Observatory (LIGO) and Virgo have detected five sources of GWs[1–4] corresponding to a system of BHB.

BHBs, can form either (i) in the field in isolation and via stellar evolution of a binary of two extended stars[5] (ii) or via dynamical interactions in a dense stellar system[6,7] Here we focus on the evolution of primordial stellar BHBs in low-mass star clusters. In such models the impulsive effect produced by the stochastic, large, fluctuations of the field felt by stars, whose amplitude over the mean field is of order $\sqrt{N}/N$, can significantly affect the BHB dynamical evolution. This effect is also reflected in the two-body relaxation time scale which is short in such systems if compared for example to globular clusters. In addition, the relatively low number of stars of OCs gives the possibility to integrate the system upon a long evolution time without needing a rescaling of the results.

We shortly resume as follows the methods and results of the recent paper by Rastello et al. (2019).[8]

## 2. Method and Models

To study the BHB evolution inside its parent cluster, we used `NBODY7`,[9] a direct summation $N$-body code that integrates in a reliable way the motion of stars in stellar systems, with a careful treatment of strong gravitational encounters, taking also into account stellar evolution. We created four sets of simulations representing OC models at varying initial number of stars (Table 1, column 1). Each cluster is modelled assuming a Kroupa IMF and a Plummer density profile at virial equilibrium with a core radius $r_c = 1$ pc, and solar metallicity ($Z_\odot$). The OCs have

masses in the range 300 $M_\odot$ − 3000 $M_\odot$ (Table 1, column 2). For simplicity, we do not take into account primordial binaries. Then we assumed that each cluster host a primordial hard massive BHB composed by two BH of mass $M_{BH} = 30\ M_\odot$ each) that is initially placed in the OC centre. The initial BHB semi major axis is 0.01 pc and we considered two initial eccentricities, $e = 0$ and $e = 0.5$ (Table 1, columns 3 and 4). To give statistical significance to the results we generated 150 different realizations of every model, which are denoted with names A00, A05, B00, B05, C00, C05, D00 and D05, where the letter refers to increasing $N$ and the digits to the initial BHB orbital eccentricity. All models were evolved up to 3 Gyr, which is about 3 times the simulated OC relaxation time.

Table 1. Model main parameters.

| $N_{cl}$ | $M_{cl}$ ($M_\odot$) | $a$(pc) | e | name |
|---|---|---|---|---|
| 512 | $3.2 \times 10^2$ | 0.01 | 0.0 | A00 |

## 3. Dynamics of the black hole binary

### 3.1. *General evolution*

Our simulations show the existence of three main evolutionary scenarios for the fate of the BHB because of the gravitational interactions (Table 2): (i) the binary shrinks, becoming harder; (ii) the BHB gains energy, increasing its semi-major axis and, finally, (iii) the BHB can be disrupted.

We can see that, typically, about 90% of all binaries shrink their semi-major axis as they evolve (Fig. 1), as one can expect upon the so-called *Heggie's law* (softer binaries get softer while hard binaries get harder). In few of the studied cases, typically those of very low dense clusters (model A and B), the BHB becomes wider. Because of the initial choice of the BHB semi-major axis, gravitational encounters with other stars rarely *ionise* it, although we observe a few such events, typically below 7%.[8] This ionisations happen in the interval between $\sim$ 5Myr and $\sim$ 100Myr, usually driven by the encounter of the BHB with a massive star ($\gtrsim 10\ M_\odot$).[8]

## 4. Sources of gravitational waves

### 4.1. *Relativistic binaries*

The fraction of BHB coalescences in our simulations is $\sim$ 3%. In particular, in low density clusters, model A and B, the percentage of mergers is quite low,

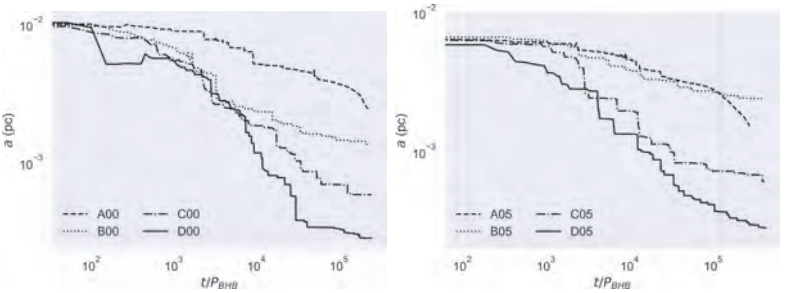

Fig. 1. Semi-major axis evolution in four of our simulations for initially circular and eccentric binaries.

Table 2. Percentage of BHBs (i) getting harder (col. 2); (ii) getting wider (col. 3) or (iii) break up (col. 4).

| Model | % Harder | % Wider | % Break up |
|---|---|---|---|
| A00 | 89.1 | 7.9 | 2.9 |
| A05 | 97.1 | 2.1 | 0.7 |
| B00 | 92.5 | 2.7 | 4.8 |
| B05 | 94.0 | 2.0 | 4.0 |
| C00 | 93.6 | 0 | 6.4 |
| C05 | 96.5 | 0 | 3.5 |
| D00 | 94.2 | 0 | 5.8 |
| D05 | 97.1 | 0 | 2.8 |

around 0.7%. As the mass (and the density) of the cluster increases, the number of relativistic mergers found is larger: 2.1% in model C00, 4.3% in C05 7.1% in D00 and 5.7% in D05. The majority of mergers occur in a time range between 5 Myr and 1.5 Gyr. As shown in Fig. 2, it is remarkable that the pericentre distances drop down to $7-8$ orders of magnitude with respect to the initial value. The eccentricities fluctuate significantly, episodically reaching values very close to unity. We found that about 50% of the mergers are mediated by a three body encounter with a perturber star which is thus a fundamental ingredient for BHB coalescence in low dense star clusters. An example of such mechanism is discussed as follows.

#### 4.1.1. *A detailed example of a merger event*

In order to check with accuracy the process of BHB coalescence upon perturbation, we followed the evolution of one of the allegedly merging BHB by mean of the few-body integrator `ARGdf`.[7] Based on the `ARCHAIN` code,[10] `ARGdf` includes a treatment of dynamical friction effect in the algorithmic regularization scheme, which models at high precision strong gravitational encounters also in a post-Newtonian scheme with terms up to the 2.5 order. We chose, at random, one of our simulations of the D00 sample to set initial conditions for the high precision evolution of a "pre merger" BHB considering its interaction with the closest 50 neighbours, number that we checked as sufficient to give accurate predictions at this regard.

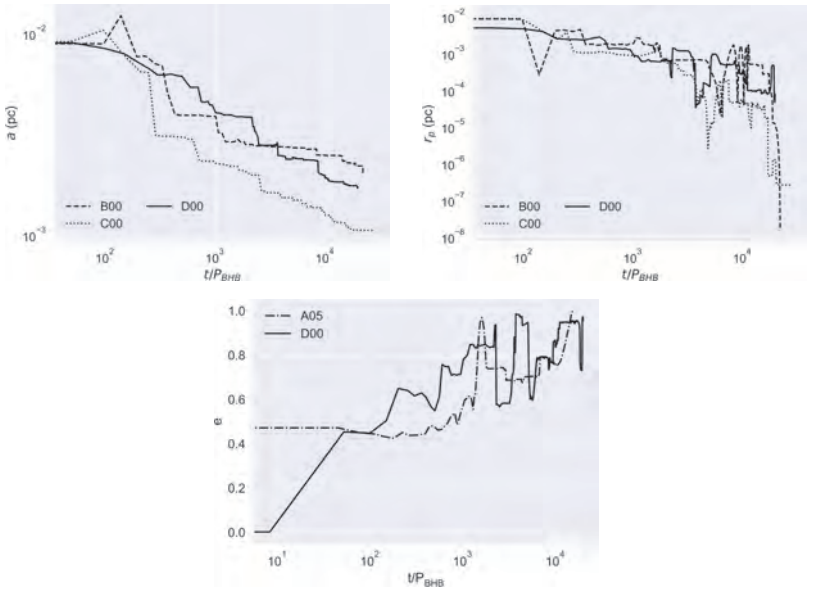

Fig. 2. Time evolution of the BHB semi major axis, pericentric distance, and eccentricity (from left to right, respectively) of some representative coalescence cases.

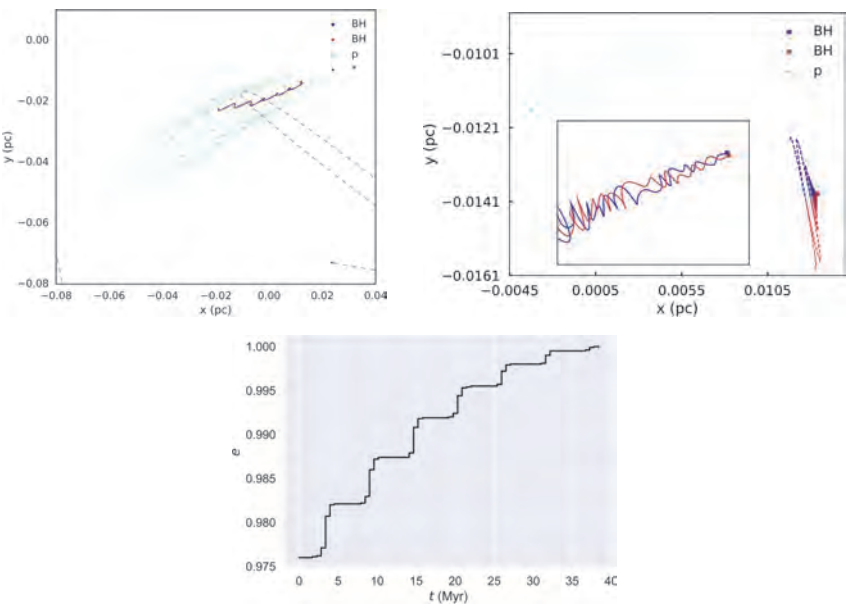

Fig. 3. *Left panel*: triple formation, *right panel*: zoom of the three body interaction, *bottom panel*: BHB eccentricity evolution.

This integration is a clear example of the relevance of dynamical interactions with other stars. Fig. 3 (*left panel*) is a snapshot of the BHB evolution and the formation of a triple system with a perturber star.[a] The BHB shrinks by interacting with such perturber, of mass 3.4 $M_\odot$, which is on a retrograde respect to the inner binary and with an inclination of 105° inducing an eccentric Kozai-Lidov mechanism. We note also a flyby star of mass 0.5 $M_\odot$ which interacts with the triple system (BHB & perturber). In Fig. 3 (*bottom panel*) we display the step-like increase of the BHB eccentricity, which is marked by the repeated interactions with the outer star. At any revolution of the perturber around the BHB we observe a step increasing of the eccentricity. On the contrary, this flyby is not sufficient to make a significant perturbation on the eccentricity evolution. Fig. 3 (*right panel*) sketches the evolution of the BHB latest orbits before the coalescence event. The plot in the rectangle is a zoom of the final part of the BHB trajectory (at its right side), spanning a length $\sim 10^{-7}$ pc. Therefore, in this particular case the triple system built up is the main ingredient that drives the BHB coalescence. A similar result is derived by Ref. 11 for low dense star clusters.

### 4.2. *Gravitational Waves*

In Fig. 4 we show the amplitude vs frequency of emitted gravitational waves for the case described in. 4.1.1 Using the last orbital parameters of the binary which correspond to the last integration made with `ARGdf`, we derive a coalescence time $T_{\rm mrg} \cong 7$ yrs. We have set the luminosity distance to that of the first source detected by LIGO,[1] which corresponds to a redshift of about $z = 0.11$. As described by the work of Chen & Amaro-Seoane (2017),[12] only circular sources are audible by LISA, which is "deaf" to eccentric binaries of stellar-mass black holes that emit their maximum power at frequencies farther away from LISA. Hence, this particular source would only enter the Advanced LIGO detection band.

### 4.3. *Merger Rate*

We estimate the merger rate following the prescription in Rastello et al., 2019[8], Sec. 4.5, Eq. (3) and Eq. (4). Assuming the total number of OCs in our Galaxy and the number of Milky way-like galaxies within redshift z = 1, we obtain a merger rate $\mathcal{R}_{\rm mrg} \approx 2{\rm Gpc}^{-3}\,{\rm yr}^{-1}$.

This estimate is however derived under the most favourable conditions, and thus represents the highest merger rate expected from low-mass OCs. Note that the BHB merger rate inferred from the first LIGO observations (GW150914) is in the range 2 - 600 $\rm Gpc^{-3}\ yr^{-1}$.[13] Our BHB merger rate is consistent with those found in Refs. 11, 14, 15 for BHB mergers in Young Massive Star Clusters. Although BHB mergers originating in open clusters-like systems might be less numerous than those

[a] An animation of the triple orbit and the eccentricity evolution is available at `https://youtu.be/zk8waNtubLk`.

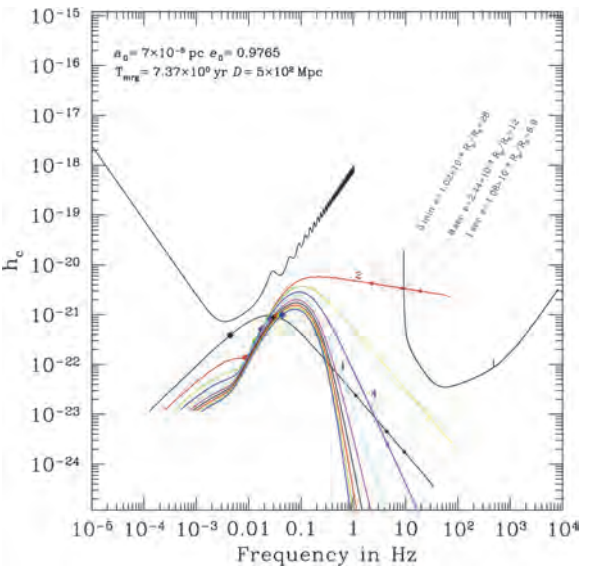

Fig. 4. Characteristic amplitude $h_c$ of the first most important harmonics for the model of described in Sec. 4.1.1 at a luminosity distance of $D = 500$ Mpc.

produced in massive star clusters, they would add a comparable amount to the BHB merger rate in the Universe because of their larger abundance.[11,15,16]

### 4.4. *Tidal Disruption Events*

As a serendipity outcome in our simulations, we found that in a few cases, the BHB disruption is mediated by a star, which binds to one of the two BHB former components.[8] The newly formed BH-star pair is characterized by a high eccentricity ($e > 0.9$) and a pericentre sufficiently small to rip the star apart and give rise to a tidal disruption event (TDE). Such events are however not linked to the BHB coalescence. In our models, TDEs involve either main sequence stars (MS), stars in the core He burning phase (HB) or in the early asymptotic giant branch (AGB) phase. Indeed, a component swap occurs in 28.5% of the cases, with the new companion star being swallowed by the heavier BH. Our findings suggest that X-ray or UV emission from OCs can be the signature of the presence of BHs with masses as high as $20 - 30$ M_$\odot$. Following the indications in Ref. 8 we found a TDE rate of $\Gamma_{\rm TDE} = 0.3 - 3.07 \times 10^{-6}{\rm yr}^{-1}$ per MW-like galaxies in the local Universe.

## 5. Conclusions

We studied the evolution of a primordial massive black hole binary in low density star clusters, and we derived that: (i) in $\sim$ 95% of the simulations performed, the BHB hardens (its semi-major axis reduces by 2 to 4 orders of magnitude) due to the repeated scatterings with flyby stars, while its eccentricity increases

significantly. This process takes place on a relatively short time-scale, $\sim$ 1 Gyr; (ii) in $\sim$ 1.2% of the cases, instead, the perturbations induced by massive stars that occasionally approach the BHB make it wider; (iii) in the remaining $\sim$ 4.8% cases, the interactions with OC stars are sufficiently strong to break up the BHB.

In $\sim$ 3% of the models, the star-BHB interactions are sufficiently effective to drive the BHB coalescence within a Hubble time. We find that a crucial ingredient to induce the BHB to merge is the interaction with a perturbing star, whose individual action considerably shortens the merger time. In our simulations, we see mergers take place in a time ranging from 5 Myr to 2.9 Gyr. In a few cases, the merging binaries emit GWs from the $10^{-3}$ to the 10 Hz frequency band. This suggests that merging BHBs in OCs can, potentially, be seen both by LISA, $\sim$ 200 yr before the merger, and LIGO, during the last phase preceding the merger.

Extrapolating our results to the typical population of OCs in MW-like galaxies in the local Universe, we found that the most optimistic merger rate for this type of BHB mergers in low-mass stellar systems is $\mathcal{R}_{\rm mrg} \sim 2$ yr$^{-1}$ Gpc$^{-3}$, a value compatible with the rate expected for galactic nuclei, but smaller than that inferred for globular clusters and young massive clusters.

Finally, we found that tidal disruption events in OCs would occur at a rate $\Gamma_{\rm TDE} = 3.08 \times 10^{-6}$ yr$^{-1}$ per MW-like galaxies in the local Universe.[8]

Nuclear Stellar Clusters are so dense stellar systems (containing up to $10^7$ stars in few parsec radius) that their dynamics cannot be followed with the high precision, direct summation available $N$-body codes over a long integration time. Here we present the main idea of our new computational approach to study the dynamics of the MW NSC exploiting the facilities of the high precision hybrid parallelized code NBODY6++GPU. This strategy will allow us to study the evolution of the NSC over its 2-body relaxation time with an acceptable numerical effort by mean of a massive computational platform.

*Keywords*: Stars: kinematics and dynamics; galaxies: black holes; galaxies: star clusters: general; methods: numerical.

## 1. Introduction

The Milky Way (MW) hosts a Super Massive Black Hole (SMBH) in its center, of mass of about $M_{SMBH} \sim 4 \times 10^6$ $M_\odot$ that is surrounded by a very dense stellar system: the Nuclear Stellar Cluster (hereafter MWNSC). The NSC is very massive ($10^6 - 10^7$ $M_\odot$) and luminous ($4.1 \times 10^7$ $L_\odot$) with a half-light radius of $\sim 4$ pc.[1,2] The density of the NSC is of the order of $\sim 10^7$ $M_\odot$ $pc^{-3}$.

A peculiarity of all NSCs known is that they always contain an old stellar population (age >1 Gyr), and most of them show also the presence of a young stellar population with ages below 100 Myr. This feature is probably connected with the NSC origin. According to the so called *in situ model*,[3] NSCs consist mostly of stars formed (locally) from radial gas inflow into the galactic center. On the other hand the *dry-merging scenario*[4,5] explains the origin of NSCs by massive clusters that migrated to the galactic center via dynamical friction and, further, merge to form a dense nucleus. Even if these models are still debated, there are many observational evidences which favor the dry merging model in case of dE galaxies and also in the case of the MW NSC.[6]

The MW NSC is the one we know better because we are able to observe with high resolution resolving many of its stars, so it constitutes a wonderful "laboratory" to study many astrophysical processes in the innermost Galactic region, within the SMBH influence radius, such as Tidal Disruption Events (TDEs) and Extreme Mass Ratio Inspirals (EMRIs).

### 1.1. *The Computational Challenge*

Despite the large quantity of works regarding the formation of NSCs, in literature there is a lack of material concerning their subsequent evolution.[7,8] This is mainly due to numerical problems because NSCs are so dense systems that their dynamics cannot be followed with high-precision, direct summation, available $N$-body codes.

The easiest way to model dense star clusters with a central massive black hole is the use of Fokker-Planck or Monte Carlo approaches, but these methods are severely approximated.[9] Actually, to achieve high accuracy and reliable results, it would me much better resorting on direct $N$-body simulations. Thanks to the recent improvements of the available $N$-body codes, it was possible to perform direct $N$-body simulation up to one million of stars[10] as done by Wang et al., (2016)[11] for globular clusters, or Panamarev et al. (2018)[12] for the Galactic centre, both using the code `NBODY6++GPU`.[10] Nevertheless, $N$-body simulations of star clusters remains very time consuming. Considering individual time-stepping, the computational cost per crossing time depends on the number of steps per particle, which varies with different time-step control criteria as well as on the integration method and star cluster properties.[10,11] Thus, an efficient parallelization of a direct $N$-body code is compulsory when dealing with large particle numbers. One of the best suitable codes for studying a very crowded star cluster as the MW NSC is `NBODY6++GPU`.[10] Such code is an MPI parallelization of the standard `NBODY6` code apt to an accurate integration of the movement of many bodies. It is optimal for collisional systems, where long times of integration and high accuracy are both required. `NBODY6++GPU` is designed to work across multiple nodes and, on a supercomputer, it allows to perform $N$-body simulations up to one million of stars. Our simulation tests and our future production simulations run on the super-computing cluster JUWELS (developed by Forschungszentrum Jülich Supercomputing Centre, Germany) qualified as the best German computer in the TOP500 list of the fastest supercomputers in the world, with a 12.6 Petaflops/s peak. It is composed by 2500 nodes equipped with Intel Xeon CPUs ($2 \times 24$ cores) and 48 nodes hosting 4 NVIDIA Tesla V100 GPUs each.

In the following section we present our planned implementation of the idea of one of the authors of this paper (RCD) as numerical strategy aiming to cope with the problem of the study of the evolution of a NSC towards relaxation with a portable numerical method and avoiding a mere re-scaling of short simulation results.

## 2. Numerical Strategy

In spite of its speed and efficiency, the `NBODY6++GPU` cannot deal with a NSC that hosts more than $\approx 10^7$ stars over many crossing times. So, some clever numerical strategy is needed which, at the same time, leads to a long term simulation run and a sufficiently high precision. A scheme of our "numerical approach" is shown in Fig. 1.

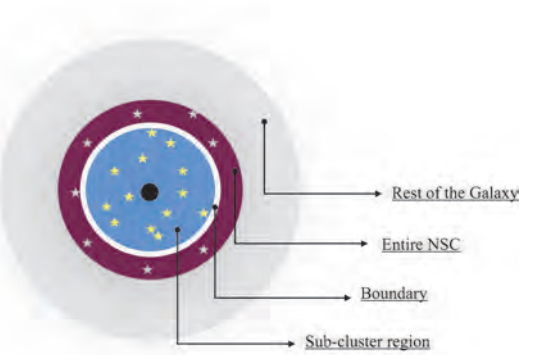

Fig. 1. Scheme of our approach (image is not to scale). The SMBH (central black circle) is surrounded by a light-blue region which corresponds to an NSC "sub-cluster" region, delimited by a (white) boundary. The magenta shell identifies the entire physical NSC. The (external) grey region refers to the external galactic components (nuclear bulge, bulge, halo and disk).

In the assumption of a "local" spherical symmetry in the NSC[a] star distribution, for computational convenience we consider a "sub-cluster" region of the NSC (light-blue region in Fig. 1) which contains approximately $N \sim 10^6$ stars (indicated in yellow in Fig. 1) which corresponds to the maximum number of stars that we can simulate with `NBODY6++GPU`. The boundary of the sub-cluster region is indicated by a white shell (Fig. 1) of radius $r_b$. The sub-cluster region is initially sampled from a Plummer density profile of solar metallicity stars whose masses follow the Kroupa IMF. The number of primordial binaries is assumed to be 5% of the total number of nuclear cluster stars. Stellar evolution is considered as implemented in the standard `SSE` and `BSE` tools.[13]

The entire NSC occupies the whole magenta sphere in Fig. 1. The dynamical role of stars which cross in or out the NSC region cannot be neglected to study the evolution of the entire NSC. Therefore to account for their contribute we developed a method described as follows:

- The boundary and the sub-cluster region are not physical limits and the stars can freely evolve across these regions. We keep track of the orbits of the stars that exit the sub-cluster region (moving through the magenta-ring) and re-enter either into the sub-cluster region or escape forever from it. This task is done by building up a proper *boundary condition* as described below.

[a]Since we are interested in the secular dynamical evolution of the MW NSC towards relaxation, the initial conditions for the $N$-body simulation are constructed assuming the dry-merger formation of the MW NSC.

We exclude or continue to consider in our computation stars that, on the base of their mechanical energy, are so energetic that they likely cross with no return within the $r_b$ boundary or, being less energetic, would actually re enter the boundary. These latter, indeed, will likely spend a time $\Delta t$ out of the sub-cluster region before re enter it. So, they are dynamically important for the global evolution of the NSC and need to be properly taken into account.

The "re-injection" of any, *i-th*, of these stars is done by a suitable estimate of the *re-enter* time $t_{re,i}$. Actually, in the hypothesis that outside the sub-cluster region the potential is spherically symmetric, the *i-th* object individual energy per unit mass is

$$E_i \;=\; \frac{1}{2}\,\dot{r_i}^2 \;+\; \frac{1}{2}\frac{L_i^2}{r_i^2} \;+\; U(r_i) \tag{1}$$

where $L_i$ is the specific angular momentum (per mass), $r_i$ is the norm of the position vector of the $i$-th-star, $U(r_i)$ is the gravitational potential.

An estimate of $t_{re,i}$ is obtained by computing

$$\Delta t_i \equiv\; 2\int_{r_b}^{r_{apo}} \frac{dr}{\sqrt{2\,E_i - \frac{L_i^2}{r_i^2} \;- 2\,U(r_i)}}, \tag{2}$$

where $r_{apo}$ is the star apocenter distance off the sub-cluster region.

As known, the apocenter distance is solution for $r_i$ of the equation:

$$E_i \;-\; \frac{1}{2}\frac{L_i^2}{r_i^2} \;-\; U(r_i) \;=\; 0. \tag{3}$$

After determination of $t_{re,i}$, we need to assign to the $i$-th-star a position and a velocity at the crossing of the boundary. We randomly derive the new position and the new velocity of the stars when it re-enters the boundary surface. In particular, in the acceptable assumption that the $i$-th-star feels out of the $r_b$ boundary only a smooth gravitational potential, we have that the norm of its velocity when it re enters the boundary is identical to the one when it exited. The orientation of the velocity vector at re-enter is done by extracting the velocity radial component ($v_{r,i}$) an inclination $-\pi/2 < \phi < \pi/2$ with respect to the plane tangent to the re-enter point on the boundary sphere.

- In our representation of the nuclear star cluster we need also to take into account stars that cross the boundary region coming from outside. If we have information on the distribution function $f(\mathbf{r}, \mathbf{v})$ of the stellar system at the boundary we can use it to sample velocity and position of such stars. Such stars, whose masses are distributed according to the chosen IMF, are indeed "inserted" within the sub-cluster region assigning them a randomly chosen initial position on the boundary.

Since the MWNSC is not an isolated system but it is embedded in Galactic environment we need to take care also of the other Galactic components. In the case of the MW center we face the interesting co-evolution of the NSC and the central SMBH, whose presence strongly influences the dynamical evolution of the entire MWNSC. According to our strategy the central SMBH is modelled as a fixed point-mass (Kepler) potential, $\mathrm{U}_{BH} = -GM_{BH}/r$. The mass, $M_{BH}$, of the SMBH is assumed 10% of the initial total mass of the NSC. Moreover, the central black hole is allowed to grow its mass via star capture within the accretion radius of. This is crucial when aiming to the study of events like tidal disruption of stars onto the central black hole.

The other, smooth, Galactic components are modelled as a Dehnen, a Miyamoto & Nagai and a logarithmic density profile, respectively, for the bulge, the disc and the halo.

In order to develop this numerical strategy we have modified the code `NBODY6++GPU` by implementing routines to ad an external potential for central black hole and unresolved stellar component and to let escaping stars return. Results of ongoing numerical simulations will be published elsewhere.

According to our current knowledge about physical and dynamical properties of the Milky Way-M31 system, it seems likely that these two galaxies will collide and eventually merge in a time very sensitive to initial conditions. Using the HiGPUs code[1], we have performed several numerical simulations to study the dynamics of the system, trying to define the role of indeterminacy in the present day observed relative velocities of the two galaxies and the time of the merger. At the same time, we have followed the dynamics of the two massive black holes sitting in the galactic centers, to check (within the space and time resolution limits of our simulation) their relative motion upon the completion of the galaxies merger process.

*Keywords*: Galaxy merger; supermassive black holes; Milky Way-Andromeda collision.

## 1. Purposes of the work

In this work we aim to follow the evolution of the "binary" system composed by our own galaxy, the Milky Way (MW), and the nearby Andromeda galaxy (M31). Observational data are currently not sufficient to strictly constrain the dynamics of this interaction and, therefore, a wide range of scenarios for their future evolution are possible. In any case, almost all of them imply an eventual merger between the two galaxies in a time which is very dependent upon parameters of the simulation.

In our study we considered a set of initial conditions spanning a range of values of the tangential component of the relative velocity of the MW and M31. This allowed us to quantify how these differences affect the interaction. A particular subtopic of relevant interest is the motion of the two massive black holes (SMBHs) known to be present in the two galaxies central regions, with especial regard to the last phase of the galactic merging process, when the two SMBHs are expected to form a close binary system. The results we obtained so far for the evolution of their orbits during the galaxies interaction, are interesting but the present simulation resolution is not enough to represent the very final stage, down to what is called the "final parsec problem".

## 2. Methods

For these simulations we have used the HiGPUs code[1], which performs direct $N$-body calculations exploiting a full parallelization on hybrid platforms (CPUs and Graphic Processing Units). So far, we have used a number of particles of order

$3.2 \times 10^4$, aiming to extend resolution by reaching, at least, one million of particles. Initial conditions are obtained with the code "GSAM" (Galaxy SAMpler), written by Arca-Sedda et al. (2015), and able to generate star clusters models with different density distributions. In our case the two galaxies are modelled according to a King density profile.

We have performed three different simulations at varying the transverse velocity of Andromeda as seen by the MW, keeping unchanged the other parameters.

In Table 1 all the initial parameters, common to the three simulations, are shown.

Table 1. Common initial conditions in the three simulations.

| | **Milky Way** | **Andromeda** |
|---|---|---|
| Mass ($M_\odot$) | $9.0 \times 10^{11}$ | $1.5 \times 10^{12}$ |
| $W_0$ | 6 | 6 |
| King radius $r_c$ (kpc) | 1.535 | 3.385 |
| Relative radial velocity (km/s) | $-120$ | |
| Initial separation (kpc) | 780 | |

## 3. Preliminary results

Modelling the two galaxies orbital evolution, we could investigate how the merger time changes at varying the relative initial transverse velocity ($V_{t0}$), as summarized in Table 2. Our results show that the great uncertainty on this kinematical parameter makes the time of merger undetermined for a factor $\sim 80$. Actually, a wide range of merger times are found in the literature: in some cases[4] a very low transverse velocity was reported ($V_{t0} \approx 17 km/s$), whereas in others[5] a value about 10 times larger, $V_{t0} \approx 164 km/s$. According to the most recent estimations[6] a reliable value seems $V_{t0} \approx 57 km/s$, but the level of uncertainty is still very large. For these reasons, our results are only indicative, as upper and lower limits. Moreover, in these present simulations the intergalactic medium (IGM) has not been considered, which, on its side, should act to reduce the time for the merger of the two galaxies.

Table 2. Time of the merger for the three initial tangential velocities of M31.

| $\mathbf{V_{t0}}$ **(km/s)** | **Time of the merger (Gyr)** |
|---|---|
| 20 | 6.7 |
| 50 | 108.8 |
| 80 | 544.6 |

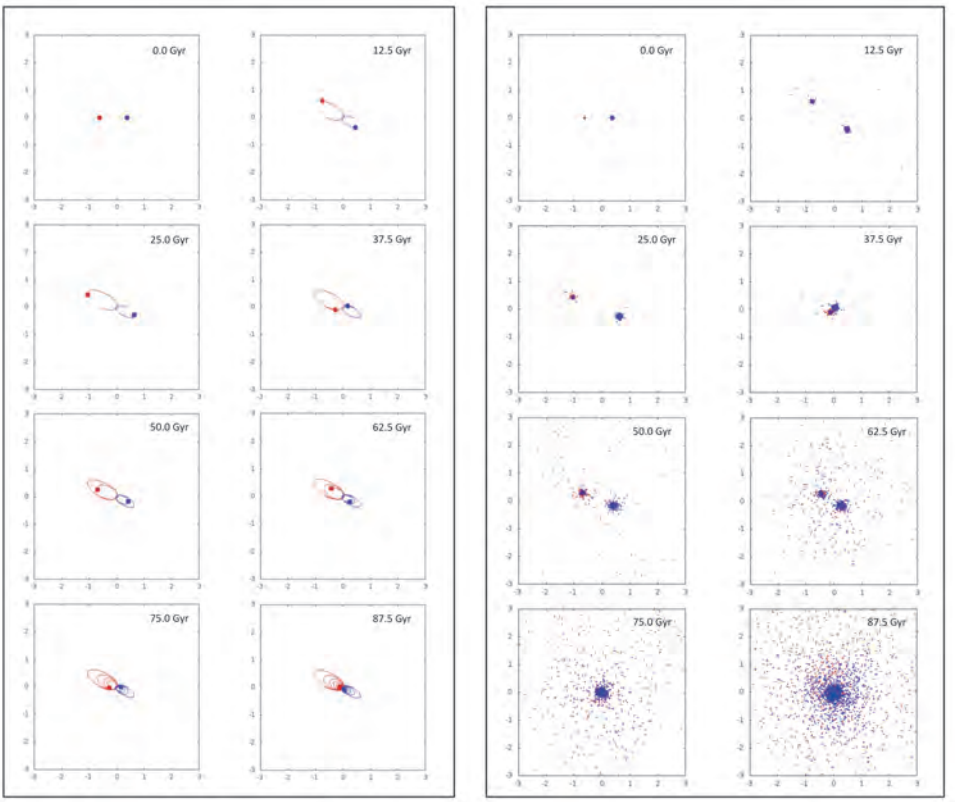

Fig. 1. Snapshots at various times of the configuration of the two BHs (left columns) and their host galaxies (right columns) in the case of $V_{t0} = 50 km/s$. Red colour refers to the Milky Way, blue to Andromeda. The unit of distance is 780 kpc. The time interval between each snapshot is 12.5 Gyr.

Figure 1 plots some snapshots of the merging process in the case with $V_{t0} =$ 50 km/s: in the left panel we show the relative motion of only the two central SMBHs while, on the right, the two interacting galaxies are shown.

We have plotted in Fig. 2 the time evolution of the distance between the two SMBHs in the three cases of $V_{t0}$ examined. It should be noticed that, after the merger of their host galaxies, the two SMBHs keep orbiting around each other at almost constant distance (roughly circular orbit). The reason why the SMBHs binary does not experience a further shrink is due to the loss of efficiency of gravitational encounters, because, due to unsufficient number of simulation particles, there are too few "stars" enclosed within the scale the two SMBHs are orbiting. This means that to reproduce satisfactorily the inner dynamics of the SMBHs binary we need at least a factor 10 larger $N$.

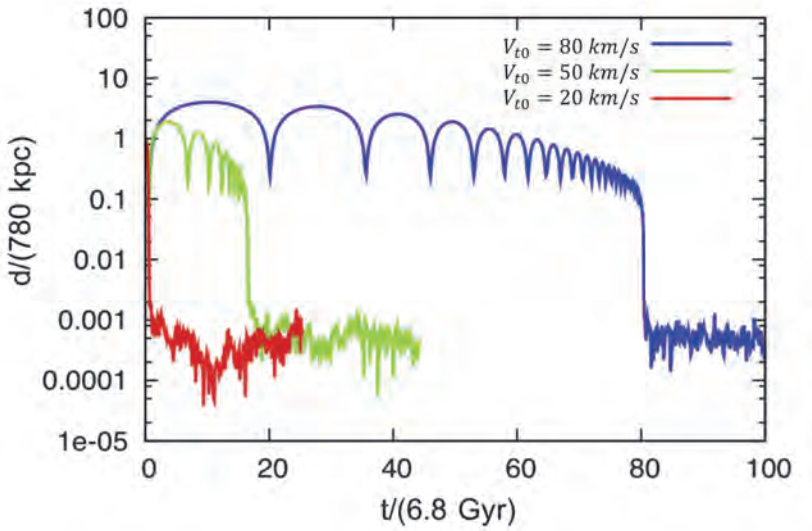

Fig. 2. Distance between the two BHs as function of time, for three different initial tangential velocities.

Anyway, an interesting result is that the distance at which the binary stalls (around 300 pc) seems to be independent of the initial tangential velocity, because it likely depends only on $N$ and not on the other initial conditions.

## 4. Tentative Conclusions

This short note reports some of our current work on the dynamics of the future merging process of our Galaxy and Andromeda. Since the tangential velocity of Andromeda is not precisely constrained by observations, we decided to perform three simulations varying this parameter. Depending of this, we have found that the time of the merger results great. This is partly due to that in these preliminary simulations we did not consider the role of the intergalactic medium, which, according to some previous simulations[3], can speed up significantly the merger process, via dynamical friction.

The relative motion of the two central SMBHs shows a regular behaviour on a large spatial scale, but we should increase the resolution to extend reliably the study also to the innermost region of the new cluster formed after the merger. Actually, we are planning other simulations with larger values of $N$, extending the range of values for $V_{t0}$, and with the inclusion of the intergalactic medium dynamical friction effect.

The recent detection of a binary neutron star merger by the LIGO and Virgo collaborations (LVC) and its corresponding electromagnetic counterpart from several astronomer teams marks the birth of multi-messenger astronomy [1]. Due to the size of the sky localization from a GW signal only, which can span tens to thousands of square degrees, there are significant benefits to rank the galaxies inside these large sky areas to maximize the probability of counterpart detection. Here we present a new procedure to query the galaxy catalogs, rank the galaxies and eventually define a prior for time allocation and scheduling algorithms.

## 1. Introduction

Multi-messenger astronomy demonstrated its scientific potential from the very first event observed via gravitational waves and via electromagnetic (EM) radiation, GW170817. The success of the observational campaign following GW170817 originates also from some lucky coincidences, beginning with the fact that this has been the closest event to Earth and with the highest signal to noise ratio (SNR) so far detected by the gravitational waves detectors. This helped significantly in localising of the source, as the skymap produced shortly after limited the area containing the source with 90% probability to just 28 deg$^2$, instead of the usual hundreds or thousands deg$^2$.

This typical large value of the 90% area of the skymap is due to the method used to identify candidates gravitational events using the coincident SNR to assign a value to the total SNR: the current strategy adopted by the pipelines used by LVC for online detection of a gravitational wave signal is to consider whether all the online detectors find a trigger with high SNR from the same template in each detector in a time window which is compatible with a gravitational wave traveling time between each other. While using the coincident SNR limits the computational costs and allows a quick identification of candidates events, it comes at the cost of neglecting some informations that could reduce the area of the 90% probability region.

Assuming that the triggers are due to a binary neutron stars gravitational wave signal coming from a certain galaxy, one expects to measure not only trigger times compatible with the traveling time of a gravitational wave between the detectors, but also coherence in phases and amplitudes of the signals recorded in each detector. The coherent SNR includes exactly these informations to assign a value to the total

SNR measured by the detectors network. Clearly, a full-sky search with coherent SNR is computationally more expensive than a full-sky search with coincident SNR, and therefore the latter is still currently preferred by the online detection pipelines.

Our idea is to use the coherent SNR only for a reduced number of points in the sky, identified by the galaxies inside the region at the 90% c.l. of the skymap produced by BAYESTAR, and subsequently rank the galaxies according to their value of coherent SNR. The computational costs are further reduced if we avoid to compute the matched filtering output for a template bank and use instead the SNR time series already produced by an online detection pipeline, such as the Multi-Band Template Analysis (MBTA) pipeline[2].

In the following we report preliminary results from a "proof of concept" analysis performed with the LaL code lalapps_cohPTF_inspiral.c[3], that worked for us to test the viability of our approach.

## 2. Coincident and coherent SNR

Following the standard matched filtering theory, given the output of the detector $i$, $s(t) = n(t) + h(t)$, we assume that the noise $n(t)$ is Gaussian and stationary and with power spectral density $S_n(f)$ defined as $\langle \tilde{n}(f)\tilde{n}^*(f')\rangle = \frac{1}{2}\delta(f-f')S_n(f)$. This is used to define the single detector inner product between two time series $a(t_0)$ and $b(t_0+t)$,

$$(a|b)(t) = 4\Re \int_0^\infty df\, \frac{\tilde{a}(f)\tilde{b}^*(f)}{S_n(f)} e^{-i2\pi ft}\,. \tag{1}$$

The odds of a signal $h$ being present in the data can be evaluated via the likelihood $\Lambda_h(t) = \frac{P(s|h)}{P(s|0)} = \frac{e^{-(s-h|s-h)/2}}{e^{-(s|s)/2}}$, and therefore the log-likelihood for the single interferometer takes the form

$$\ln \Lambda_h(t) = (s|h)(t) - \frac{1}{2}(h|h)(t)\,. \tag{2}$$

This allows us to define the SNR time series for the waveform $h$ as

$$\rho_h^2(t) = 2\ln \Lambda_h(t) \tag{3}$$

Consider now to have two detectors, $i$ and $j$. What a typical online detection pipeline does in order to identify interesting candidates is to compute $\rho_h(t)$ for each detector output $(s^i(t)\,, s^j(t))$ and for every waveform template within a template bank. If the time series $(\rho_h^i(t), \rho_h^j(t))$ of the same template $h$ exceed a fixed threshold $\bar{\rho}$ for times $(t_i\,, t_j)$ such that $|t_i - t_j| \leq d_{ij}/c$, where $d_{ij}$ is the distance between the detectors, then the pipeline denotes it as a candidate event with coincident SNR given by

$$\rho_{coinc} = \sqrt{[\rho_h^i(t_i)]^2 + [\rho_h^j(t_j)]^2}\,. \tag{4}$$

The coherent SNR can be defined from a straightforward generalisation to a multi-detector likelihood given by $\ln \Lambda_h(t) = (\mathbf{s}|\mathbf{h}) - \frac{1}{2}(\mathbf{h}|\mathbf{h})$, where we denote the

scalar product for multiple detectors $i$ as $(\mathbf{a}|\mathbf{b}) := \sum_i (a^i|b^i)$. Taking advantage of some peculiarities of the compact binaries coalescence signals we are interested into,[a] we can obtain a simple expression for the coherent SNR as

$$\rho^2_{coh}(t) = 2\max(\ln \Lambda_h(t)) = (\mathbf{s}|\mathbf{h}_\mu)\mathcal{M}^{\mu\nu}(\mathbf{s}|\mathbf{h}_\nu)\,, \tag{5}$$

where $h^i_\mu$ are given by

$$\begin{aligned} h^i_1(t) &= F^i_+(\theta^i,\,\phi^i,\,\chi^i)h_0(t)\,,\\ h^i_2(t) &= F^i_\times(\theta^i,\,\phi^i,\,\chi^i)h_0(t)\,,\\ h^i_3(t) &= F^i_+(\theta^i,\,\phi^i,\,\chi^i)h_{\frac{\pi}{2}}(t)\,,\\ h^i_4(t) &= F^i_\times(\theta^i,\,\phi^i,\,\chi^i)h_{\frac{\pi}{2}}(t)\,, \end{aligned} \tag{6}$$

$F^i_{+,\times}$ being the detector response functions to the plus (+) and cross (×) polarization components of the waveform.[b] The matrix $\mathcal{M}^{\mu\nu}$ depends only on the sensitivities and response functions of the detectors.

The computation of the matched filtering terms $(\mathbf{s}|\mathbf{h}_\nu)$ are responsible for most of the computational cost of the coherent SNR, but are precisely what MBTA computes for its independent task of online detection. Computing coherent SNR using MBTA output will simply consists in summing these time series, properly time-shifted depending on the galaxy within the skymap for which we want to estimate the coherent SNR.

## 3. Methods

We select about 90 gravitational wave sky localizations from Ref. 4 in which a triple detection is considered. The 90% confidence level for each probability skymap is build using the MOC (Multi Order Coverage map) method based on HEALPix sky tessellation[5]. MOC is a multi-scale mapping based on HEALPix sky tessellation. It is essentially a simple way to map irregular and complex sky regions into hierarchically grouped predefined cells. Each MOC cell is defined by two numbers: the hierarchy level (HEALPIX ORDER) and the pixel index (HEALPIX NPIX). The NUNIQ scheme defines an algorithm for packing an (ORDER, NPIX) pair into a single integer for compactness[6]. We compute the MOC region at a given probability level and subsequently, we query databases for retrieving objects whose position falls within this MOC map at 90% confidence level. The GLADE catalog is used in the analysis[7].

We compute the sky position of the maximum probability pixel defined by the BAYESTAR pipeline with the healpy package[8].

The values of component masses of the template with highest coincident SNR are passed to a script that prepares a single-template bank that is used for the

[a] The interested reader can find a detailed derivation in Ref. 9.

[b] These are given in terms of $h_0$ and $h_{\frac{\pi}{2}}$ by $h_+(t) = \mathcal{A}^1 h_0(t) + \mathcal{A}^3 h_{\frac{\pi}{2}}(t)$, $h_\times(t) = \mathcal{A}^2 h_0(t) + \mathcal{A}^4 h_{\frac{\pi}{2}}(t)$.

analysis. The template bank and the GPS times related to the each event are input of the function that computes the coherent SNR, lalapps_cohPTF_inspiral, looping over the selected galaxies from the GLADE catalog cutting at 1-sigma distance reported in the image's header[3].

## 4. Preliminary results

In a small fraction of our datasample (10 cases) the injection positions meet with the highest coherent-SNR values. This fact has motivated our investigation to set up a EM follow-up strategy. Two different strategies are planned to optimise a follow-up activity in a few minutes after the first rapid sky localization using the coherent SNR measured for the galaxies within the 90% c. l. The skymap tiling is performed by the GWsky tool[10].

### 4.1. *Strategy for telescope with a large Field of View*

We measure the sky distances between (i) the position of the injection and the position of the galaxy with the highest coherent SNR; Dist (inj - MAXsnr), with median = 6.6. (ii) the position of the injection and the maximum probability pixel; Dist (inj - MAXpix), with median = 9.7. The two distances are compared in Fig. 1. The distance Dist (MAXsnr - inj) is narrower. If the trend will be confirmed, the injection could be promptly imaged in a one/few tile(s) by centering the FoV telescope at the position of the maximum coherent SNR.

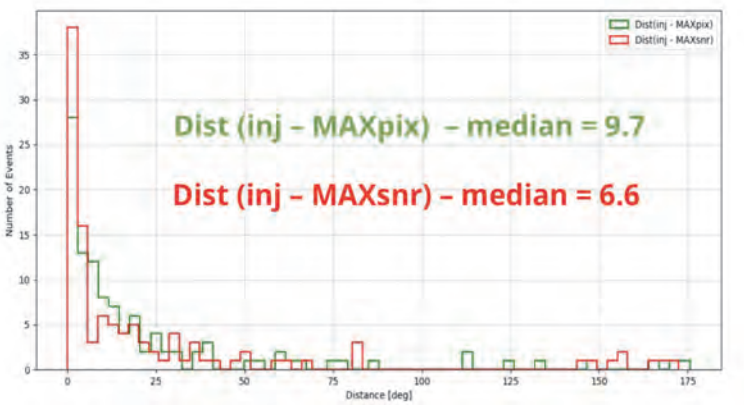

Fig. 1. Distributions of the angular distances between the true location of the injection and the pixel of maximum probability (green) or the galaxy with greatest coherent SNR (red). There is a mild indication of a better performance of our method.

### 4.2. *Strategy for telescope with a small Field of View*

We rank the coherent SNR from the highest value to the lowest value. The injection position in the rank is determined for testing. In 48 cases over 84 under examination, the galaxy target using the coherent SNR information captures the injection in a better position than galaxies localized in the confidence levels gradually growing. In Fig. 2, we show a case in which the injection is ranked at the position 3 using the the coherent SNR scenario while in the contour plots approach it is localized at the 41% c.l. in which 285 galaxies are distributed.

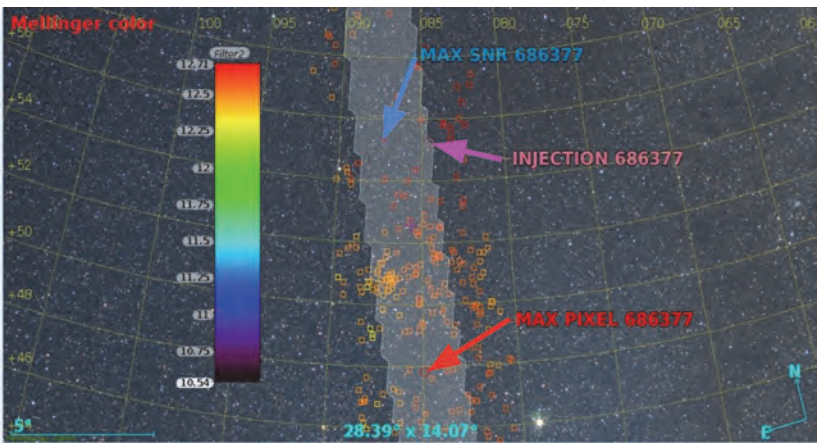

Fig. 2. A particular case in which the injection is ranked at the position 3 using the the coherent SNR scenario while in the contour plots approach it is localized at the 41% c.l. in which 285 galaxies are distributed.

## 5. Conclusion

We are testing our method to ensure its validity for a very large sample and to verify if it could significantly decrease the allocated time for an EM follow-up activity (or in which special cases, if there are). At this stage, we note a positive trend when the coherent SNR approach (measured for each galaxy in 90% c. l.) is applied to tile the skymap compared to the traditional contour- plot method provided in a rapid GW sky localization.

We are also preparing a separate code that implements this general algorithm on MBTA. Taking advantage of the matched filtering already performed by MBTA during the online search we expect to be able to obtain the rank of galaxies within few minutes from the trigger.

# Data analysis techniques to search for the stochastic gravitational-wave background

Giancarlo Cella*

*INFN sez. Pisa,*
*Largo B. Pontecorvo 3, 56127 Pisa, Italy*
**E-mail: giancarlo.cella@pi.infn.it*

A stochastic background of gravitational waves can be described basically as the superposition of several unrelated events, of cosmological or astrophysical origin. This is a generic definition: depending on specific cases the background can show a rich statistical structure, both in the space and time domain, and in principle several physical information of great interest can be extracted from it. I will discuss the features of this kind of signal, giving some details about how detection and parameter estimation procedures can be designed to obtain optimal performances.

*Keywords*: Gravitational waves; Data Analysis, Stochastic Background.

## 1. Introduction

A stochastic background of gravitational waves can be seen as a gravitational wave field which evolves from an initially random configuration, or equivalently as the result of a superposition of signals generated by many uncorrelated and unresolved sources.

Expected stochastic backgrounds can be of cosmological origin. They can be generated by several physical mechanisms in the early evolution of the Universe, such as inflation, phase transitions, cosmic strings. These are of great importance as they can carry information about early Universe[1].

A background can be generated also by astrophysical sources[2], such as for example compact binaries coalescences, supernovae, rotating neutron stars.

The stochastic background couples to a given detector which gives as an output a signal $s_i^{\mathcal{A}}$, modeled by a stochastic process. This is really the sum of a contribution coming from the background $h_i^{\mathcal{A}}$ and another given by the detector's noise $n_i^{\mathcal{A}}$, namely

$$s_i^{\mathcal{A}} = h_i^{\mathcal{A}} + n_i^{\mathcal{A}} \tag{1}$$

Here the capital index labels the detectors, and the lowercase one enumerate the data.

## 2. Detection

If we know the statistical properties of the stochastic processes $h_i^{\mathcal{A}}$ we can evaluate the possibility of detecting a stochastic background[3]. We suppose that the noises $n_i^{\mathcal{A}}$ are Gaussian stochastic processes. We do not make at this stage particular assumptions about the signals $h_i^{\mathcal{A}}$: they are described by some probability density $p_h(h_i^{\mathcal{A}}|\underline{\alpha})$ which depends by a set of parameters $\underline{\alpha}$. Then the probability density for

observed data can be written as

$$p_s(s^{\mathcal{A}}|\underline{\alpha}) = \mathcal{N} \int p_h(h^{\mathcal{A}}|\underline{\alpha}) \exp\left\{-\frac{1}{2}[\mathbb{C}_n^{-1}]_{ij}^{\mathcal{A}\mathcal{B}}(s_i^{\mathcal{A}} - h_i^{\mathcal{A}})(s_j^{\mathcal{B}} - h_j^{\mathcal{B}})\right\} \mathcal{D}h_k^{\mathcal{A}} \quad (2)$$

where $\mathbb{C}_h$ is the covariance array of the background. Using the Bayes theorem this can be converted to the probability density for the model parameters $\underline{\alpha}$

$$p_s(\underline{\alpha}|s^{\mathcal{A}}) = \frac{p_s(s^{\mathcal{A}}|\underline{\alpha})p(\underline{\alpha})}{\int p_s(s^{\mathcal{A}}|\underline{\alpha})p(\underline{\alpha})d\underline{\alpha}} \quad (3)$$

where $p(\underline{\alpha})$ is the prior for these. This can be used to infer the properties of the background from the data. For example marginalizing over non interesting parameters we can get the joint probability distribution between the one we are interested to. It is also, at least in principle, the starting point to design a detection test such as

$$\frac{\int p_s(s^{\mathcal{A}}|\underline{\alpha}_1; \mathcal{H}_1)p(\underline{\alpha}_1)d\underline{\alpha}_1}{\int p_s(s^{\mathcal{A}}|\underline{\alpha}; \mathcal{H}_0)p(\underline{\alpha}_0)d\underline{\alpha}_0} > \lambda \quad (4)$$

where $\mathcal{H}_1$ and $\mathcal{H}_0$ are the hypothesis of presence and absence of a background. This approach is however not commonly used because it leads to quantities which are difficult to manage: a simpler strategy will be discussed in the following.

### 2.1. *The Gaussian case*

We give some details for a Gaussian stochastic background, which is the simpler to analyze. In this case

$$p_h(h^{\mathcal{A}}|\mathcal{H}_1) = \mathcal{N}' \exp\left\{-\frac{1}{2}[\mathbb{C}_h^{-1}]_{ij}^{\mathcal{A}\mathcal{B}} h_i^{\mathcal{A}} h_j^{\mathcal{B}}\right\} \quad (5)$$

where $\mathbb{C}_h$ is the spectral covariance array of the stochastic background signal. The integral (2) can be computed explicitly in this case. However here we want to follow a different but almost equivalent approach. Given a network of detectors, we want to find a statistic of the form

$$\hat{Y} = \int \hat{\mathbb{Q}}^{\mathcal{A}\mathcal{B}}(\omega)\mathbb{S}^{\mathcal{A}\mathcal{B}}(\omega)d\omega, \qquad \mathbb{S}^{\mathcal{A}\mathcal{B}}(\omega) = s^{\mathcal{A}*}(\omega)s^{\mathcal{B}}(\omega) \quad (6)$$

with the best signal to noise ratio. We work in the frequency domain assuming a stationary background and we set $\hat{\mathbb{Q}}^{\mathcal{A}\mathcal{B}} = 0$ when $\mathcal{B} = \mathcal{A}$. The signal to noise ratio is given (when $\mathbb{C}_h \ll \mathbb{C}_n$) by

$$\frac{<\hat{Y}>}{\sqrt{<\hat{Y}^2> - <\hat{Y}>^2}} \simeq \frac{T\sum_{\mathcal{A}\neq\mathcal{B}} \int \hat{\mathbb{Q}}^{\mathcal{A}\mathcal{B}}(\omega)\mathbb{C}_h^{\mathcal{A}\mathcal{B}}(\omega)d\omega}{\sqrt{2T\sum_{\mathcal{A}\neq\mathcal{B}} \int |\hat{\mathbb{Q}}^{\mathcal{A}\mathcal{B}}(\omega)|^2 \mathbb{C}_n^{\mathcal{A}\mathcal{A}}(\omega)\mathbb{C}_n^{\mathcal{B}\mathcal{B}}(\omega)d\omega}} \quad (7)$$

where $T$ is the observation time. This is maximized by choosing

$$\mathbb{Q}^{\mathcal{A}\mathcal{B}}(\omega) \propto \frac{\mathbb{C}_h^{\mathcal{B}\mathcal{A}}(\omega)}{\mathbb{C}_n^{\mathcal{A}\mathcal{A}}(\omega)\mathbb{C}_n^{\mathcal{B}\mathcal{B}}(\omega)} \quad (8)$$

The statistic of $\hat{Y}$ is a Gaussian one, and we can compute the false alarm probability for a given threshold $\lambda$ as

$$P_{FA}(\lambda) = \int_{\lambda}^{+\infty} \mathcal{N}(x; \mu_0, \sigma_0^2) dx = \frac{1}{2}\mathrm{erfc}\left(\frac{\lambda - \mu_0}{\sqrt{2}\sigma_0}\right) \tag{9}$$

The detection probability can be obtained in the same way, by substituting the mean $\mu_0 = 0$ and the variance $\sigma_0$ of $\hat{Y}$ evaluated in absence of the signal with the analogous quantities $\mu_1$ and $\sigma_1 \simeq \sigma_0$ evaluated when the signal is present. The detection probability for a given false alarm can now be written as

$$P_D \simeq \frac{1}{2}\mathrm{erfc}\left(\mathrm{erfc}^{-1}\left(2P_{FA}\right) - \frac{1}{2}\sqrt{T\sum_{A\neq B}\int \frac{|\mathbb{C}_h^{\mathcal{AB}}(\omega)|^2}{\mathbb{C}_n^{\mathcal{AA}}(\omega)\mathbb{C}_n^{\mathcal{BB}}(\omega)} d\omega}\right) \tag{10}$$

Note that $\mathbb{C}_n^{\mathcal{AA}}$ is the noise power spectrum in the detector $\mathcal{A}$. The detection probability increases with the square root of the measurement time, and is reduced when there is a loss of coherence between the detectors. This coherence is usually described by the overlap reduction function

$$\gamma^{\mathcal{AB}}(\omega) \equiv \mathbb{C}_h^{\mathcal{AB}}(\omega) / \sqrt{\mathbb{C}_h^{\mathcal{AA}}(\omega)\mathbb{C}_h^{\mathcal{BB}}(\omega)} \tag{11}$$

which depends on the separation and orientation of the two detectors.

## 3. Models

We can write the observed background as a superposition of modes in some specific basis, for example

$$h_{ij}(\vec{x}, t) = \sum_P \int df \int d\Omega_{\hat{n}} A^P(\hat{n}, f) \epsilon_{ij}^P(\hat{n}) e^{i\frac{2\pi f}{c}(\hat{n}\cdot\vec{x} - ct)} \tag{12}$$

where the amplitudes $A^P(\hat{n}, f)$ are modeled as stochastic variables. Here the sum is over the polarizations $P$ and the integrals over frequencies and directions of propagation. In this way the background is described by a (multivariate) probability distribution $p\left(A^P(\hat{n}, f)\right)$ or equivalently by the amplitude's moments (we can safely assumed the first order one to be zero)

$$\left\langle A^{P_1}(\hat{n}_1, f_1) \cdots A^{P_k}(\hat{n}_k, f_k) \right\rangle \qquad k = 2, \cdots \tag{13}$$

The coupling between the background and a detector is given by

$$h^{\mathcal{A}}(t) = D_{ij}^{\mathcal{A}}(t) h_{ij}(\vec{x}^{\mathcal{A}}(t), t) \tag{14}$$

Here $D_{ij}^{\mathcal{A}}(t)$ is the detector tensor, which is time dependent because the orientation of the $\mathcal{A}$–th detector can change with time owing to the earth's rotation. The gravitational wave strain field is evaluated at the position $\vec{x}^{\mathcal{A}}$ of the detector. Using Eq. (12) we get

$$h^{\mathcal{A}}(t) = \sum_P \int df \int d\Omega_{\hat{n}} A^P(\hat{n}, f) D_{ij}^{\mathcal{A}}(t) \epsilon_{ij}^P(\hat{n}) e^{i\frac{2\pi f}{c}\hat{n}\cdot\vec{x}^{\mathcal{A}}(t)} e^{i2\pi f t} \tag{15}$$

so we can associate a set of stochastic processes to the set of detectors.

If the amplitudes $A^P(\hat{n}, f)$ follow a (multivariate) Gaussian distribution, then the processes $h^{\mathcal{A}}$ are completely described by

$$\begin{aligned}\mathbb{C}_h^{\mathcal{AB}}(t,t') &= \left\langle h^{\mathcal{A}}(t) h^{\mathcal{B}}(t') \right\rangle \\ &= \sum_{P,Q} \int df \int d\Omega_{\hat{n}} \int df' \int d\Omega_{\hat{m}} \left\langle A^P(\hat{n}, f) A^Q(\hat{m}, f')^* \right\rangle \\ &\quad \times D_{ij}^{\mathcal{A}}(t) D_{kl}^{\mathcal{B}}(t')^* \epsilon_{ij}^P(\hat{n}) \epsilon_{kl}^Q(\hat{m})^* e^{i\frac{2\pi}{c}\left(f\hat{n}\cdot\vec{x}^{\mathcal{A}}(t) - f'\hat{m}\cdot\vec{x}^{\mathcal{B}}(t')\right)} e^{i2\pi(ft - f't')}\end{aligned} \tag{16}$$

On the typical time scale of observations, we can assume that the statistical properties of the background do not change. Under this assumption of stationarity we can write

$$\left\langle A^P(\hat{n}, f) A^Q(\hat{m}, f')^* \right\rangle \equiv \Lambda^{PQ}(\hat{n}, \hat{m}, f) \delta(f - f') \tag{17}$$

and we obtain

$$\begin{aligned}\mathbb{C}_h^{\mathcal{AB}}(t,t') &= \sum_{P,Q} \int df \int d\Omega_{\hat{n}} \int d\Omega_{\hat{m}} \Lambda^{PQ}(\hat{n}, \hat{m}, f) \\ &\quad \times D_{ij}^{\mathcal{A}}(t) D_{kl}^{\mathcal{B}}(t')^* \epsilon_{ij}^P(\hat{n}) \epsilon_{kl}^Q(\hat{m})^* e^{i\frac{2\pi f}{c}\left(\hat{n}\cdot\vec{x}^{\mathcal{A}}(t) - \hat{m}\cdot\vec{x}^{\mathcal{B}}(t')\right)} e^{i2\pi f(t-t')}\end{aligned} \tag{18}$$

Note that this does not mean that the stochastic processes $h^{\mathcal{A}}$ are stationary. The reason is that a non stationarity is induced by the motion of the detectors, which change their positions and their orientations owing to the earth's rotation and revolution around the sun. If we neglect revolution, which gives an effect which is usually negligible, we can write

$$\vec{r}^{\mathcal{A}}(t) = \mathbf{R}(t) \vec{r}^{\mathcal{A}} \tag{19}$$

where $\mathbf{R}$ is a rotation matrix and

$$\begin{aligned}\mathbb{C}_h^{\mathcal{AB}}(t,t') &= \sum_{P,Q} \int df \int d\Omega_{\hat{n}} \int d\Omega_{\hat{m}} \Lambda^{PQ}(\mathbf{R}(t)\hat{n}, \mathbf{R}(t')\hat{m}, f) \\ &\quad \times D_{ij}^{\mathcal{A}} D_{kl}^{\mathcal{B}*} \epsilon_{ij}^P(\hat{n}) \epsilon_{kl}^Q(\hat{m})^* e^{i\frac{2\pi f}{c}\left(\hat{n}\cdot\vec{x}^{\mathcal{A}} - \hat{m}\cdot\vec{x}^{\mathcal{B}}\right)} e^{i2\pi f(t-t')}\end{aligned} \tag{20}$$

The simpler situation is when the background is isotropic and there are no correlations between different directions in the sky. In this case $\Lambda^{PQ}$ does not depend on the directions and is insensitive to the rotation of the detectors. By using the previous expressions to connect $\mathbb{C}^{\mathcal{AB}}$ to physical quantities we obtain

$$\Omega_{gw}(f) = \frac{1}{\rho_c} \frac{d\rho_{gw}}{d\log f} = \frac{4\pi^2 f^3}{3H_0^2} \mathbb{C}_h^{\mathcal{AA}}(f) \tag{21}$$

where $\rho_{gw}$ is the energy density of the background and $\rho_c$ the present value of the critical energy density for closing the universe. In the same way it is possible to evaluate the overlap reduction function.

### 3.1. *Non standard polarizations*

General relativity predict only two different polarizations for gravitational waves. But a general metric theory can have up to six independent polarizations.

In principle it is possible to disentangle these polarizations[4] by using the signals of a network of detectors[5]. The idea is that each polarization has a peculiar overlap reduction function, so it is possible to introduce the statistics

$$Y^{\mathcal{AB}}(f) = \frac{20\pi^2}{3H_0^2 T} f^3 s^{\mathcal{A}}(f)^* s^{\mathcal{B}}(f) \tag{22}$$

whose expectation values are connected to the energy densities of the different polarizations by the overlap functions

$$\langle Y^{\mathcal{AB}}(f) \rangle = \gamma_P^{\mathcal{AB}}(f) \Omega_{gw}^P(f) \tag{23}$$

The different contributions are obtained by inverting this relation.

### 3.2. *Anisotropic backgrounds*

It is possible to investigate an anisotropic stochastic background[6] by exploiting the time dependence in Eq. (20). The basic idea[8] is that contribution to the measured signal are modulated in phase and amplitude in a way which depends on the detector and on the direction. If we introduce on each detector a demodulation factor which is appropriate for a given direction, when we evaluate the correlation we wash out other contributions. In this way it is possible to reconstruct a map of the background intensity in the sky, with an angular resolution which scales as $\lambda_{gw} d^{-1}$, where $d$ is the spatial separation between the detectors.

This can be seen as a solution of an inverse problem, and it comes out that at least three detectors are needed to remove the degeneracies.

### 3.3. *Non Gaussian backgrounds*

As we said in the introduction we can look at a stochastic background as a result of the superposition of many uncorrelated events. This is especially true for an astrophysical stochastic background[7], where the events can be for example coalescences of binary compact objects.

A key parameter that characterize the background is the duty cycle for a given upper cut-off in the red shift parameter $z$

$$D(z) = \int_0^z (1+z')\tau \times \frac{d\mathcal{R}}{dz'} dz' \tag{24}$$

where the first factor is the observed duration of the event and the second the observed rate of events. When $D \ll 1$ the events does not overlap and can be detected separately. When $D \gg 1$ we are in the opposite situation, there is a very large overlap and the signal can be described by a Gaussian stochastic background.

The intermediate regime $D \sim 1$ is a peculiar one. It is not possible to resolve each events owing to the overlap, but the typical number of overlapped signals is not too large and the stochastic background is not a Gaussian one.

Several approaches have been elaborated in order to deal with this, details can be found in the literature[9–13].

## 4. Conclusions and perspectives

During the last years several kind of analysis have been applied to the data, attempting to detect a stochastic background of gravitational waves.

No detections have been obtained until now, but interesting upper limit exists[14]. There are some promising candidates[15,16] that hopefully will be detected when the final sensitivity of current advanced detectors will be reached.

In the next generation of detectors, with an improvement of one order of magnitude in sensitivity, it will be possible to test for non trivial models, to detect sub–threshold events as a background, and maybe to start a synergy with other kind of detectors using multimessenger strategies.

*DING, University of Sannio, Benevento, 82100, Italy*
*E-mail: {mejutovilla, pierro, pinto, troiano}@unisannio.it*
*www.unisannio.it*

The localization of Gravitational Wave (GW) sources, that is crucial in identifying their physical nature via the joint use of GW interferometers and other messengers (electromagnetic, neutrino, etc.), is mainly based on the observed delays between pairs of interferometers. Time-Frequency (TF) representations can be effectively used for GW detection and parameter estimation. In particular, it is possible to estimate the arrival time delay between the GW signals detected by two interferometers by suitably aligning the related TF maps. In this work we compare different TF representatons and alignment techniques, by using numerical simulation based on recent public-domain GW data.

*Keywords*: Gravitational Waves, Time-Frequency Analysis, Wigner-Ville distribution, Constant Q Transform, Triangular Norms, Phase Correlation, Delay Estimation.

## 1. Introduction

Direction of arrival (DOA) estimation is a crucial aspect of gravitational wave (GW) and multi-messenger astronomy. The DOA can be retrieved with high accuracy from the observed arrival-time delays $d$ between the GW signals detected by different pairs of interferometers in a network of three or more non-colocated detectors.

Time-Frequency (TF) maps are tools of choice used for unmodeled transient GW signals affected by *nonstationary* disturbances of instrumental and/or environmental origin. The Constant Q-Transform (CQT) [1], in several flavours (including Q, Omega and Omicron pipelines), is currently used in LIGO-Virgo Collaboration (LVC) data analysis. Among available alternatives, the Wigner-Ville (WV) distribution features the best localization/resolution properties [2], but contains intermodulation artifacts, due to its bilinear nature. The Radial-Gaussian Kernel (RGK) *smoothed* WV [3] removes these artifacts, that hinder the visual readability of the WV distribution, with minimal resolution loss. The main purpose of this paper is to evaluate the effectiveness of the TF maps in estimating the GW signals DOA. Due to the image-like structure of the TF maps, it is possible to use alignment techniques borrowed from image processing. In particular, we will test the *Phase Correlation* (PhC) method [4] and the *Łukasiewicz Triangular Norm* (LTN) method [5], both implemented with *sub-pixel* accuracy, by using numerical simulations.

## 2. TF Maps for Delay Estimation: CQT and WV

The CQT of a signal $x(t)$ for a given value of the (so-called *quality factor*) parameter $Q$ is defined as follows:

$$X_{CQ}(t, f, Q) = \int_{-\infty}^{+\infty} x(\tau) w(\tau - t, f, Q) e^{-i2\pi f \tau} d\tau. \tag{1}$$

The best performance (the finest time-frequency resolution) is achieved when $w(\tau - t, f, Q)$ is a *Gaussian window*, but this latter has infinite support. Therefore, in GW data analysis pipelines the so-called *bisquare window* is used instead. For increasing values of $Q$, the CQT has lower temporal resolution. This effect is evident also in Fig. 1, displaying two CQT maps of the GW150914 signal as received by the LIGO-Hanford interferometer[6]. Lower values of $Q$ are therefore better suited for time delay $d$ estimation.

The WV distribution of a signal $x(t)$ is defined as follows

$$W_x(t, f) = \int_{-\infty}^{+\infty} \tilde{x}\left(t + \frac{\tau}{2}\right) \tilde{x}^*\left(t - \frac{\tau}{2}\right) e^{-i2\pi f \tau} d\tau, \tag{2}$$

where $\tilde{x}(t) = x(t) + i\,\mathcal{H}[x(t)]$ is the the analytic mate of $x(t)$, $\mathcal{H}[\cdot]$ denoting the Hilbert transform operator.

The WV transform is a *quadratic* representation and is affected by artifacts due to intermodulation (e.g. see Fig. 1). A possibility to solve this issue is to perform a *smoothing* procedure[3]. This amounts to computing the *Ambiguity Function* (AF), i.e. the 2D-Fourier transform of WV distribution[2]

$$A(\xi, \tau) = \mathcal{F}[X_W(t, f)], \tag{3}$$

where $\mathcal{F}[\cdot]$ denotes the $(t, f) \to (\xi, \tau)$ Fourier operator, and using a suitable kernel $K(\xi, \tau)$ to produce a new TF representation, given by

$$X_S(t, f) = \mathcal{F}^{-1}[A(\xi, \tau) K(\xi, \tau)], \tag{4}$$

where $\mathcal{F}^{-1}[\cdot]$ denotes the $(\xi, \tau) \to (t, f)$ inverse Fourier operator. In particular a radially-Gaussian smoothing kernel can be used, that in the polar coordinates $(\rho, \theta)$, of the AF domain can be written:

$$K(\rho, \theta) = \exp\left\{-\frac{\rho^2}{2\sigma^2(\theta)}\right\}. \tag{5}$$

Note that the AF symmetry property $A(-\xi, -\tau) = A(\xi, \tau)$ implies $K(\rho, \theta + \pi) = K(\rho, \theta)$. Therefore we may determine $\sigma(\theta)$ to maximize the energy content of the kernel-weighted AF subject to a volume constraint, namely:

$$\max_{\sigma(\theta)} \int |A(\rho, \theta) K(\rho, \theta)|^2 \rho d\rho d\theta : \int |K(\rho, \theta)|^2 \rho d\rho d\theta \leq \alpha. \tag{6}$$

The smoothed version of the WV distribution is thus tailored to the actual (energy) distribution in the AF plane. In Fig. 1 we show the WV-based TF maps of the GW150914 signal, as received by the LIGO-Hanford detector[6].

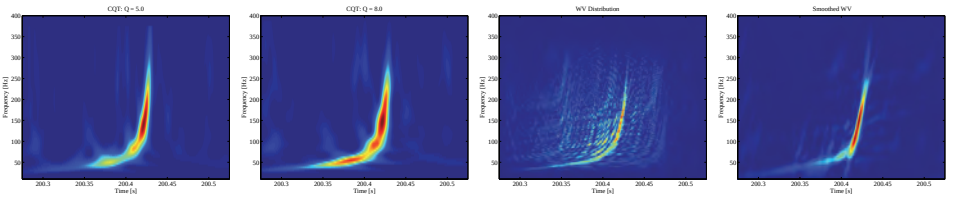

Fig. 1. TF maps for GW150914 (LIGO-Hanford)[6]: the two leftmost images are CQT with $Q = 5$ and $Q = 8$; the last rightmost ones are the plain and smoothed WV.

## 3. Delay Estimation

Consider two detectors that (disregarding the different directional gains) receive signals $x(t)$ and $y(t) = x(t-d)$ respectively, yielding the TF representations $|X(t, f)|$ and $|Y(t - d, f)|$. In practice, each TF map is evaluated at discrete times and frequencies, $(t_n, f_m) = (n/f_s, m/f_s)$, where $f_s$ is the sampling rate and $n$ and $m$ are integers such that $n \in [0, N - 1]$ and $m \in [0, M - 1]$, yielding a discrete 2D image $\mathbf{X} \in \mathbb{R}^{N\times M}$, whose elements are $X(n, m) = |X(t_n, f_m)|$.

In this subsection we will present two techniques to estimate the delay $d$ by aligning the two discretized TF representations $\mathbf{X}$ and $\mathbf{Y}$ at subpixel level, so as to minimize the effect of TF discretization on the time delay estimation.

### 3.1. *Phase Correlation*

The first alignment technique is based on the well known *Phase Correlation* (PhC) method, using a subpixel accuracy version implemented in a computational efficient way[4]. The 2D Discrete Fourier Transform (DFT) is denoted as $\mathcal{F}_{a\times b}[\cdot] : (n, m) \to (k, l)$, where $a \times b$ is the matrix dimension. Then, we compute the normalized cross-spectrum

$$\mathbf{S} = \circ \frac{\mathcal{F}_{N\times M}[\mathbf{Y}] \circ \mathcal{F}_{N\times M}[\mathbf{X}]^*}{|\mathcal{F}_{N\times M}[\mathbf{X}] \circ \mathcal{F}_{N\times M}[\mathbf{X}]^*|} \circ, \tag{7}$$

where $\mathbf{S} \in \mathbb{R}^{N\times M}$, and $\circ$ , $\circ - \circ$ denote element-wise (Hadamard) product and quotient, respectively. In order to implement a subpixel time shift estimator, $\mathbf{S}$ should be embedded in a suitably larger matrix of zeros $\mathbf{0} \in \mathbb{R}^{\kappa N\times \kappa M}$, where $\kappa > 1$ is an integer. Therefore, the inverse DFT will be performed on a larger dimension to compute the cross-correlation matrix via

$$\mathbf{R} = \mathcal{F}^{-1}_{\kappa N\times \kappa M}[\mathbf{S}] \in \mathbb{R}^{\kappa N\times \kappa M}. \tag{8}$$

Finally, we seek the cross-correlation maximum location, i.e.

$$(u, v) = \arg\max_{(n,m)} \mathbf{R}, \tag{9}$$

yielding the time delay estimator (for $\kappa N$ even, as usual)

$$\widehat{d}_{PhC} = \begin{cases} \dfrac{u}{\kappa f_s}, & u \in [0, \kappa N/2 - 1], \\ \dfrac{u - \kappa N}{\kappa f_s}, & u \in [\kappa N/2, \kappa N - 1]. \end{cases} \tag{10}$$

### 3.2. *Łukasiewicz Triangular Norm*

The second alignment technique considered in this work is based on *Łukasiewicz Triangular Norm* (LTN), selected for its simplicity and appealing properties[7], and defined as

$$T_L(x_0, y_0) = \max\{0, x_0 + y_0 - 1\}, \forall x_0, y_0 \in [0, 1]. \tag{11}$$

In order to implement a subpixel estimator, we interpolate the original TF map. To this end, we use the *bicubic interpolator*[8], denoted as $\mathcal{B}_{a\times b}[\cdot]$, where $a \times b$ is the dimension of the output matrix. Therefore, disregarding border effects, it is possible to define the estimator:

$$\widehat{d}_{LTN} = \frac{1}{\kappa f_s} \arg\max_u \sum_{k=1}^{\kappa N} \sum_{j=1}^{M} T_L \left( X_b(k, m), Y_b(k + u, m) \right), \tag{12}$$

where $X_b(k, m)$ and $Y_b(k + u, m)$ are elements of the interpolated matrices $\mathbf{X_b} = \mathcal{B}_{\kappa N\times M}[\mathbf{X}]$ and $\mathbf{Y_b} = \mathcal{B}_{\kappa N\times M}[\mathbf{Y}]$, respectively.

Note that it is possible to speed up the algorithm (otherwise rather slow) by finding a raw estimate of $d$ without performing the interpolation step, and then refining it via the subpixel version in Eq. (12) by considering only values of $d$ close to the raw estimate.

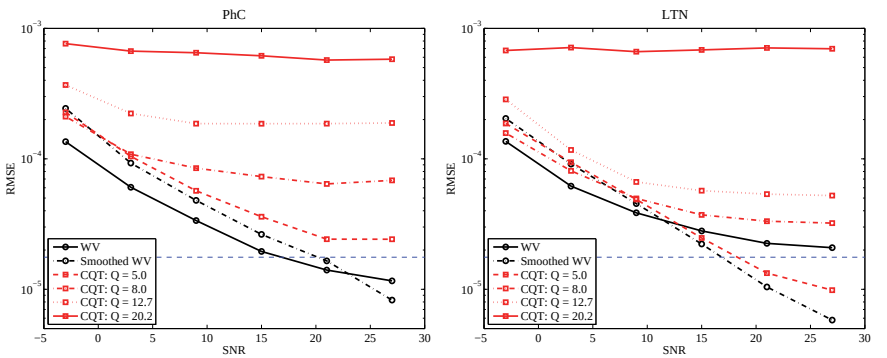

Fig. 2. RMSE for different time delay estimators, namely $\widehat{d}_{PhC}$ (left plot) and $\widehat{d}_{LTN}$ (right plot). The blue dashed lines refer to the quantization error $= 1/(f_s\sqrt{12})$. Other relevant parameters are the number of Monte Carlo trials ($N_{MC} = 100$) and the coefficient $\kappa = 100$ in Eq. (10) and Eq. (12).

## 4. Numerical Results

In this section we discuss the performance of the above TF-based time delay estimators via numerical simulations. We generate two chirping signals $s_x(t)$ and $s_y(t)$ differing by a time-delay $d$, using the *IMRPhenom* model[9], whose relevant parameters are the companion masses $M_1$ and $M_2$, and the *effective spin* $\chi_{\text{eff}}$. We set these parameters so as to fit the GW150914 signal [10]. Moreover, we set the observation interval $T = 1/8$ s, so that, for $f_s = 16384$ Hz, both discretized signals $s_x(n)$ and $s_y(n)$ consist of $N = 2048$ samples. Then, we add independent realizations of Gaussian white noise to the signal to obtain two noisy signals $x(n) = s_x(n) + w_x(n)$ and $y(n) = s_y(n) + w_y(n)$, with the same *Signal-to-Noise Ratio* (SNR), defined as $SNR = \sum_{n=0}^{N-1} s^2(n) / \sum_{n=0}^{N-1} w^2(n)$.

Finally, we compute the TF-maps of $x(n)$ and $y(n)$ and estimate the time delay $d$ using the techniques presented in the previous section. We gauge the estimation performance via standard Monte Carlo counting procedures, computing the Root Mean Square Error (RMSE), defined as

$$RMSE = \sqrt{\frac{1}{N_{MC}} \sum_{i=1}^{N_{MC}} (\widehat{d}_i - d)^2}, \tag{13}$$

where $N_{MC}$ is the number of Monte Carlo trials (here $N_{MC} = 100$) and $\widehat{d}_i$ is the time delay estimate for the $i$-th trial.

The results are shown in Fig. 2. We can see that, as expected, the sharpness of the TF representation is key for both PhC and LTN estimators. Indeed, the CQT performs poorly for high values of the Q factors (corresponding to lower time resolution), while the RMSE is significantly lower for low Q values. For low and medium SNR values, the uniform sharpness of the WV distribution has a clear advantage, but for high SNR its intermodulation artifacts cause performance degradation. This doesn't happen in the *smoothed* WV that, for high SNR, clearly outperforms the other TF representations considered. The combination *smoothed* WV-LTN outperforms PhC for high SNR values; on the other hand, for low and medium SNR values the combination WV-PhC yields the best performance.

## 5. Conclusion

In this paper we compared the performance of different Time-Frequency representations and alignment techniques for estimating the time delay between the GW signals received by two interferometers. The WV-based representations, as expected, outperform the CQT, due to their uniformly higher resolution. Moreover, the LTN is more effective than PhC for delay estimation, for high SNR values. even if its computational burden is higher. Future works will analyze more sophisticated TF maps capitalizing on *sparse* representations[11,12], and refined alignment techniques to further improve the DOA estimation.

The most general gravitational wave is composed of six polarization modes in metric theories of gravity. Polarization modes of gravitational waves can be used for the gravitational-wave tests of general relativity because the properties of polarization modes depend on the specific theory of gravity. We study the separability of the polarizations and the degeneracies between binary and polarization parameters for the inspiral gravitational waves from the compact binary coalescences.

*Keywords*: Gravitational waves, polarization, compact binary, modified gravity.

## 1. Introduction

The detection of gravitational waves from compact binary coalescences by Advanced LIGO and Advanced Virgo provides experimental approach to test general relativity [1-3]. In general metric theory of gravity, there are four non-tensorial polarization modes of gravitational waves in addition to two tensor modes allowed in general relativity [4]. Moreover, the number and the properties of the polarization modes reflect the nature of the theory of gravity. Thus, polarization test of gravitational waves make it possible to test general relativity. We focus on the polarization test of the inspiral gravitational waves from compact binary coalescences. We need to consider the source parameters, which are correlated with each other and determine the frequency evolution, to separate the polarizations from compact binary coalescences unlike some other waveforms. Polarization search by GW170814 had been conducted by the substitution of the antenna pattern functions [5]. However, the observational results of the polarizations may be affected by the inclination-angle dependence or the existence of other polarization modes. Thus, we study the separability of the polarizations and the degeneracies between binary and polarization parameters for the inspiral gravitational waves from the compact binary coalescences [6].

## 2. Angular dependence of a gravitational-wave waveform in modified gravity

In general relativity, the detector signal of I-th detector can be expressed as,

$$h_I = \frac{2}{5}\mathcal{G}_{T,I} h_{\rm GR}, \tag{1}$$

where $h_{\rm GR}$ is the gravitational-wave waveform in general relativity and $\mathcal{G}_{T,I}$ is the geometrical factor for the tensor modes defined by

$$\begin{aligned}\mathcal{G}_{T,I} := \frac{5}{2}\{&(1+\cos^2\iota)F_{+,I}(\boldsymbol{\theta_s},\boldsymbol{\theta_e}) \\ &+ 2i\cos\iota F_{\times,I}(\boldsymbol{\theta_s},\boldsymbol{\theta_e})\}e^{i\phi_{D,I}(\theta_s,\phi_s,\theta_e,\phi_e)}.\end{aligned} \tag{2}$$

Here $\iota$ is the inclination angle, $\boldsymbol{\theta_s} := (\theta_s, \phi_s, \psi_p)$ is the source direction angle parameters $(\theta_s, \phi_s)$ and polarization angle $\psi_p$, $\boldsymbol{\theta_e} := (\theta_e, \phi_e, \psi)$ is the detector location and orientation angle parameters, and $\phi_{D,I}$ is the Doppler phase. We calculated geometrical factors for non-tensorial modes having different inclination-angle dependence from those of tensor modes by quadrupole formula,

$$\mathcal{G}_{V_x,I} := \sqrt{\frac{525}{56}}\sin 2\iota F_{V_x,I}(\boldsymbol{\theta_s},\boldsymbol{\theta_e})e^{i\phi_{D,I}(\theta_s,\phi_s,\theta_e,\phi_e)}, \tag{3}$$

$$\mathcal{G}_{V_y,I} := \sqrt{\frac{15}{2}}\sin\iota F_{V_y,I}(\boldsymbol{\theta_s},\boldsymbol{\theta_e})e^{i\phi_{D,I}(\theta_s,\phi_s,\theta_e,\phi_e)}, \tag{4}$$

$$\mathcal{G}_{S_2,I} := \sqrt{\frac{225}{8}}\sin^2\iota F_{b,I}(\boldsymbol{\theta_s},\boldsymbol{\theta_e})e^{i\phi_{D,I}(\theta_s,\phi_s,\theta_e,\phi_e)}. \tag{5}$$

The inclination-angle dependence for the scalar dipole radiation is proportional to $\sin\iota$ in modified gravity theories with a scalar degree of freedom [7],

$$\mathcal{G}_{S_1,I} := \sqrt{\frac{45}{2}}\sin\iota F_{b,I}(\boldsymbol{\theta_s},\boldsymbol{\theta_e})e^{i\phi_{D,I}(\theta_s,\phi_s,\theta_e,\phi_e)}. \tag{6}$$

## 3. Polarization model

We adopt polarization models using the above geometrical factors and adding additional polarization amplitude parameters $A$s. The followings are examples of our polarization models.

Model TS1 is a tensor-scalar dipole model in which a scalar mode having the inclination-angle dependence of dipole radiation is added.

$$h_I = \{\mathcal{G}_{T,I} + A_{S_1}\mathcal{G}_{S_1,I}\}h_{\rm GR}. \tag{7}$$

Model TS2 is a tensor-scalar quadrupole model in which a scalar mode having the inclination-angle dependence of quadrupole radiation is added.

$$h_I = \{\mathcal{G}_{T,I} + A_{S_2}\mathcal{G}_{S_2,I}\}h_{\rm GR}. \tag{8}$$

Model TV is a tensor vector model in which the combination of vector x and vector y mode is added.

$$h_I = \{\mathcal{G}_{T,I} + A_{V_x}\mathcal{G}_{V_x,I} + A_{V_y}\mathcal{G}_{V_y,I}\}h_{\rm GR}. \tag{9}$$

## 4. Results

We estimate model parameters for 500 BBHs or 500 BNSs whose angular parameters are uniformly random, with a detector network such as three detectors aLIGO-AdV(HLV) or four detectors aLIGO-AdV-KAGRA(HLVK) in each polarization model by Fisher analysis. We use the inspiral waveform up to 3 post-Newtonian order in amplitude and 3.5 post-Newtonian order in phase as $h_{\rm GR}$, and consider 11 model parameters in general relativity and additional polarization amplitude parameters. Table 1 is the results of the medians of parameter estimation errors and correlation coefficients. We say that the polarization modes would be separable when the errors of the additional polarization amplitude parameters are less than unity because their fiducial values are set to be unity.

Table 1. Medians of parameter estimation errors and correlation coefficients. Here, $d_L$ is the luminosity distance of the source and $\Delta\Omega_s$ is the sky localization error. Masses of BBH and BNS are $10M_\odot - 10M_\odot$ and $1.4M_\odot - 1.4M_\odot$, respectively. Only correlation coefficients larger than 10% are shown.

| | parameter | BBH(HLV) | BBH(HLVK) | BNS(HLV) | BNS(HLVK) |
|---|---|---|---|---|---|
| | SNR | 33.3 | 40.2 | 36.4 | 44.3 |
| Model TS1 | $\Delta \ln d_L$ | 0.678 | 0.179 | 0.359 | 0.134 |
| | $\Delta\Omega_s[\mathrm{deg}^2]$ | 4.74 | 0.912 | 0.919 | 0.250 |
| | $\Delta A_{S1}$ | 1.16 | 0.284 | 0.606 | 0.197 |
| | $C(A_{S1}, \log d_L)$ | 0.998 | 0.989 | 0.996 | 0.984 |
| | $C(A_{S1}, \cos\iota)$ | -0.553 | -0.500 | -0.231 | -0.159 |
| Model TS2 | $\Delta \ln d_L$ | 0.676 | 0.182 | 0.358 | 0.134 |
| | $\Delta\Omega_s[\mathrm{deg}^2]$ | 4.74 | 0.913 | 0.862 | 0.246 |
| | $\Delta A_{S2}$ | 1.51 | 0.385 | 0.765 | 0.256 |
| | $C(A_{S2}, \log d_L)$ | 0.997 | 0.989 | 0.996 | 0.984 |
| | $C(A_{S2}, \cos\iota)$ | -0.609 | -0.564 | -0.246 | -0.189 |
| Model TV | $\Delta \ln d_L$ | 1.98 | 0.310 | 1.22 | 0.193 |
| | $\Delta\Omega_s[\mathrm{deg}^2]$ | 5.68 | 0.795 | 0.813 | 0.187 |
| | $\Delta A_{V_x}$ | 2.55 | 0.420 | 1.37 | 0.241 |
| | $\Delta A_{V_y}$ | 3.91 | 0.513 | 2.12 | 0.298 |
| | $C(A_{V_y}, \log d_L)$ | 0.999 | 0.993 | 0.998 | 0.991 |
| | $C(A_{V_y}, \cos\iota)$ | -0.846 | -0.335 | -0.307 | -0.207 |
| | $C(A_{V_x}, A_{V_y})$ | 0.987 | 0.814 | 0.948 | 0.624 |

In all models, the additional polarization amplitude parameters are strongly correlated with the amplitude parameters such as the luminosity distance and the inclination angle. In the model TS1 and TS2 having three polarizations, $A_S$ is determined even by three detectors HLV for BNS. However, it is difficult to separate the additional polarization mode by three detectors HLV for BBH due to the short

duration of the signal although the number of the detectors is equal to the polarization modes. In the model TV, the errors of the amplitude parameters are larger than unity with HLV for both BBH and BNS so that four detectors are always necessary to determine two additional polarizations.

Thus, we found that at least the same number of detectors is necessary to separate the polarization modes and obtain the polarization information of gravitational waves in principle. However, even when the number of detectors is equal to the number of the polarization modes, the modes would be inseparable in some cases, depending on the correlation among the amplitude parameters. Therefore, there are two conditions for the separation of polarization modes; (i) the same number of detectors or more as the number of polarization modes and (ii) significant signal-to-noise ratio (SNR) and the long duration of the signal.

## 5. Discussions

The second condition for the separation of polarizations (ii) indicates that the duration of the signal or frequency band of the detector has essential role in polarization test. Here, we use the networks composed of the second generation gravitational-wave detectors. However, a single next generation gravitational-wave detector such as the Einstein Telescope and the Cosmic Explorer could test several polarization modes because they have great sensitivity at lower frequency so that they could be effectively treated as a detector network including a set of detectors along its trajectory due to the Earth's rotation.

# Follow-up efforts of multi-messenger events and observational strategies with the MAGIC telescopes

Michele Peresano* on behalf of the MAGIC Collaboration

*Universit di Udine, and INFN Trieste, I-33100 Udine, Italy*
** E-mail: peresano.michele@gmail.com*

The MAGIC Collaboration operates two Imaging Atmospheric Cherenkov Telescopes (IACTs) which investigate the gamma-ray sky from 50 GeV to 50 TeV. In recent years, the ever-increasing development of new measurement instruments and the new synergies between research teams world-wide have contributed to the beginning of the multi-messenger era. The performance characteristics of the MAGIC telescopes make them well suitable for multi-messenger studies: numerous follow-ups of gravitational and neutrino alerts have been performed, along with the historic detection of the first neutrino-blazar association TXS 0506+56. In this context, since recent years it is also possible for external scientists to contribute to the MAGIC Collaboration observations and scientific output.

*Keywords*: Multi-messenger; neutrino; gravitational waves; MAGIC.

## 1. Introduction

The era of multi-messenger astronomy began formally already in the middle of the 20th century, with the study of cosmic rays and neutrinos from the Sun. It then progressed a few decades later progressed with the neutrino detection of SN1987A. In 2017 it acquired a more widespread and public interest. The discovery of gravitational waves (GW) from the neutron star merger GW170817 triggered a multi-messenger observational campaign. Such a multi-collaboration effort found another application also in the case of the first neutrino-blazar association of TXS 0506+056.

In the case of GWs, interest has been fueled by the possibility of detecting electromagnetic counterparts, required to constrain nature and physics of sources emissions - GW are not affected by gamma-ray attenuation during intergalactic propagation at Very-High-Energies (VHE). This happened only after the first pure GW signals reached the LIGO detectors (first binary black hole mergers - GW150914[1] and GW151226[2]).

Neutrinos have been studied for a longer time, since they represent a neutrally charged messenger which is also weakly interacting with matter. These properties made neutrinos the perfect tool for studies aiming to pinpoint sources responsible for Ultra-High-Energy (UHE) cosmic-rays acceleration. The interplay between neutrinos and electromagnetic radiation - in particular VHE photons - is critical in order to link the presence of neutrinos in a source's total emission to the production of cosmic rays at VHE and UHE.

Multi-messenger astronomy represents also a milestone in a multi-collaborative effort between many observatories and experiments world-wide. The MAGIC telescopes have been part of this community for many years, putting effort in both neutrino and GWs follow-ups.

## 2. The MAGIC telescopes and the IACT technique

The MAGIC collaboration is composed by more than 200 members from more than 10 countries, and operates a pair of Imaging Atmospheric Cherenkov Telescopes (IACTs) on the island of La Palma (Canary Islands, Spain). These instruments aim to detect and study astrophysical sources responsible for the emission of Very-High Energy (VHE) radiation.

Such phenomena cannot be properly investigated with sufficient statistics and precision by space-borne instruments, given the prohibitive energy domain of the emitted particles. In particular, due to their limited sizes, any material comprising scientific payloads on board of satellites will suffer from limited radiation lengths and collection areas at increasing energies. This effect results in a progressive decrease in the triggering rates of events with energies over hundreds of GeV.

The Imaging Cherenkov Atmospheric technique (IACT) aims to solve this issue by exploiting the atmosphere as part of the measuring process. In this way it is possible to gain more powerful stopping power and greater effective area at higher energies.

Instruments like MAGIC detect VHE primary particles which impact the Earth's atmosphere by observing the product of such impacts: cascade showers. Any primary particle (gamma rays, electrons or hadrons) will produce an associated shower, which develops through the atmospheric medium due to successive diffusion between secondary particles and nuclei. In the case of IACT facilities, the signal is constituted often by primary gamma rays, whereas the remaining particle populations are to be considered background.

Instead of detecting directly the secondary products of each shower, the IACT technique aims to detect the Cherenkov radiation emitted as a result of the propagation in the atmosphere of such particles. This radiation is collected by each IACT telescope in a camera, after the shower's image is projected on a reflecting surface. Each camera is composed of more than 1000 pixels, each represented by a photo-multiplier (PMT) which converts light signals into electrical impulses. Starting from this input, each event's image is properly cleaned, removing background features which will depend on the observing conditions. Subsequently, a statistical analysis is performed in order to retrieve, energy, direction and nature of the primary particle (gamma ray or hadron), given the cascade shower it produced. All the analysis chain is dependent on specific MonteCarlo simulations covering both the instrument's performance and a model of the atmosphere at the observing site.

Modern IACT facilities are composed of more than one of such instruments, providing increased precision in the estimation of the shower's directions which in turn results in competitive angular resolutions and collection areas at VHE.

The current setup of the MAGIC telescopes is the result of an upgrade performed in 2011-2012[3], which produced an identical configuration between the two telescopes, operating in stereoscopic mode since 2009. Multi-messenger studies have in particular few critical requirements, which are covered at VHE by the current

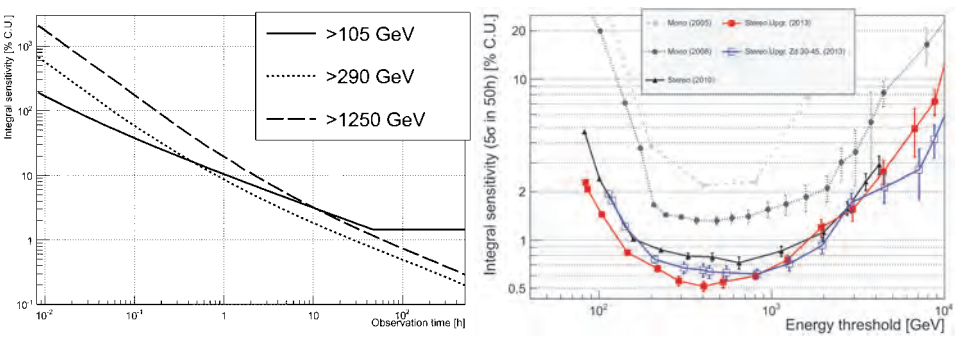
MAGIC performance:

- fast repositioning,
- low energy thresholds,
- high sensitivities within hour timescales.

In Table 1 we emphasise the MAGIC performance features more relevant for multi-messenger studies.

Table 1. Summary of the main features of the MAGIC telescopes and performance relevant for multi-messenger studies.

| Hardware features | Performance |
|---|---|
| 3.5° Field Of View | Angular resolution of 0.06° @ 1TeV - 0.1° at 100 GeV |
| Low voltage photo-multipliers | moderate / strong moonlight operations |
| $\sim 480m^2$ total reflective surface | Energy resolution of 15% at 1TeV and 23% at 100 GeV |
| Lowest structural weight | Fast repositioning up to 7 deg/s |
| Standard and "Sum" trigger systems | Energy range from $\lesssim$50 GeV to $\sim$50 TeV |



(a) (b)

Fig. 1. See Ref. 4 for details. (a) Dependence of the integral sensitivity of the MAGIC telescopes against observation time for different energy thresholds. (b) Evolution of the integral sensitivity of the MAGIC telescopes as a function of energy threshold for different configurations of the system.

Such characteristics result in a sensitivity of $\sim$ 10% of the Crab Nebula flux in 1 hour above 100 GeV ($\sim$ 0.66% Crab, $5\sigma$ in 50 hours above 220 GeV) as shown in Fig. 1(a) and Fig. 1(b).

Particularly relevant for multi-messenger studies have been the continuous improvements of the MAGIC telescopes in increasing their duty cycle. This has been done not only by progressively reducing technical and operational delays each year, but also by developing new hardware and software resources in order to allow observations during higher Night-Sky Background conditions, such as moderate and strong moonlight.

The effect that this kind of observing conditions have on registered data results mainly in a higher energy threshold, due to the higher cleaning levels required to extract the shower signal from a stronger NSB. Depending on moonlight intensity, the MAGIC telescopes can compensate by reducing the high voltage (HV) in the PMTs (which in turn reduces their gain by $\sim$1.7 times) and by inserting an additional UV-pass filter in front of both cameras.

The overall performance in such conditions has been recently described in Ref. 5 and results in a sensitivity which is still competitive, even if affected by unavoidable degradations dependent on the single setups:

- $\lesssim 10\%$ for nominal HV,
- $\lesssim 15-30\%$ for nominal HV,
- $\lesssim 60-80\%$ when using UV-pass filters.

## 3. Multi-messenger astronomy with the MAGIC telescopes

### 3.0.1. *Neutrinos*

Since 2012 MAGIC is part of the Gamma-Ray Follow-up program[6]. Only during the last observation cycle in 2017 the MAGIC telescopes have invested more than 30 hours on mainly two different types of neutrino follow-up searches from IceCube astrophysical neutrinos:

- a persistent source searches of $\nu_\mu$ tracks (HESE-37, HESE-38 and a multi-PeV track[7]),
- follow-ups of HESE/EHE real-time alerts (HESE-160427 and HESE/EHE-160731A).

A visualisation of both population of alerts observed by the MAGIC telescopes is shown in Fig. 2. No significant VHE gamma-ray signal has been detected by MAGIC for such events, which have been described in Ref. 8.

A major historical milestone in multi-messenger astrophysics was achieved by MAGIC being the first VHE instrument to detect gamma rays from a direction consistent with a HE neutrino. The blazar TXS 0506+056 became the first known source to emit both messengers.

Given the performance of MAGIC over neutrino follow-ups, it has been also possible to preliminary constrain the flux of astrophysical neutrino sources at at $\lesssim 0.1\%$ of the diffuse flux of neutrinos (3 years of Icecube data) - such result is comparable to the recent limits from IceCube in the Northern Sky[9].

### 3.0.2. *Gravitational waves*

MAGIC is has been also part of MoU with LIGO/Virgo, aimed to identify and follow gravitational wave candidate events since 2014. This kind of follow-ups are still limited by the difficult search for the possible EM counterpart, due to the

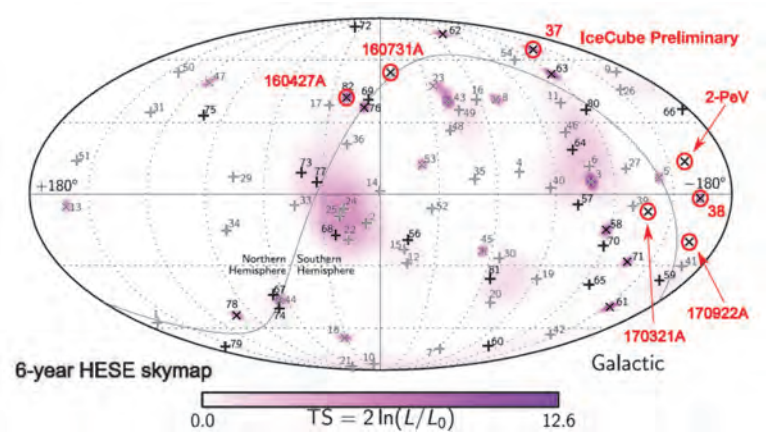


Fig. 2. Arrival directions of the HESE/EHE real-time alerts and $\nu_\mu$ tracks searches performed by the MAGIC collaboration, superimposed over a 6-years point-source clustering made by Icecube. Credits: Berti A., adapted from Ref. 10.

limited field of view of IACTs and the extent of the localisation areas of the available GW facilities (which reached a sensible improvement with the addition of the Virgo detector to the LIGO ones).

An important milestone for the Collaboration and the IACT community has been set during the Observation-1 (O1) cycle of LIGO, when the MAGIC telescopes performed the first ever IACT ToO observation of GW151226.

The case of GW151226 has been of particular importance for MAGIC, IACT and GW communities because it represented the first experiment of multi-messenger communication between these two kinds of facilities. Delays due to e.g. the interplay between the different types of alerts (GCN and MAGIC notices) and duty cycle (bad weather in particular), contributed to the development of early strategies to select LIGO sky regions within maximum source probability confidence level, in particular:

- choice of the visibility region area depending on a chosen probability threshold (50%, 90%),
- additional observations of other EM partners,
- overlap with existing catalogs[11].

## 4. Latest developments and future perspectives

These multi-messenger efforts have encouraged the members and working groups of the MAGIC Collaboration to develop and adapt new ideas and apply them to software, hardware and strategies:

- Off-axis upper limit calculation on flux over sky-maps for multi-messenger related alerts,

- GW follow-up observational strategies with selection of potential host galaxies from catalogs and application of emission models to estimate detectability,
- update of the MAGIC Automatic Alert system to improve prompt response,[12]
- plans to apply "Sum-trigger" to future automatic follow-ups in order to reach a lower energy threshold,
- Very Large Zenith Angle observations will expand the available observational limits while shifting sensitivity to higher energies[13].

In 2016 the MAGIC Collaboration started a program aimed at fostering scientific cooperation with external scientists. Each year this program is renewed with usual deadline around October. Interested individuals or teams are invited to visit the web page `https://magic.mpp.mpg.de/outsiders/magicop` and make contact as soon as possible.

The MAGIC telescopes continue to monitor the VHE sky with continuous developments on both hardware and software, keeping up with the latest discoveries.

PKS 1510-089 ($z = 0.361$), one of only a handful of flat spectrum radio quasars detected in the very high energy (VHE, $E > 100$ GeV) $\gamma$-rays, is known for its flux variability and complex multiwavelength behaviour. VHE observations by H.E.S.S. and MAGIC in May 2016 detected an unprecedented flare, both in intensity and in the shortness of its variability timescale. The flare lasted less than 48 hours, during which time the flux reached about 80 per cent of the Crab Nebula flux above 200 GeV. In addition, the intranight variability of this source was detected for the first time. Simultaneous observations in high energy (HE, $E > 100$ MeV) $\gamma$-rays performed with Fermi-LAT and optical $R$-band performed with ATOM show behaviour not consistent with simple simultaneous brightening in all bands. While a significant hardening of the spectrum is visible in HE, the flux increased only moderately. A simultaneous rise in daily-averaged optical flux was seen in the $R$-band. However, the intranight $R$-band flux evolution shows two prominent peaks, while only one is visible in the VHE range. These intriguing features of the flare will be presented in detail. We will also discuss possible explanations for the observed emission.

*Keywords*: Gamma-rays; multiwavelength; blazars; PKS 1510-089.

## 1. Introduction

PSK 1510-089 is a flat spectrum radio quasar located at RA=$15^{\rm h}12^{\rm m}52.2^{\rm s}$, Dec=$-09°06'21.6''$ (J2000), with the redshift of $z = 0.361$. It is a highly variable source of electromagnetic radiation in all energy bands, exhibiting a complex MWL behaviour.[1–4] It was first detected in the very high energy (VHE, $E > 100$ GeV) $\gamma$-ray band with High Energy Stereoscopic System (H.E.S.S., see Section 2.1) in 2009[5] Major Atmospheric Gamma-Ray Imaging Cherenkov (MAGIC, see Section 2.1) detected VHE $\gamma$-ray signal from PSK 1510-089 in 2012.[6] The first detection of variability in the VHE band occurred during an outburst in 2015.[7,8] The flux was variable on a daily time-scale. An exceptional VHE $\gamma$-ray outburst of PKS 1510-089 in May 2016 was observed both with H.E.S.S. and MAGIC, revealing intra-night variability for the first time, on which we report here. We also present results in the high energy (HE, $E > 100$ MeV) $\gamma$-rays and optical band.

## 2. Data analysis and results

### 2.1. *VHE γ-ray band*

H.E.S.S. is an Imaging Atmospheric Cherenkov Telescope (IACT) array located in the Khomas Highland in Namibia at an altitude of about 1800 m a.s.l. It consists of four 12-m telescopes (CT1-4) and a 28-m telescope (CT5) in the centre of the array. The energy threshold of the system under optimal conditions is $\sim 50$ GeV. However, because of technical problems in the observation period, only CT2 − 4 data were used in the present analysis, resulting in higher energy threshold of $\sim 200$ GeV. H.E.S.S. observed PSK 1510-089 from MJD 57535 to 57545. A total of 31 runs (about 28 min per run) passed the standard quality selection[9] resulting in a total live time of 13.6 h. The data were analysed with the Model analysis chain using loose cuts.[10] The results were cross-checked and verified using the independent reconstruction and analysis chain ImPACT.[11]

The H.E.S.S. light curve for the entire observation period (MJD 57535 − 57545) with nightly averaged flux above 200 GeV is shown with red points in panel (a) of Fig. 1. The signal was significantly detected only on the nights of MJD 57537/8 and 57538/9. The average flux above 200 GeV on the night of the highest flux (MJD 57538) was $(14.3\pm0.6)\times10^{-11}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$, corresponding to 56% of the flux from Crab Nebula above the same energy threshold (0.56 C.U.).[12] This was $\sim 15$ times higher than what H.E.S.S. measured in 2015.[8] We fitted the run-by-run based light curve with a constant. The hypothesis of constant flux was rejected at the level of $> 10\,\sigma$. On the night of the highest flux the source was observed for 4 runs, totalling in 1.8 h of data. The light curve with flux above 200 GeV is shown with red points in panel (a) of Fig. 2. Again the constant flux is ruled out on a run-by-run basis with $5.4\,\sigma$, confirming the first ever detection of VHE intra-night variability in PSK 1510-089. The flux above 200 GeV reached $(20 \pm 1) \times 10^{-11}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$, equivalent to 0.8 C.U. The spectrum is best fitted with a power-law (PL) $F(E) = N_0 \times (E/E_0)^{-\Gamma}$ folded with exponential function representing $\gamma$-ray flux attenuation due to the extragalactic background light (EBL).[13] Spectral parameters are as follows: normalisation flux $N_0 = (19.0 \pm 0.8) \times 10^{-10}\,\mathrm{TeV}^{-1}\,\mathrm{cm}^{-2}\,s^{-1}$, spectral index $\Gamma = 2.9 \pm 0.2$ and decorrelation energy $E_0 = 268$ GeV.[12] The intrinsic spectrum is shown in Fig. 3 with red points.

MAGIC is a stereoscopic system located in Canary Island of La Palma, at the height of 2200 m a.s.l.[14] It consists of two identical 17-m IACTs. The standard trigger threshold of the MAGIC telescopes for low zenith angle observations is $\sim 50$ GeV.[15] However, from the MAGIC location, PSK 1510-089 is observable at zenith angles above 38°, resulting in higher trigger threshold of $\sim 90$ GeV for the present analysis. Nevertheless, we integrated flux above 200 GeV, in order to have both H.E.S.S. and MAGIC light curves in the same energy range. MAGIC observed PSK 1510-089 on MJD 57535/6 and for five consecutive nights between MJD 57538/9 and 57542/3. A total of 7.5 h of data were collected for the whole observation period, while 2.7 h of data were collected on the night of flare. For

(red) and MAGIC (green). **(b)** Flux above 100 MeV averaged over 24 h and centred on VHE observations as measured by *Fermi*-LAT. **(c)** *Fermi*-LAT spectral index above 100 MeV obtained from integration over 24 h assuming PL spectral shape. **(d)** Nightly-averaged optical light curve in *R*-band from ATOM. Plot adopted from Ref. 12.

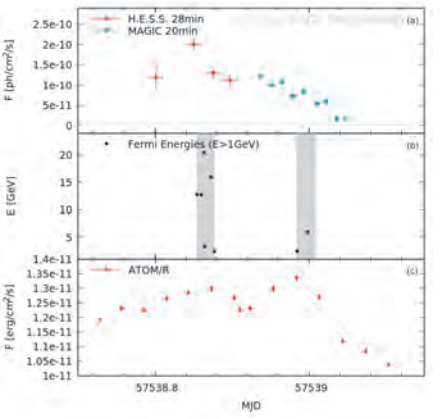

Fig. 2. PSK 1510-089 light curves for the night of the flare (MJD 57538/9). **(a)** Flux measured with H.E.S.S. (red) and MAGIC (green) above 200 GeV. **(b)** *Fermi*-LAT detected photons with $E > 1$ GeV. Grey bands represent LAT visibility windows of PSK 1510-089. **(c)** Optical light curve in *R*-band from ATOM. Each point represents an individual exposure of $\sim$ 8 min. Plot adopted from Ref. 12.

a short period during the observation on MJD 57538/9, partial cloudiness caused variable rates in the MAGIC data acquisition. Those data were excluded based on pyrometer measurements,[16] leaving the final data sample of 2.53 h. The data were analysed using the the MAGIC analysis and reconstruction software (MARS).[15,17]

The MAGIC light curve for the entire observation period with nightly averaged flux above 200 GeV is shown with green points in panel (a) of Fig. 1. The signal was significantly detected only on the night of MJD 57538/9, when the average flux above 200 GeV was $(7.36 \pm 0.40) \times 10^{-11}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$,[12] equivalent to 0.32 C.U. This was $> 5$ times higher than upper limits of the flux on the rest of the nights from this data set, $\sim 4$ times the flux MAGIC measured in 2015,[7] and as much as $\sim 20$ times the flux MAGIC measured in 2012.[6] Intra-night variability on MJD 57538/9 was also detected in MAGIC light curve, shown with green points in panel (a) of Fig. 2. Each point represents one 20-min run. A fit with a constant is ruled out with $> 10\,\sigma$. The flux changed from $\sim 0.5$ C.U. in the first to $\sim 0.075$ C.U. in the last run. The observed spectrum on the night of the flare was reconstructed between 60 and 700 GeV. Again it is best fitted with a PL folded with the EBL attenuation.[13] Spectral parameters are: $N_0 = (34.7 \pm 1.5) \times 10^{-10}\,\mathrm{TeV}^{-1}\,\mathrm{cm}^{-2}\,s^{-1}$, $\Gamma = 3.37 \pm 0.09$

and $E_0 = 175\,\mathrm{GeV}$.[12] The intrinsic spectral energy distribution (SED) is shown in Fig. 3 with green points.

All uncertainties quoted are statistical only, for both observatories, while the systematic uncertainty on the energy scale is 15%.

We calculated variability time-scale from $t_{var} = \frac{1}{2}(F_i + F_{i+1})(t_{i+1} - t_i)/|F_{i+1} - F_i|$.[18] Smallest $t_{var}$ is $18 \pm 5\,\mathrm{min}$ between $7^{th}$ and $8^{th}$ MAGIC points (see Fig. 2). Based on causality argument we set upper limit on the size of the VHE $\gamma$-ray emission region $R \leq c\delta t_{var}/(1+z) = 1.2 \times 10^{15}(\delta/50)\,\mathrm{cm}$, where $\delta$ is relativistic Doppler factor. Adopting $\theta_j \sim 0.2/\Gamma$ for the jet opening angle,[19] where $\Gamma$ is the relativistic Lorentz factor (here we use $\Gamma = \delta$), and assuming the $\gamma$-ray emission region fills the entire cross section of the jet, we estimated the distance of the emission region from the black hole (BH) to be $d \sim R/\theta_j \sim 3 \times 10^{17}(\delta/50)^2\,\mathrm{cm}$. It should be noted that both $\theta_j \sim 0.2/\Gamma$ and $\delta \sim 50$ are extreme values. Larger opening angle, or smaller Doppler factor would put the emission region closer to the BH. On the other hand, abandoning the assumption of filling the entire cross section of the jet, would allow the emission region to be located further down the jet.

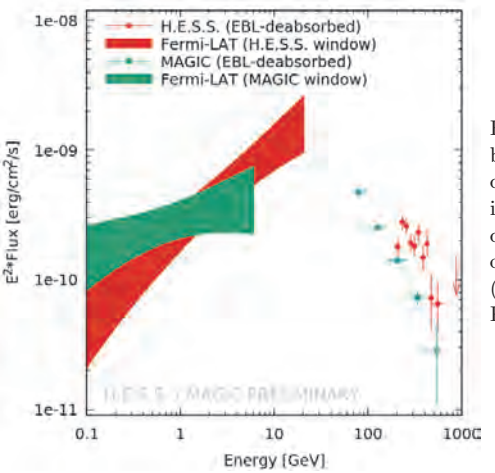

Fig. 3. PSK 1510-089 SED in HE and VHE band for the night of the flare. The H.E.S.S. data are given in red and the MAGIC ones in green points. The *Fermi*-LAT confidence regions are obtained by integrating over precise H.E.S.S. (red) and MAGIC (green) observation windows respectively. Plot adopted from Ref. 12.

### 2.2. *Multiwavelength picture*

We combined our data with observations in HE with *Fermi*-LAT and optical *R*-band observations with ATOM.

LAT is sensitive in the $0.02 - 300\,\mathrm{GeV}$ interval.[20] In an all-sky-survey mode, it scans the entire sky in 3 hours, while any point in sky is observed continuously for 30 min. We analysed publicly available Pass 8 SOURCE class events with energy $> 100\,\mathrm{MeV}$ in the region within 15° from the PSK 1510-089 position. We applied a zenith angle cut of $< 90°$. The analysis was performed with the ScienceTools

software package version v10r0p5 using the P8R2_SOURCE_V6 instrument response function and the GLL_IEM_v06 and ISO_P8R2_SOURCE_V6_v06 models for the Galactic and isotropic diffuse emission,[21] respectively. We produced a light curve for the whole period of VHE observations, shown in panel (b) in Fig. 1, where each point represents flux integrated over 24 h, centred on VHE observation. For this purpose, we assumed a PL spectral model with parameters free to vary between bins. The flux variability is apparent, however smaller than in the VHE band. Indeed the change is slower and the flux level significantly lower than the historical maximum[2] in this band.

Inspecting the spectral index on 24-hour scale, a hardening of the HE spectra with the increase of the VHE flux can be seen, reaching $1.7 \pm 0.1$, and then dropping to average value of $2.368 \pm 0.004$ after the flare (see Fig. 1c). On the night of the flare, LAT detected 8 photons with $E > 1\,\mathrm{GeV}$ (Fig. 2b); 6 of them in the H.E.S.S. observation window (4 with energies in the $10 - 25\,\mathrm{GeV}$ interval), when the VHE flux was higher, compared to the MAGIC observation window when only two photons were detected, both with energies below 10 GeV. Combined HE – VHE SED is shown in Fig. 3. The LAT confidence regions were obtained by integrating over precise VHE observation windows and calculated up to the highest detected energies for the respective period. The spectral indices were $\Gamma = 1.4 \pm 0.2$ and $\Gamma = 1.7 \pm 0.2$ in the H.E.S.S. and MAGIC windows, respectively. We calculated the difference in the spectral indices between HE and VHE spectra ($\Delta\Gamma$) and logarithm of ratio between extrapolated HE and measured VHE fluxes ($\tau = \ln(F_{extra}/F_{obs})$) for both observation windows. We obtained $\Delta\Gamma = 1.5 \pm 0.3$ and $\Delta\Gamma = 1.7 \pm 0.2$, and $\tau = 3.9 \pm 1.4$ and $\tau = 5.4 \pm 0.9$ for H.E.S.S. and MAGIC windows, respectively. The SED peak was located in the $10 - 60\,\mathrm{GeV}$ interval. Possible causes of the spectral break are absorption of $\gamma$-rays in the broad line region (BLR), but also intrinsic effects such as Klein-Nishina regime, break in electron spectrum etc. Our calculations put the emission zone (see Section 2.1) just outside of the BLR if $R_{BLR} = 2.6 \times 10^{17}\,\mathrm{cm}$[6] is adopted.

ATOM is a 75 cm optical telescope located on the H.E.S.S. site,[22] monitoring H.E.S.S. $\gamma$-ray sources. The magnitudes of each flux point were derived with differential photometry using five comparison stars in the same field of view. The resulting fluxes were corrected for Galactic extinction. Nightly averaged light curve (Fig. 1d) shows a similar flux evolution as in VHE band. However, a comparison on a finer time-scale for the flare night (Fig. 2c) shows double-peaked structure, in contrast to the VHE light curve shape.

## 3. Summary

H.E.S.S. and MAGIC observed an exceptionally strong and fast flare from PSK 1510-089 in VHE, detecting for the first time intra-night variability in this band. Although we saw no obvious counterparts in lower energies, a significant hardening of the spectrum was detected in the HE. A HE–VHE spectral break could

indicate a BLR absorption, however the shortest variability time-scale of $18 \pm 5$ min put the $\gamma$-ray emission region just outside of the BLR.

# On the potential of KM3 Neutrino Telescopes and Cherenkov Telescope Arrays for the detection of extended sources

Silvia Celli*

*Gran Sasso Science Institute, Viale F. Crispi 7, 67100, L'Aquila, Italy*
** E-mail: silvia.celli@gssi.infn.it*

The detection of a cosmic neutrino flux by the IceCube telescope triggers the search for the astrophysical accelerators responsible for it. Among them, Galactic sources are expected to contribute at some level: thanks to its location in the Northern hemisphere, KM3NeT is optimally suited to constrain their contribution with a clean event sample of upgoing muon tracks. Therefore, it is timely to investigate the discovery potential of KM3NeT to extended sources of very-high-energy neutrinos. The study presented is based on a comparative analysis of the sensitivity of KM3NeT and CTA. The methods are then applied to two interesting Galactic gamma-ray sources: the brightest TeV supernova remnant, RX J1713.7-3946, and the Galactic Center Ridge.

*Keywords*: Neutrino telescopes; Imaging atmospheric Cherenkov telescopes; Extended sources: RX J1713.7-3946, Galactic Center Ridge.

## 1. Introduction

The identification of the sources contributing to the diffuse neutrino flux detected by IceCube (Ref. 1), as well as the discovery of discrete sources of VHE neutrinos, are the major objective of neutrino astronomy for the coming years. In the feasible future, the upgraded IceCube and the planned KM3NeT will serve as the major tools of neutrino astronomy. The production mechanisms of very-high-energy (VHE) neutrinos are connected to the hadronic interactions of ultra-relativistic protons with the ambient gas and radiation. These processes are accompanied by the production at comparable rates of VHE gamma rays. The ground-based gamma-ray detectors, in particular the current arrays of Imaging Atmospheric Cherenkov Telescopes (IACTs) provide lower flux sensitivities for point-like sources around 1 TeV, compared to the sensitivities of present neutrino detectors, as IceCube, and forthcoming ones, as KM3NeT. With the exception of compact objects and sources located at cosmological distances, TeV gamma-ray fluxes should be taken as a robust criterion regarding the expectations of discovery of discrete VHE neutrino sources. Given the difference in the TeV flux sensitivities of IACT arrays and KM3-scale neutrino detectors, the gamma-ray fluxes are especially constraining for point-like sources. For mildly-extended sources with an angular size $\sim 1^{\circ}$, which is one order of magnitude larger than the point spread function (PSF) of IACTs but still comparable to the PSF of VHE neutrino detectors, the gamma-ray flux sensitivity degrades, while the flux sensitivity of neutrino detectors does not change significantly. Here, this question is studied based on the comparative analysis of the sensitivities of CTA and KM3NeT for extended sources. In Sec. 2 the procedure defined to compute the instrument sensitivity is defined, considering different sizes of the sources and analyzing the different impact they have on the sensitivity of these instruments.

As an application of this study, the case of two Galactic objects is considered, for which the gamma-ray and neutrino connection has been widely discussed in literature: the young supernova remnant (SNR) RX J1713-3946 is presented in Sec. 3, while the region of the Galactic Center Ridge is investigated in Sec. 4. Finally, conclusions are derived in Sec. 5.

## 2. Sensitivity studies to extended sources

A common procedure for gamma-ray and neutrino telescopes is here introduced for the computation of the sensitivity curves: the same analytical approach is applied, thus the calculated sensitivities of two detectors can be compared. Since the sensitivity curves have to be compared point by point, the same energy binning is used for both the gamma-ray and the neutrino sensitivities. Three bins per logarithmic decade are defined, so that the energy resolution of both instruments is covered in each bin. The minimum detectable flux is defined as the flux that gives in each energy bin: (i) a minimum number of signal events, $N_s^{min}$, (ii) a minimum significance level of background rejection, $N_\sigma^{min}$, and (iii) a minimum signal excess over the background uncertainty level. Thus, the instrument sensitivity is fixed by the one condition among the three listed above which dominates over the other two. The number of signal events, $N_s$, is obtained by folding an $E^{-2}$ power-law spectrum with the instrument response: these are reported in Fig. 1 for the CTA Southern Array configuration (4 large size telescopes, 24 medium size telescopes and 72 small size telescopes) and to the six building block KM3NeT in the observation channel of up-going muons.

In the following, $N_s^{min} = 10$ is set for CTA and $N_s^{min} = 1$ for KM3NeT. The significance level of the detection is expressed by the standard deviation $\sigma$, defined as $\sigma = N_s/\sqrt{N_b}$, where $N_b$ is the number of background events in the energy bin. The threshold on the minimum number of $\sigma$ is set to $N_\sigma^{min} = 5$ for CTA and to $N_\sigma^{min} = 3$ for KM3NeT. The values of $N_s^{min}$ and $N_\sigma^{min}$ are smaller in the case of neutrino telescopes in order to investigate the limits of the source detection capability. Concerning the condition on the background uncertainty, in the case of CTA a 1% systematic uncertainty on the modeling of the background is assumed and a signal of at least five times this background accuracy level is required, i.e. $N_s/N_b \geq 0.05$, following the approach adopted by CTA in Ref. 3. In the case of neutrinos, instead, the approach adopted by KM3NeT in Ref. 4 is followed and a 25% background systematic uncertainty is assumed, mainly related to uncertainty in the theoretical modeling of the atmospheric neutrino background. In the neutrino case, a signal of at least three times higher than the background accuracy is assumed: this converts into requiring a signal to background ratio of at least $N_s/N_b \geq 0.75$. An observation time of 50 hours is assumed for the CTA (a pointing of the source is required), while 10 years are assumed for KM3NeT.

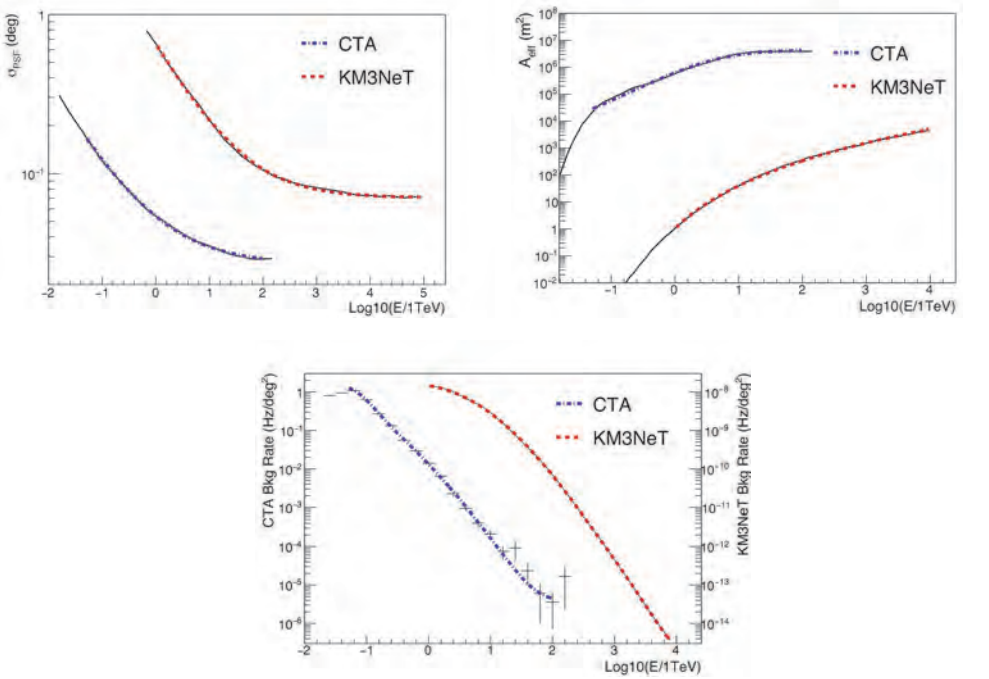

Fig. 1. Performances of the CTA and KM3NeT telescopes: angular resolution (top-left), effective area (top-right) and background rates per unit of solid angle (bottom). For both the telescopes, black lines correspond to the publicly available instrument responses, respectively for CTA Southern array (see Ref. 5) and KM3NeT (see Ref. 4). Dotted curves are the best fits, valid in the energy range $E \in [0.05 - 100]$ TeV for CTA and above 1 TeV for KM3NeT. The KM3NeT angular resolution is for $\nu_\mu$ charged current events and the muon neutrino effective area (six building blocks) corresponds to triggered events with a zenith angle greater than 80°, averaged over both $\nu_\mu$ and $\bar{\nu}_\mu$. Further details in Ref. 2.

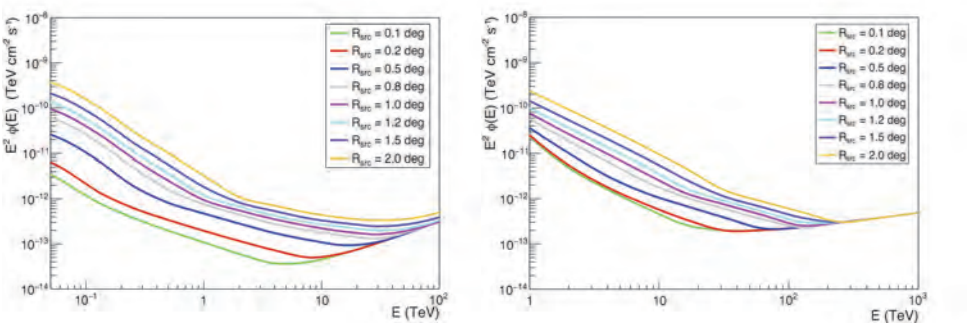
The radial dimension of the source strongly affects the sensitivity of detection. Here eight different source sizes are considered, i.e. $R_{src} = [0.1, 0.2, 0.5, 0.8, 1.0, 1.2, 1.5, 2.0]$ deg. In the sensitivity computation, the angular resolution $\sigma_{PSF}$ affects the actual size of the observed region of interest (ROI). The radius of the ROI is defined as $R_{ROI} = \sqrt{\sigma^2_{PSF} + R^2_{src}}$. Spherical sources placed at the center of the field of view are considered, covering a solid angle $\Omega = \pi R^2_{ROI}$ for the background computation. The resulting sensitivity curves are shown in Fig. 2(a) for the gamma-ray telescope and in Fig. 2(b) for the neutrino telescope: note that these curves correspond to the differential sensitivities, thus the per bin sensitivity allows not only the identification of a source but also its spectroscopic analysis. Fig. 2 demonstrate that the deterioration of the sensitivity with source size shows an energy dependence for both instruments. In principle, a simple re-scaling of the point-source sensitivity according the actual extension of the source (i.e. through an energy-dependent scaling-factor proportional to $R_{ROI}/\sigma_{PSF}$), would predict a

stronger deterioration of the sensitivity for extended objects at energies at which the angular resolution is smaller. Thus, since the angular resolution is improved with energy, one would expect stronger effect at higher energies. Nevertheless, Fig. 2 does not show such a tendency for both telescopes. The reason is that at very high energies the detection of the signal proceeds at the very low background rate, thus the detection condition is determined by the signal statistics rather than by the background, i.e. by condition 1) listed in Sec. 2. Indeed, it is seen from Fig. 2 that the sensitivities become almost independent of the source extension at few tens of TeV for both gamma rays and neutrinos.



(a) (b)

Fig. 2. Minimum detectable flux computed according to the procedure described in Sec. 2 in the case of extended sources for: (a) 50 hour observation with CTA and (b) 10 year exposure with KM3NeT.

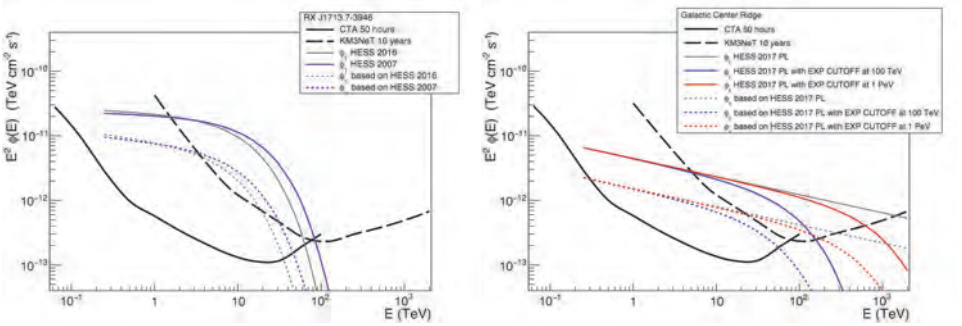
## 3. The case of RX J1713.7-3946

The case of such SNR is of great interest for neutrino telescopes, given that it is one of the brightest sources in the TeV sky. Moreover, its location in the sky makes it observable with up-going events at the latitude of KM3NeT for 70% of the time. The recent data from the H.E.S.S. Collaboration (see Ref. 6) suggest a spectrum in the form of a power-law with an exponential suppression as:

$$\frac{dN_\gamma}{dE}(E) = \phi_0 \left(\frac{E}{E_0}\right)^{-\alpha} \exp\left[-\frac{E}{E_{\rm cut}}\right] \tag{1}$$

with $E_0 = 1$ TeV, $\phi_0 = 2.3 \times 10^{-11}$ TeV$^{-1}$ cm$^{-2}$ s$^{-1}$, $\alpha = 2.06$ and $E_{\rm cut} = 12.9$ TeV for the best-fit model. Note that the best-fit flux of the source, previously published by the H.E.S.S. Collaboration in Ref. 7, with the parameters $\phi_0 = 2.13 \times 10^{-11}$ TeV$^{-1}$ cm$^{-2}$ s$^{-1}$, $\alpha = 2.04$ and $E_{\rm cut} = 17.9$ TeV, predicts a noticeably higher flux of neutrinos at the most relevant energies for their detection, namely

$E \geq 10$ TeV. This is visible in Fig. 3(a), where the expected neutrino fluxes from both H.E.S.S. measurements are shown together with the flux sensitivities of the two instruments for a source with a radius of 0.6 deg (the $5\sigma$ minimum detectable flux is shown for CTA and the $3\sigma$ one for KM3NeT). High quality spectroscopic measurements of gamma rays at the highest energies are still missing, due to the limited sensitivity of current instruments. Apparently, this uncertainty will be substantially diminished by CTA for a rather short observation time. Remarkably, even for the lowest predicted neutrino flux, a statistically significant detection of the latter by KM3NeT seems realistic within a time scale of 10 years.



(a) (b)

Fig. 3. Minimum detectable flux computed according to the procedure described in Sec. 2 for CTA and KM3NeT to: (a) the extended SNR RX J1713.7-3946 (spherical source with radius of 0.6 deg) and (b) the diffuse emission from the Galactic Center Ridge (rectangular box with longitudinal size of 2.0 deg and latitudinal size of 0.6 deg). Solid lines refer to gamma-ray fluxes, dashed curves to muon neutrino fluxes, computed in the hypothesis that the corresponding gamma-ray flux results entirely from hadronic *pp* interactions (see Ref. 8).

## 4. The case of the Galactic Center Ridge

Another promising object from the point of view of detection of multi-TeV neutrinos is the Galactic Center Ridge. The observations with the H.E.S.S. telescope revealed the presence of a diffuse component in the emission from the 200 pc region of the Galactic Center (see Refs. 9, 10). The hard energy spectrum of the emission, as reported in Ref. 10, extends above 10 TeV without any indication of a spectral break or a cut-off. This condition makes such source another candidate to be detected by KMeNeT (see Ref. 11). The most recent H.E.S.S. measurements of the Galactic Center Ridge in Ref. 12 point toward an unbroken power-law spectrum of the form:

$$\frac{dN_\gamma}{dE}(E) = \phi_0 \left(\frac{E}{E_0}\right)^{-\alpha} \tag{2}$$

with $E_0 = 1$ TeV, $\phi_0 = 1.2 \times 10^{-8}$ TeV$^{-1}$ cm$^{-2}$ sr$^{-1}$ s$^{-1}$, $\alpha = 2.28$. This spectrum corresponds to the region $|l| \leq 1.0$ deg, $|b| \leq 0.3$ deg. The estimation of the

sensitivities is thus done for a rectangular box with longitudinal size of 2.0 deg and latitudinal size of 0.6 deg. The results are shown in Fig. 3(b), where three spectra of neutrinos are calculated: the unattenuated power law that closely follows the gamma-ray measurements and two more spectra obtained assuming an exponential cut-off in gamma rays at 100 TeV and 1 PeV. One can see that only in the case of location of the gamma-ray cut-off beyond 100 TeV, the gamma-ray data could guarantee a statistically significant detection of the counterpart neutrinos by KM3NeT. Gamma-ray data above 100 TeV are too weak to be detected by the H.E.S.S. telescopes, even after a decade of continuous monitoring of this region. The exploration of this energy domain requires more powerful gamma-ray instruments, such as CTA. This can be seen in Fig. 3(b). However, it is worth to note that gamma rays, even in the case of their effective production above 100 TeV, would hardly escape the Ridge because of the absorption at interactions with the enhanced far infrared radiation fields in the central 100 pc region. Thus it is likely that the neutrinos remain the only messengers of information about the cosmic-ray protons with energies larger than 1 PeV. This opens a unique opportunity for KM3NeT to provide a major contribution to the exploration of the inner Galactic Center region.

## 5. Conclusions

This analysis presented here shows that, assuming a source emitting a gamma-ray $E^{-2}$ differential energy spectrum through a fully hadronic mechanism, a minimum gamma-ray flux of $E^2\phi_\gamma(10\ \mathrm{TeV}) > 1 \times 10^{-12}$ TeV cm$^{-2}$ s$^{-1}$ is necessary in order to investigate with a $3\sigma$ significance its neutrino counterpart on a time scale of 10 years with KM3NeT, if the source has an angular size of $R_{\mathrm{src}} = 0.1$ deg. In the extreme case of a source with a radial extent of $R_{\mathrm{src}} = 2.0$ deg, only sources brighter than $E^2\phi_\gamma(10\ \mathrm{TeV}) > 2 \times 10^{-11}$ TeV cm$^{-2}$ s$^{-1}$ will be in the reach of neutrino telescopes. In particular, RX J1713.7-3946 and the Galactic Center Ridge remain potential sources for the upcoming generation of neutrino detectors.

We explore the sensitivity of the relic supernova neutrino background from core-collapse supernova explosions to the nuclear equation of state (EoS). This sensitivity arises largely from the contribution to neutrino emission from failed supernovae (fSNe). We consider a variety of astrophysical scenarios, including different progenitor masses, different cosmological star formation rates, starbursts, quiescent star formation, and a metallicity dependence of the initial mass function. We find that the EoS signature remains robust under a variety of conditions. We demonstrate the viability of future neutrino detectors to distinguish the nuclear EoS via the relic supernova neutrino spectrum.

*Keywords*: Diffuse radiation - neutrinos - stars: formation - stars: massive - supernovae: general - stars: supergiants.

## 1. Introduction

We have studied[1–3] the contribution to the relic supernova neutrino (RSN) spectrum from different types of SNe. These previous works have shown that there is a clear EoS dependence in the spectrum. In particular in Ref. 3 we clarified the sensitivity to various astrophysical scenarios in order to quantify the EoS dependence of the RSN spectrum. For example, any change in the occurrence of core-collapse supernovae (CCSNe) vs. failed supernovae (fSNe) can affect the expected spectrum. Therefore, we have applied different criteria for a successful SN explosion and analyzed their effects on the RSN spectrum.

Moreover, the observational estimation of the cosmic star formation rate (SFR) is an involved procedure based upon different sources, e.g., UV light from galaxies and the far infrared (FIR) luminosity[4]. It also depends on modeling for the interpretation of the observational data, e.g., the fit to the spectral energy distribution

(SED).[5] Therefore, it is valuable to consider different SFR estimates and study their effects on the RSN spectrum.

The star formation rate also depends upon the choice of the stellar initial mass function (IMF). The IMF is a fundamental quantity not only for SFR estimation but also for the occurrence of each type of SN. A universal IMF, typically Salpeter-like IMF, is commonly assumed in almost every aspect of the astronomical derivation. Theoretical studies have attempted to derive this universality[6,7]. Nevertheless, a convincing theory for the universal IMF has not yet been established. Another uncertainty surrounding the IMF is its metallicity dependence. In general cooler molecular clouds should more easily collapse to form stars. Therefore, metal-poor molecular clouds, which may be common at high redshift, could tend to form more massive stellar objects. This leads to the concept of a top-heavy IMF in the early universe, i.e., a $z$-dependent IMF.

In Refs. 1, 2, 3 we have investigated the EoS dependence of the RSN spectrum by applying a variety of scenarios. These works show that the EoS dependence is sufficiently robust that the relic supernova neutrino spectrum can be used to gain insight into the nuclear EoS for core-collapse supernova explosions almost independently of the many uncertainties in the astrophysical scenarios.

One must know which progenitors become which type of SN because each SN emits a different spectrum of neutrinos [cf. Ref. 1]. Many numerical simulations have been performed which produce supernova explosions similar to SN1987A. Recent progress in multi-dimensional supernova simulations has led to successful explosions[8–11]. There is a common feature in the relationship between the structure of the progenitor and successful explosions[12–17]. The progenitors with greater compactness are less able to explode because they experience more accretion of material before the shock passes through the core. Indeed, successful/failed SNe occur with a non-monotonic dependence on progenitor mass[12,14,16,17]. Previously, most of studies of relic supernova neutrinos assumed definitive mass ranges within which a certain type of SN can occur. The relic neutrino spectrum must be re-evaluated by taking into account the sporadic dependence of the SN explosion on the progenitor mass.

In Ref. 3 we followed the work of Ref. 14 and adopted the fraction $f_{\rm fSN} = 0.26$ for progenitors in the mass range of $10 - 40{\rm M}_\odot$ to include the dependence of the SN explosion on progenitor in this mass range. We then take $f_{\rm fSN} = 1.00$ for ${\rm M} > 40{\rm M}_\odot$. We use this SN-progenitor relationship as the fiducial case throughout this work. For comparison, we also apply $f_{\rm fSN} = 1.00$ for ${\rm M} > 18{\rm M}_\odot$, which has been adopted in previous work with respect to the red supergiant problem[2].

Several different SFR formulae have been proposed to fit the observational data. The data mostly are interpreted from the UV luminosity of galaxies at different redshifts (e.g., Refs. 20, 21). This derivation is complicated because of the possible extinction due to the dust surrounding galaxies[22]. Also, the stellar composition at different ages must be taken into consideration so that the color of each galaxy is

matched to the observations.[5] Typically a Salpeter-like IMF is assumed for both the deduction of the SFR from the UV light and the color matching. Moreover, not only the UV source but also the IR emission is used for the SFR estimate.[23,24]

The relic supernova neutrino spectrum depends strongly upon the SFR through the rate of occurrence for each type of SN. In Ref. 3 the SFR fitting formula proposed by Ref. 4 was adopted. It has been argued[25] that the observationally deduced supernova rate tends to be smaller than the theoretical value. This is the so-called supernova rate problem[1,25]. This depends upon the choice of SFR. The SFR adopted in this work, gives a more conservative relic SN neutrino estimation and is independent of the supernova rate problem.[4]

As mentioned above, most evaluations of the SFR are based upon the UV luminosity, which is mainly emitted by OB stars. The dust surrounding galaxies, however, always complicates the evaluation of the UV. There is a claim[26] that the SFR based upon UV light is an underestimate especially for starburst galaxies. Recently, a new method based upon SED modeling has been proposed[26] in order to take into account the star formation embedded in dense molecular clouds. This study has shown that the SFR for $z > 3.5$ is higher by a factor of 2 to 3 than the estimate from UV light. We also apply this SFR to see how it affects the relic SN neutrino spectrum compared to the fiducial case.

The IMF is commonly assumed to be a universal function that is independent of the physical conditions of the star formation site. One of the popular functional forms is the Salpeter-A IMF (Sal-A).[27] This is a two-segment power-law given by $\phi_0(M) = M^{-\zeta} = M^{-(1+\Gamma)}$, with $\zeta = 2.35 \pm 0.2$ ($\Gamma = 1.35 \pm 0.2$) for stars with $M \geq 0.5 M_\odot$ and $\zeta = 1.5$ ($\Gamma = 0.5$) for stars with $0.1 < M < 0.5 M_\odot$. This is the adopted IMF for the present work. Most of the popular IMFs including the Sal-A are observationally deduced for stars in the Milky Way. There are also theoretical derivations of the power-law index for the IMF. For example, a power law IMF is explained by the turbulent motion of molecular clouds in a magnetic field[7]. There is, however, no definitive theory for the IMF, and the universality of the IMF remains an open question.

The relationship between metallicity and the IMF was also considered.[5,28–30] The IMF in metal poor environments molecular clouds may not sufficiently cool to collapse gravitationally on small scales. We explored[3] the IMF-metallicity relationship by adopting a cosmological metallicity evolution. If we consider a variable IMF, it is necessary to make a correction to the SFR, which is IMF dependent.

We follow the standard method to evaluate the detection rate of relic SN neutrinos as described in Refs. 1, 2, 3, 31, 33. For each type of SN we adopt $z_{max} = 5$ as the redshift at which star formation begins and $R_{SN}$ is the cosmic supernova rate. $dN_\nu(E'_\nu)/dE'_\nu$ is the neutrino spectrum emitted at the source, and the energy $E'_\nu = (1+z)E_\nu$ is the energy at emission. $E_\nu$ is the redshifted energy observed in the detector. A standard cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$[25,34] was adopted and a Fermi-Dirac distribution was assumed

for all neutrino species from each type of SN. Two models of fSNe, one with a soft EoS[35] (LS-EoS, $K = 180$) and a stiff EoS[36] (Shen-EoS) were considered from the numerical models of Ref. 37.

The supernova rate $R_{SN}$ is depends on the cosmic SFR, and $\phi_0(M)$ is the IMF. Here, $M_{SN}$ denotes the range of progenitor masses that lead to a particular type of SN. Hence, it is obvious that the neutrino flux depends not only upon the cosmic SFR and the IMF, but also upon the occurrence of each type of SN. Then, the detector event rate is

$$\frac{dN_{\rm event}}{dE_{e^+}} = N_{\rm target}\frac{1}{c}\frac{dN_\nu}{dE_\nu}\sigma(E_\nu)\frac{dE_\nu}{dE_{e^+}}, \tag{1}$$

where $N_{target}$ is the number of target particles in the detector. $\sigma(E_\nu)$ is the cross section for neutrino interactions within the detector. In the calculations, we assume a water Čerenkov detector so that the neutrino absorption is dominated by the $\bar{\nu}_e + p \rightarrow e^+ + n$ reaction with $E_\nu = E_{e^+} + 1.3$ MeV.

The effects of neutrino oscillations on the final neutrino signals have also been considered.[1–3] Two possible cases were considered i.e. either a normal or inverted mass hierarchy associated with complete non-adiabatic mixing (Case I) and an inverted mass hierarchy associated with complete adiabatic mixing (Case II) through the MSW high-density resonance. We denote the case without neutrino oscillations as Case III. These schemes were applied to each different astronomical scenario.

## 2. Results

We numerically treated both Type-II SNe and SNeIb,c as luminous core-collapse SNe in the same manner and denote them simply as CCSNe. We then showed the results within different astrophysical scenarios. For each case we considered the neutrino oscillations (Cases I & II) in the inverted and normal hierarchy and cases without neutrino oscillations (Case III). Comparisons among different scenarios for Case I, II, and III are made by looking at the locations of peak and tail of spectrum.

Figure 1 shows the the esseential result of these studies. It shows the differences between the peak and the tail of the observable observed neutrino detector response for all uncertainties included in the no-oscillations studies (Case III). This figure reveals the robustness of the EoS dependence by indicating the characteristic locations with the rectangular symbols as described above. The EoS dependence appears as a robust separation between the predicted RSN spectra for a stiff vs. a soft EoS. Other cases show a similar pattern.[3]

In summary, the fiducial case in this study, we have adopted the SFR parametrized by Ref. 4 along with the sporadic CCSN/fSN occurrence in the mass range of $10-40M_\odot$ based upon the numerical studies of Ref. 14. We then estimated the RSN spectrum. In addition, we have considered a wide variety of astrophysical scenarios and investigated the EoS dependence of the RSN spectrum for each case with and without the occurrence of neutrino oscillations. We find that the EoS dependence of the RSN spectrum manifests prominently in the high energy tail in

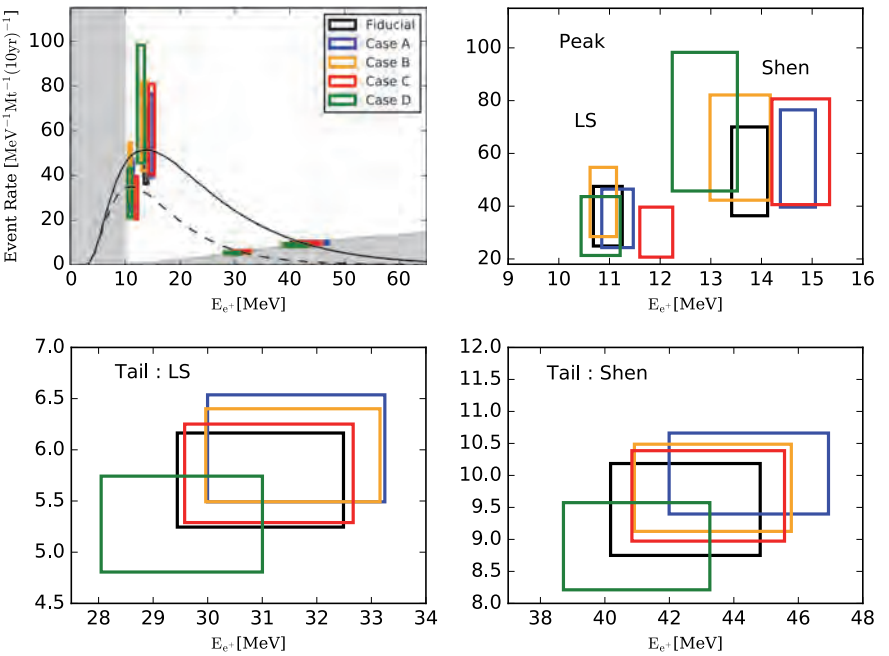

Fig. 1. Comparison of Case III (without neutrino oscillation) for all scenarios.. The figure includes only rectangles for the location of peak and tail which characterize the spectrum for each cases. In the left upper panel, the spectrum of the fiducial case without the error band are included for reference. The solid line is for the Shen EoS and the dashed line for the LS EoS. The right upper panel shows the detail of the peak locations for both the Shen and LS EoSs. Similarly the details of tails are shown in the left bottom (for the LS EoS) and right bottom panel (for the Shen EoS).

any scenario considered. The robustness of this EoS dependence can be understood in that the RSN spectrum is determined mostly by the SFR for $z < 2$. For example, in the case which adopts an enhanced cosmic SFR for $z > 3$, it is clearly seen that the RSN exhibits an EoS dependence similar to that of the fiducial cosmic SFR.

The Chinese mission Insight–HXMT allows for a high sensitivity study of the X-ray sky in 1250 keV, thanks to a smart combination of collimated detectors operating in different energy bands and providing a source location accuracy of 1 arcmin for a 20-$\sigma$ source. In addition to observing Galactic sources, the HXMT High Energy (HE) instrument also operates in the so-called GRB mode, that makes it possible to detect and characterise GRB prompt emission from 200 keV to 3 MeV with an effective area as high as 2000 cm$^2$, thus filling the sensitivity gap of presently flying main GRB detectors in this energy range. We report the results of intensive simulations of the expected performances of HXMT for GRB science, showing how, especially in combination with, e.g., Swift/BAT and Fermi/GBM, the HXMT/HE will provide a significant improvement in the characterisation of temporal and spectral properties of the prompt emission of long GRBs, as well as an improved detection rate and better spectral characterisation of short GRBs.

*Keyword*: Gamma-ray bursts.

## 1. Introduction

The Insight Hard X-ray Modulation Telescope (HXMT) was launched June 15, 2017 in a 43°-inclination orbit and is devoted to X-ray astrophysics. The payload consists of three collimated instruments covering a total energy band of 1–250 keV[1]. The High–Energy instrument (HE), made of 18 phoswich detection units NaI(Tl) + CsI(NaI), operates in the 20–250 keV and has a total geometric area of $\sim$5000 cm$^2$, time resolution of 25$\mu$s and energy resolution of 19% at 60 keV. All the information for each photon is recorded. The detection system and the design of the HE units are very similar to those of the BeppoSAX/PDS instrument[2], thus making it an excellent instrument for the study of hard X-ray sources as well as a sensitive full-sky gamma-ray burst (GRB) monitor. In the normal operation mode, the energy band is 20–250 keV for NaI detectors and 40–600 keV for CsI detectors. The HE electronics and on-board data handling system are designed in such a way

to identify NaI and CsI events, and to measure the energy of these events along with their occurrence time. In the normal mode, the CsI detectors above 100 keV exhibit an effective area ranging from few hundreds $cm^2$ for front incident radiation, to ∼1500–2000 $cm^2$, for radiation coming from the rear of the instrument. In the GRB operation mode, activated during Earth occultation of pointed sources, the HV of the HE instrument units is lowered to reduce the gain by a factor of ∼5, thus changing the energy band of the NaI detectors from 20–250 keV to 100–1250 keV and that of the CsI from 40–600 keV to 200–3000 keV (right panel of Fig. 1). In

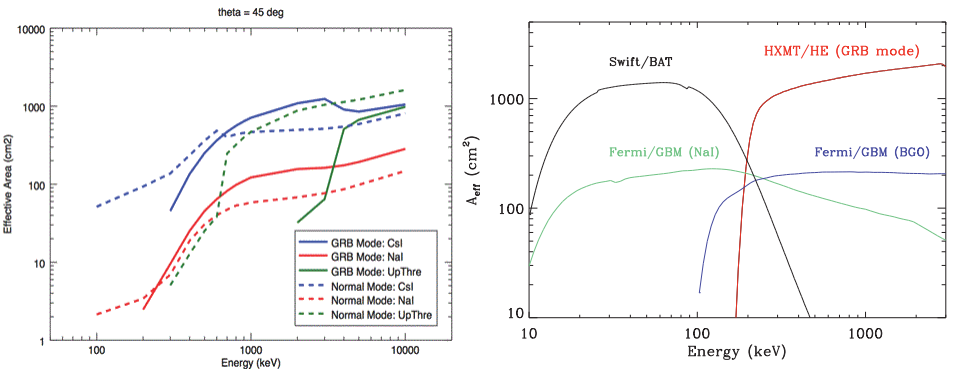

Fig. 1. *Left*: effective area of the NaI and CsI detectors of the HXMT/HE instrument in both normal and GRB modes, for an offset angle $\theta = 45°$ with respect to the detector axis. For each mode green lines show the efficiency of the high-energy threshold as a function of photon energy. The response function at different directions were determined through extensive Monte Carlo simulations (GEANT4) of the whole satellite. *Right*: effective area as a function of energy for Swift/BAT (on–axis), Fermi/GBM (sum of two NaI detectors and BGO, for a random direction in the sky) and HXMT/HE (GRB mode, $\theta = 135°$).

this paper we focus on the capabilities of HXMT/HE to detect and characterise the prompt emission of GRBs. In fact, the HE instrument is also operated in a GRB mode that allows to derive with high accuracy the temporal and spectral properties of the detected GRBs in the energy range from 200 keV to 3 MeV, thanks to an average effective area of ∼1500–2000 $cm^2$. This way, HXMT complements the sensitivities of other important and presently flying GRB detectors, like, e.g., Swift/BAT (15–150 keV) and Fermi/GBM (8 keV–30 MeV but with small effective area), thus providing a relevant contribution to the understanding of the physics of the prompt emission, one of the main open issues in the GRB field (e.g., see Ref. 3 for a review), and to the use of spectrum–intensity correlations for cosmology[4] (left panel of Fig. 1). For instance, the spectral peak energy, $E_{\rm p}$, corresponding to the peak of the $\nu F_\nu$ spectrum, is a key parameter for GRB prompt emission models. In addition, $E_{\rm p}$ strongly correlates with the GRB radiated energy during the prompt emission[5,6], during the early X-ray afterglow[7], and with the time variability and properties of the power density spectrum of the gamma-ray time profile[8]. With

reference to the "Band function" [9], the high-energy spectral index $\beta$ is also very important for testing and discriminating among various models, thus providing clues to the physics and geometry of the ultrarelativistic jet that is thought to act in a GRB. Swift/BAT measures mostly power-law spectra, thus providing estimates of $E_{\rm p}$ only for a few GRBs and almost no estimates of $\beta$, whilst most Fermi/GBM spectra can be fitted with a cut-off power-law, with no clues on $\beta$.

## 2. GRB spectroscopy

We quantified the improvements expected by joining HXMT/HE with other missions through simulations with the XSPEC package (v.12) in terms of the accuracy in determining $E_{\rm p}$ and $\beta$. The response matrix of HXMT/HE in GRB mode was obtained through intensive Monte Carlo simulations of the instrument and of the whole satellite, combined with extensive on-ground calibrations [1]. We used the response matrix for an offset incident angle of $\theta = 135°$, which is the rear side direction. The background spectrum was derived by taking into account the expected in-flight background components, including CXB, primary and albedo protons, electrons and positrons, gamma-rays albedo and SAA proton activated fluorescence by instrument and satellite structures [10]. Figure 2 (*left*) shows the Swift/BAT (measured)

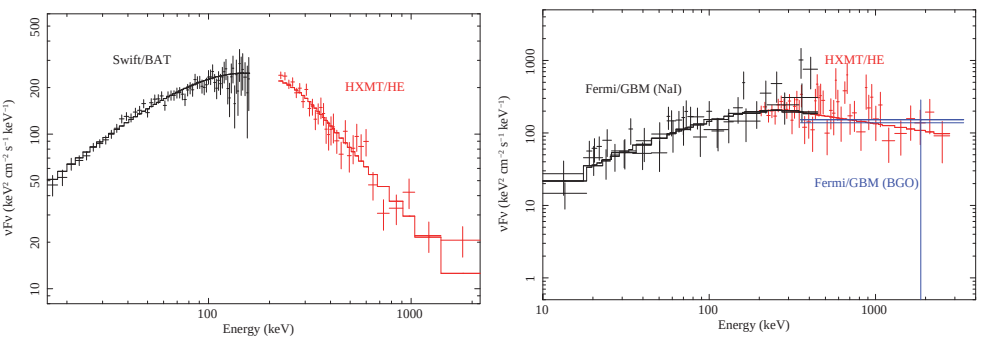

Fig. 2. Left: $\nu F_\nu$ spectrum of GRB 161218A as measured by Swift/BAT and expected with HXMT/HE (GRB mode) by assuming the spectral parameters measured by Konus–WIND [11]. Right: simulated Fermi/GBM and HXMT/HE (GRB mode) spectra of a medium–weak GRB (10–1000 keV fluence of $5 \times 10^{-6}$ erg cm$^{-2}$) with a typical Band spectral shape with $\alpha = -1$, $\beta = -2.3$ and $E_{\rm p} = 300$ keV and 25-s duration. Channels have been grouped to ensure $> 2\sigma$ significance.

and HXMT/HE (simulated) joint spectrum of the medium intensity GRB 161218A. While BAT alone would measure a simple power-law spectrum, the HE data are essential to constrain both $E_{\rm p}$ and $\beta$ by measuring the whole spectral curvature. A comparison between Fermi/GBM and HXMT/HE spectral capabilities is also shown (*right*): we simulated the spectrum of a medium–weak GRB (10–1000 keV fluence of $5{\times}10^{-6}$ erg cm$^{-2}$) with a typical Band spectral shape: $\alpha = -1$, $\beta = -2.3$ and $E_{\rm p} = 300$ keV. In particular, we simulated the spectra of the two NaI detectors and

the BGO detector most illuminated by the considered GRB, as usual with real data. Although the nominal energy band of the GBM extends up to 20–30 MeV, its effective area is poor with respect to that of HXMT/HE at energies higher than ∼300 keV (Fig. 1). Thus, also in this case HXMT/HE data are essential to constrain the spectral shape and determine $E_{\rm p}$ and $\beta$. We then simulated a set of Fermi/GBM (using real background data) and HXMT/HE (GRB mode) spectra by assuming the above typical spectral shape and a 10–1000 keV fluence in the range $10^{-4}$–$10^{-7}$ erg cm$^{-2}$. The results are shown in Fig. 3 in terms of fractional $1\sigma$ uncertainty in the estimates of $E_{\rm p}$ and $\beta$ as a function of GRB fluence. Clearly, HXMT/HE

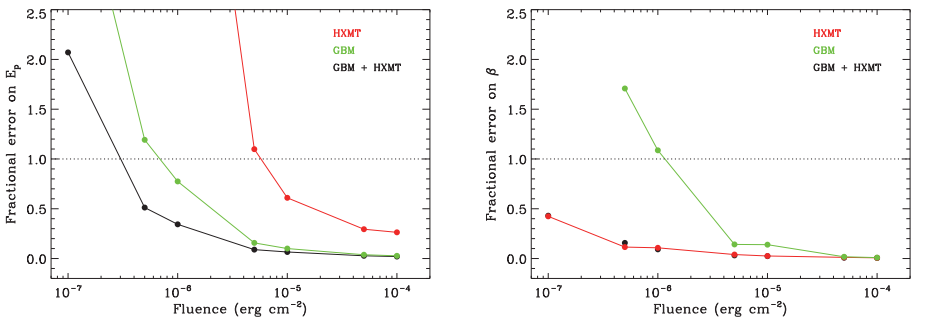

Fig. 3. Fractional error on spectral parameters $E_{\rm p}$ (*left*) and $\beta$ (*right*) as a function of fluence (10–1000 keV) for a GRB with $\alpha = -1$, $\beta = -2.3$ and $E_{\rm p} = 300$ keV, and duration 25 s, as would be measured with Fermi/GBM alone, HXMT/HE alone and a joint spectral analysis of spectra from the two instruments.

alone constrains $E_{\rm p}$ well only for the brightest GRBs, whereas $\beta$ is measured well down to the faintest ones. Conversely, the Fermi/GBM alone constrains $E_{\rm p}$ down to medium-bright GRBs. Yet, only the joint analysis of both instruments enables a good estimate of $E_{\rm p}$ down to fluences as low as $5{\times}10^{-7}$ erg cm$^{-2}$. This will significantly increase the number of GRBs that can be used for testing prompt emission models and for the study of the $E_{\rm p}$–intensity correlations. For progressively lower GRB fluences and higher values of $E_{\rm p}$ the HXMT spectral capabilities become increasingly relevant, especially for short GRBs, whose average $E_{\rm p}$ is higher than that of long ones[12].

## 3. GRB timing

The degree of variability exhibited by GRB light curves is long known to be related to luminosity[13,14] and spectral properties[8]. Among the various characterising temporal observables, such as the average[15] and the individual power density spectrum[8,16], noteworthy is the so-called spectral (or "time") lag, i.e. the delay between the time profiles of a given GRB at two different energy channels with softer photons lagging behind harder ones. The spectral lag is important for several aspects: (i) it anti-correlates with luminosity for long GRBs[17,18] as well as for GRB X-ray

flares[19]; (ii) it discriminates between long and short GRBs, for which typical values are several ten or hundred ms vs. just a few ms, respectively[20]; (iii) an exhaustive self-consistent explanation is still missing, although two main interpretations have been put forward: (a) a spectral hard-to-soft evolution within the fluid comoving frame, or (b) a kinematic/geometric effect due to the Doppler factor connected with the bulk Lorentz factor of the jet, or the combination of both. The spectral lag is usually calculated through the cross-correlation function (CCF) of the two profiles. As such, its accuracy strongly depends on the number of counts, especially in the harder channel, which is more significantly hampered by low-count statistics: indeed, above $> 300$ keV the lag calculation is an almost uncharted territory, apart from rare, exceptionally bright events. This limitation is even more severe for short GRBs due to the lower fluence and harder photons than for long GRBs. Thanks to its large effective area above a few hundreds keV, HXMT/HE holds a great promise for the spectral lag calculation even for less fluent GRBs, such as short ones. We assessed the potential of joining HXMT/HE to Fermi/GBM through a number of simulations of short GRB profiles, assuming the response function for an off axis angle of $\theta = 135°$ in GRB mode. In particular, we simulated a fast-rise exponential decay (FRED) with an instantaneous spectrum described by a Band function with typical values for short GRBs: $\alpha = -0.5$, $\beta = -2.3$, and $E_{\rm p}$ monotonically decreasing from the initial value of 1 MeV according to Ref. 21. Figure 4 shows

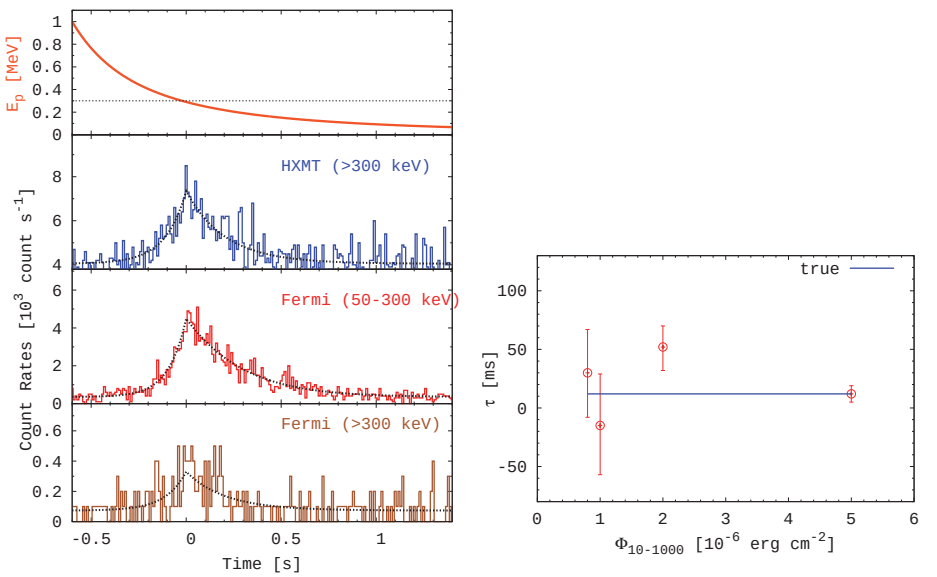

Fig. 4. *Left*: simulated profile of a short GRB ($T_{90} = 0.84$ s; 10–1000-keV fluence of $5 \times 10^{-6}$ erg cm$^{-2}$) with hard-to-soft evolution due to a decreasing $E_{\rm p}$ (top). The HXMT/HE profile above 300 keV is shown in comparison with the Fermi/GBM soft (50–300 keV) and hard ($> 300$ keV) bands. In the hard channel the better statistical quality of HXMT/HE is evident. *Right*: spectral lag between HXMT/HE ($> 300$ keV) and Fermi/GBM (50–300 keV) profiles as a function of the 10–1000-keV fluence of the short GRB, compared with the true value (solid line).

the different simulated profiles for HXMT/HE and for Fermi/GBM (*left*), where the statistical quality of the latter is clearly lower than that of the former. We then calculated the lag via CCF between the soft energy channel of Fermi/GBM and that of HXMT/HE for a number of identically shaped short GRBs within increasing $\gamma$–ray fluences and compared the results with the true value (measured without statistical noise): the result (right panel) shows the unprecedented good accuracy obtained at any given fluence in the considered range. This will allow for a better characterisation of the spectral lag of a larger number of short GRBs, whose relevance cannot be overstated given their association with the mergers of binary neutron stars revealed through the detection of gravitational waves, as was first the case for GRB170817A/GW170817[22].

# An updated calculation of the high energy diffuse gamma and neutrino flux from the galactic disk

Francesco L. Villante[1,2], Maddalena Cataldo[1,2], Giulia Pagliaroli[2,3] and Vittoria Vecchiotti[2,3]

[1] *Department of Physical and Chemical Science (DSFC), University of L'Aquila, L'Aquila I-67100, Italy*

[2] *Laboratori Nazionali del Gran Sasso (LNGS), Istituto Nazionale Fisica Nucleare (INFN), Assergi (AQ) I-67100, Italy*

[3] *Gran Sasso Science Institute (GSSI), L'Aquila I-67100, Italy*

We provide updated expectations for the diffuse gamma and neutrino emission produced in the TeV domain by the interaction of cosmic rays with the gas contained in the galactic disk. Motivated by recent analyses of the Fermi-LAT data, we consider different assumptions for the cosmic ray space and energy distribution in the Galaxy, including the possibility that cosmic ray energy spectrum depends on the galactocentric distance.

*Keyword*: High energy photons and neutrinos.

## 1. Introduction

Cosmic rays (CR) that propagate in different regions of the Galaxy interact with the gas contained in the galactic disk through hadronic processes and produce a diffuse flux of high energy (HE) gammas and neutrinos. These particles propagate to Earth along straight lines providing us with information on the CR space and energy distributions and, thus, in turn, on the CR transport in the galactic magnetic field. In this work, we present updated predictions for the diffuse galactic gamma-ray and neutrino flux produced by this mechanism in the TeV domain. Our results are obtained by using the phenomenological approach introduced in Ref. 1 that allows us to implement different assumptions for the CR space and energy distribution in a simple and direct way, including the possibility of a position dependent CR spectral index, recently emerged from analyses of the Fermi-LAT data[2–5].

## 2. The diffuse gamma and neutrino fluxes

The diffuse gamma (at energies $E_\gamma \leq 20\,\text{TeV}$ where gamma ray absorption in the Galactic radiation field is expected to be negligible) and neutrino fluxes produced by the interaction of CR with the interstellar medium in the galactic plane can be written as:

$$\varphi_{i,\text{diff}}(E_i,\hat{n}_i) = A_i \left[ \int_{E_i}^{\infty} dE \; \frac{\sigma(E)}{E} \; F_i\left(\frac{E_i}{E}, E\right) \right.$$
$$\left. \int_0^{\infty} dl \, \varphi_{\text{CR}}(E, \mathbf{r}_\odot + l\,\hat{n}_i)\, n_{\text{H}}(\mathbf{r}_\odot + l\,\hat{n}_i) \right], \qquad (1)$$

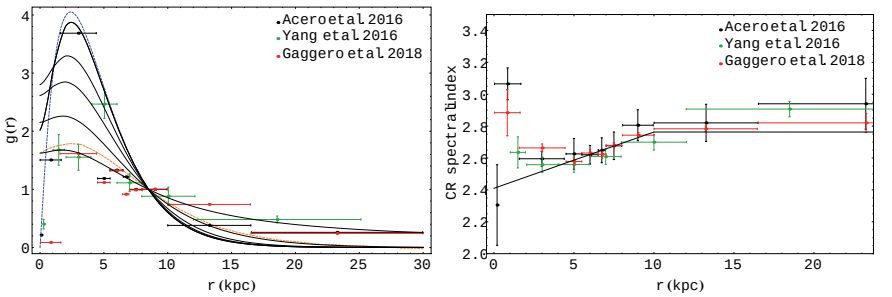

Fig. 1. Left Panel: The black lines show the functions $g(\mathbf{r})$ obtained from Eq. (5) for different smearing radii $R$. Going from top to bottom at $r \simeq 2\,\mathrm{kpc}$, the different lines correspond to $R = 1, 3, 5, 10, \infty$ kpc, respectively. The data points[3–5] show the CR density at $E \simeq 20\,\mathrm{GeV}$ (normalized to one at the Sun position) and the $\gamma$-ray emissivity above $E_\gamma = 1\,\mathrm{GeV}$, as a function of the galactocentric distance obtained from Fermi-LAT data. Right Panel: The black line gives the spectral index of CR at $E_{\mathrm{CR}} = 20\,\mathrm{GeV}$ adopted in this calculation. The data points[3–5] show the CR spectral index as a function of the galactocentric distance obtained from Fermi-LAT data.

where $i = \nu, \gamma$ stands for neutrinos and gamma respectively, $E_i$ and $\hat{n}_i$ indicate the energy and arrival direction of the considered particles and $r_\odot = 8.5$ kpc is the position of the Sun. The total inelastic cross section in nucleon-nucleon collision, $\sigma(E)$, is given by:

$$\sigma(E) = 34.3 + 1.88\ln(E/1\mathrm{TeV}) + 0.25\ln(E/1\mathrm{TeV})^2 \ \ \mathrm{mb},$$

where $E$ is the nucleon energy, while the spectra $F_i\,(E_i/E, E)$ of produced secondary particles are described (with 20% accuracy) by the analytic formulas given in Ref. 6. The constant $A_i$ is equal to 1 for photons and 1/3 for neutrinos, since the one flavour neutrino flux $\varphi_{\nu,\mathrm{diff}}$ is obtained by summing over the production rates of $\nu_e$ and $\nu_\mu$ in the sources, i.e.:

$$F_\nu\,(E_i/E, E) \equiv F_{\nu_\mu}\,(E_\nu/E, E) + F_{\nu_e}\,(E_\nu/E, E)\ , \tag{2}$$

and then assuming flavour equipartition at Earth, as it is expected with good accuracy due to neutrino mixing, see e.g. Ref. 7. The gas density $n_{\mathrm{H}}(\mathbf{r})$ is described as in Ref. 8; the heavy element contribution is included by assuming that the total mass of the interstellar gas is a factor 1.42 larger that the mass of hydrogen, as it is expected if the solar system composition is considered representative for the entire galactic disk.

Following Ref. 1, the CR nucleon flux is given as a function of position and nucleon energy by:

$$\varphi_{\mathrm{CR}}(E, \mathbf{r}) = \varphi_{\mathrm{CR},\odot}(E)\, g(\mathbf{r})\, h(E, \mathbf{r}) \tag{3}$$

where $\varphi_{\mathrm{CR},\odot}(E)$ represents the local flux,[a] $g(r)$ is an adimensional function (normalized to one at the Sun position $\mathbf{r}_\odot$) introduced to describe the spatial distribution

[a] In this work, we use the symbol $\varphi$ for angle-differential fluxes and $\Phi$ for angle-integrated fluxes.

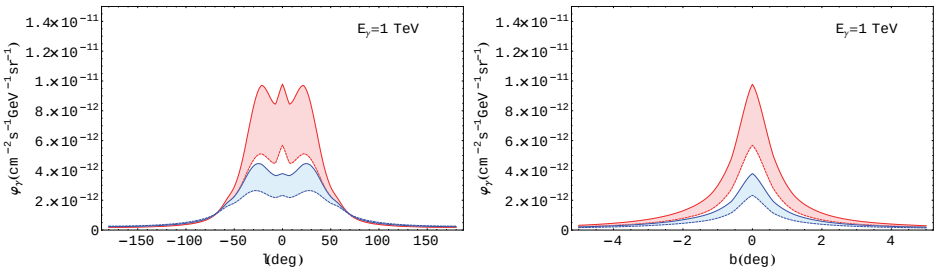

Fig. 2. The diffuse HE gamma-ray flux at $E_\gamma = 1\,\mathrm{TeV}$ as a function of the Galactic longitude $l$ (for $b = 0$) obtained by assuming that the CR spectrum is position-independent (blue lines) and by implementing CR spectral hardening in the inner Galaxy (red lines) as described by Eqs. (4), (8). Solid and dashed lines (in each group) are obtained by assuming that the CR spatial distribution follows that of SNR with smearing radius $R = 1\,\mathrm{kpc}$ and $R = \infty$, respectively.

of CR while the function $h(E, \mathbf{r})$, given by:

$$h(E, \mathbf{r}) = \left(\frac{E}{\overline{E}}\right)^{\Delta(\mathbf{r})} \tag{4}$$

with $\overline{E} = 20\,\mathrm{GeV}$ and $\Delta(\mathbf{r}_\odot) = 0$, introduces a position-dependent variation $\Delta(\mathbf{r})$ of the CR spectral index.

We describe the local CR nucleon flux $\varphi_{\mathrm{CR},\odot}(E)$ according to the data driven parameterization given in Ref. 9 that relies as little as possible on theoretical assumptions. In the energy range of interest for the present analysis, that roughly corresponds to $E \simeq 10 \times E_\gamma \sim 10\,\mathrm{TeV}$ when we consider photons with energy $E_\gamma \sim 1$ TeV, the total nucleon flux is lower than the broken-power law parameterization[10] adopted in our previous calculation[1] by $\sim 12\,\%$. For neutrinos, we are interested at larger CR energies $E \simeq 20 \times E_\nu \sim 2\,\mathrm{PeV}$, as can be understood by considering that the astrophysical signal emerges from background components at $E_\nu \sim 100$ TeV in IceCube data. At these energies, the determination of the local flux is affected by relevant uncertainties and the total nucleon flux adopted in this work is reduced by a factor $\sim 2$ with respect to that given in Ref. 10.

The function $g(\mathbf{r})$ is determined by the distribution of the CR sources $f_\mathrm{S}(\mathbf{r})$, that is assumed to follow the Supernova Remnants (SNR) number density parameterization given by Ref. 12, and by the propagation of CR in the Galactic magnetic field. Following Ref. 11, we define the function $g(\mathbf{r})$ as:

$$g(\mathbf{r}) = \frac{1}{\mathcal{N}} \int d^3x \; f_\mathrm{S}(\mathbf{r} - \mathbf{x}) \; \frac{\mathcal{F}(|\mathbf{x}|/R)}{|\mathbf{x}|} \tag{5}$$

where $\mathcal{N}$ is a normalization constant given by:

$$\mathcal{N} = \int d^3x \; f_\mathrm{S}(\mathbf{r}_\odot - \mathbf{x}) \; \frac{\mathcal{F}(|\mathbf{x}|/R)}{|\mathbf{x}|} \tag{6}$$

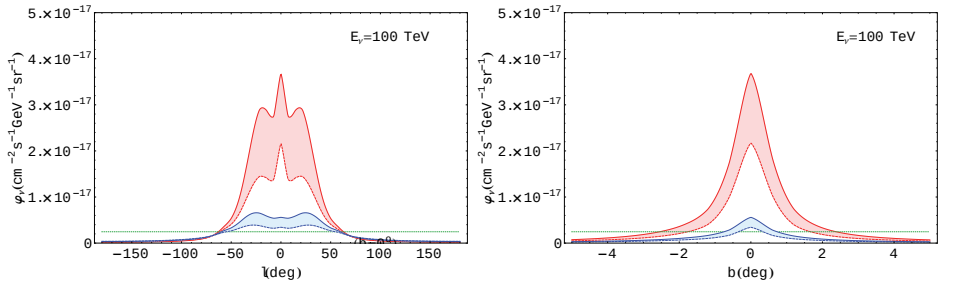

Fig. 3. The diffuse HE neutrino flux at $E_\nu = 100\,\mathrm{TeV}$ as a function of the Galactic longitude $l$ (for $b = 0$) obtained by assuming that the CR spectrum is position-independent (blue lines) and by implementing CR spectral hardening in the inner Galaxy (red lines) as described by Eqs. (4), (8). Solid and dashed lines (in each group) are obtained by assuming that the CR spatial distribution follows that of SNR with smearing radius $R = 1\,\mathrm{kpc}$ and $R = \infty$, respectively.

while the function $\mathcal{F}(\nu)$ is defined as:

$$\mathcal{F}(\nu) \equiv \int_\nu^\infty d\gamma \, \frac{1}{\sqrt{2\pi}} \exp\left(-\gamma^2/2\right) \tag{7}$$

This kind of behaviour can be motivated as the solution of 3D isotropic diffusion equation with constant diffusion coefficient and stationary CR injection. In this context, the smearing parameter $R$ represents the diffusion length $R = \sqrt{2\,D\,t_\mathrm{G}}$, where $D$ is the diffusion coefficient and $t_\mathrm{G}$ is the integration time.

The functions $g(\mathbf{r})$ calculated for different smearing radii $R$ are shown as a function of the galactocentric distance by the black lines in the left panel of Fig. 1 where they are compared with the CR density at $E \simeq 20\,\mathrm{GeV}$ and the $\gamma$-ray emissivity integrated above $E_\gamma = 1\,\mathrm{GeV}$ (which is a proxy of the CR flux) obtained from Fermi-LAT data in Refs. 3, 4, 5. While we believe that the data show a clear trend as a function of $r$, we think that they still do not allow to discard any of the proposed curves. We thus consider the two extreme assumptions $R = 1\,\mathrm{kpc}$ and $R = \infty$, corresponding to the thick black lines in Fig. 1, in order to encompass a large range of possibilities and to provide a conservative estimate of the uncertainty in the gamma-ray flux connected with different descriptions of the CR spatial distribution in the Galaxy.[b]

The possibility of CR spectral hardening in the inner Galaxy is implemented by modelling the function $\Delta(\mathbf{r})$ in Eq. (4) as:

$$\Delta(r, z) = \Delta_0 \left(1 - \frac{r}{r_\odot}\right) \tag{8}$$

with $r_\odot = 8.5\,\mathrm{kpc}$, in galactic cylindrical coordinates. This choice is equivalent to what is obtained in Ref. 2 by considering a phenomenological CR propagation model

[b]Since the assumed smearing length is larger than the thickness of the galactic disk, we neglect in both cases the variation of the CR flux along the galactic latitudinal axis. In other words, we assume $g(r, z) \simeq g(r, 0)$ in the disk, where we used galactic cylindrical coordinates.

characterized by radially dependent transport properties. The numerical parameter $\Delta_0$ that physically corresponds to the difference between the CR spectral index at the Sun position, $\alpha_\odot \simeq 2.7$ at $E = 20\,\mathrm{GeV}$, and its value close to the galactic center, is taken as $\Delta_0 = 0.3$ since this assumption allows us to reproduce the trend with $r$ observed in Refs. 3, 4, 5 for $r \leq 10\,\mathrm{kpc}$, as it is shown in the right panel of Fig. 1.[c] In more external regions, the evidence for a variation of CR energy distribution is much weaker and we assume that $\Delta(r)$ is constant, as shown by the black solid line.

## 3. Results

The diffuse HE gamma-ray flux at $E_\gamma = 1\,\mathrm{TeV}$ is plotted in Fig. 2 as function of the Galactic longitude (at the fixed latitude $b = 0$, left panel) and latitude (at the fixed longitude $l = 0$, right panel). Blue lines are obtained by assuming that the CR spectrum is independent from the position in the Galaxy (we refer to this in the following as the "standard" scenario) while red lines implement CR spectral hardening in the inner Galaxy. Solid and dashed lines in (each group) are obtained by assuming that the CR spatial distribution is described by the function $g(r)$ given in Eq. (5) with smearing radius equal to $R = 1\,\mathrm{kpc}$ and $R = \infty$, respectively.

The angle-integrated gamma-ray flux is equal to $\Phi_\gamma = (7.0 - 8.0) \cdot 10^{-13}\ \mathrm{cm}^{-2}\ \mathrm{s}^{-1}\ \mathrm{GeV}^{-1}$ at 1 TeV in the standard scenario with upper and lower bounds corresponding to $R = 1\,\mathrm{kpc}$ and $R = \infty$, respectively. The inclusion of CR hardening increases the integrated flux by $1.2 - 1.3$, the exact enhancement factor being dependent on the assumed CR spatial distribution. Even if the effect on the total flux is relatively small, CR hardening may be responsible for a much more significant increase of the gamma-ray flux in the central region $-60^\circ \leq l \leq 60^\circ$. We see indeed from Fig. 2 that the enhancement factor can be as large as $\sim 2$ in the direction of the Galactic center. This factor is larger than the uncertainty due to CR spatial distribution that can be conservatively estimated from the width of the coloured bands in the figure. Additional uncertainty sources are the normalization of the local CR flux at $E \sim 10\,E_\gamma \sim 10\,\mathrm{TeV}$, the distribution of gas in the Galaxy, the hadronic interaction cross section, etc. All these are expected to produce a total error smaller than the difference between red and blue lines in the figure, suggesting that effects of CR hardening can be probed by TeV scale gamma-ray observations of the galactic central region. A detailed comparison of the obtained predictions with the observational data in the TeV domain by Argo-YBJ, HESS, Milagro and HAWC experiments is performed in Ref. 11.

Finally, the diffuse neutrino flux at $E_\nu = 100\,\mathrm{TeV}$ is given as a function of the galactic longitude and latitude in Fig. 3 where we also show with a green line the isotropic astrophysical neutrino flux that is obtained from the six years HESE event rate observed by IceCube[13]. Our new calculations provide $\sim 40\%$ smaller neutrino

[c] Refs. 4, 5 report the spectral index $\alpha_\gamma$ of gamma emission associated to $\pi_0$ decay. This is converted into the spectral index $\alpha$ of the parent CR by $\alpha_\gamma \simeq \alpha + 0.1$.

fluxes than what obtained in our previuos work[1], as a combined consequence of the revised description of the local CR flux (which accounts for a factor $\sim 2$ reduction) and the inclusion of heavy element contribution to the galactic gas distribution (which is responsibile for a $\sim 40\%$ enhancement). The angle-integrated neutrino flux is equal to $\Phi_\nu = (1.0-1.2)\cdot 10^{-18}\ \mathrm{cm}^{-2}\ \mathrm{s}^{-1}\ \mathrm{GeV}^{-1}$ at 100 TeV in the standard scenario and it is equal to $\sim 3-4\%$ of the isotropic astrophysical flux observed by IceCube. The inclusion of CR hardening increases the integrated flux by $1.5-1.8$, the exact enhancement factor being dependent on the assumed CR spatial distribution. The effect is larger in the direction of the inner Galaxy where CR spectral hardening increases the predicted neutrino flux up to a factor $\sim 6$, producing a visibly different angular distribution with respect to the standard scenario.

"Gap"-type particle acceleration in the vicinity of supermassive black holes (BHs), accompanied by curvature and Inverse Compton radiation, could in principle lead to variable gamma-ray emission that may be detectable with current instruments. We shortly comment on the occurrence of magnetospheric gaps at the jet base, and the realisation of different potentials. The detection of rapid variability becomes most instructive by imposing a constraint on possible gap sizes, thereby limiting extractable gap powers and allowing to assess the plausibility of a magnetospheric origin. The relevance of this is discussed for the radio galaxies M87 and IC310. The detection of magnetospheric gamma-ray emission generally allows for a sensitive probe of the near black hole region and is thus of prime interest for advancing our understanding of the (astro)physics of extreme environments.

*Keywords*: Acceleration of particles — galaxies: individual (M87, IC310) — gamma rays.

## 1. Introduction

With the experimental progress during the last few years the high energy processes occurring in the vicinity of a supermassive black holes (BHs) have gained particular attention.[2,4–9,13,14] The occurrence of strong, unscreened electromagnetic field components around rotating BHs could in principle facilitate an efficient particle acceleration to very high energies (Ref. 11 for a review). This process is naturally accompanied by $\gamma$-ray production via curvature emission (the radiation of charged particles moving along curved magnetic fields) and inverse Compton upscattering of ambient (accretion disk) soft photons. Provided that suitable conditions are met, the close BH environment could enable high (Blandford-Znajek-type) power extraction and account for rapid gamma-ray variability on timescales of $\sim r_g/c = 1.4(M_{BH}/10^9 M_\odot)$ hr and shorter (Ref. 2). A characteristic feature in this context is the occurrence of charge-deficient regions (the so-called "gaps") close to the BH.

## 2. "Gaps" around supermassive black holes

Magnetospheric emission models usually rely on efficient "gap"-type particle acceleration. According to Ohm's law, $\mathbf{J} = \sigma(\mathbf{E} + \mathbf{V}/c \times \mathbf{B})$, a deficiency of electric charges (i.e., low conductivity $\sigma$) within the BH magnetosphere can lead to the formation of regions with an unscreened parallel electric field component, i.e. where $\mathbf{E} \cdot \mathbf{B} \neq 0$. Thus, magnetospheric particles moving along magnetic fields into such charge-empty regions ("gap") can be strongly accelerated to high energies by these parallel electric field components.

The formation of "gaps" is closely associated with mechanisms for the charge density supply into the magnetospheric environment. The conditions under which charges are injected in the magnetosphere are still not fully understood. It seems likely, however, that the presence of a hot, radiatively inefficient accretion flow (RIAF) could facilitate particle injection via photon annihilation ($\gamma+\gamma \rightarrow e^+ + e^-$) of MeV disk photons (Bremsstrahlung peak). As it turns out, below a certain accretion rate the resulting charge density is not sufficient to screen the electric field, so that magnetospheric particle acceleration becomes a plausible process (Ref. 6).

## 3. The structure of magnetospheric "gaps"

It is usually believed that the magnetospheric structure of astrophysical BH can be reasonably approximated (at least in a time-averaged sense) by an electromagnetic force-free solution. Such a configuration is known to facilitates an efficient electromagnetic extraction of the rotational energy of the BH (Ref. 3). For this to be possible, however, some quasi-steady electric currents that pervade the magnetospheres as sources of the magnetic field and that are carried by charged particles flowing through them, need to be sustained despite the presence of inflows and outflows. If we suppose, to the contrary, that under-dense ($\rho_e < \rho_{GJ}$) regions ("gaps") are formed in which a parallel electric field $E_\parallel$ is established, this does not necessarily invalidate over-all force-freeness.

Vacuum "gaps" could occur around at least two locations, the null surface (NS) and the stagnation surface (SS) (Refs. 5, 7, 8). Figure 1 provides an illustration of their locations for an exemplary (split monopole) BH magnetosphere (split monopole). The former surface (NS) designates the region where the generalised Goldreich-Julian charge density $\rho_{GJ}$ vanishes, changing sign across it (red solid line). This happens close to the location where the field line rotation frequency $\Omega_F$ equals the Lense-Thirring angular frequency $\omega(r)$, i.e., usually on radial scales $r \sim r_g = GM/c^2$. In order for the BH magnetosphere to be force-free (vanishing $E_{||}$) the real charge density $\rho_e$ should correspond to $\rho_{GJ}$. As $\rho_{GJ}$ changes signs across the null surface, $\rho_e$ is required to have opposite signs on opposite sites, hence a parallel electric field component could easily arises around this surface (Refs. 5, 7). The stagnation surface (SS), on the other hand, naturally occurs in an MHD outflow driven by a rotating (Kerr) BH and designates the surface that separates plasma motion inwards (inflows) due to the gravitational field from plasma motion outwards (outflows) above it (green solid line). This surface is in general non-spherical and located inside the (outer) light cylinder, typically on radial scales of some $r_g$. To allow for a general (time-averaged) force-free MHD description, plasma would need to be continuously replenished to maintain a charge density $\rho_e \geq \rho_{GJ}$.

## 4. Different realisations of the "gap" potential

In its simplest (one-dimensional, non-relativistic) form the "gap" electric field $E_\parallel$ and potential $\Phi_e$ along a path length $s$ in the presence of a non-zero charge density

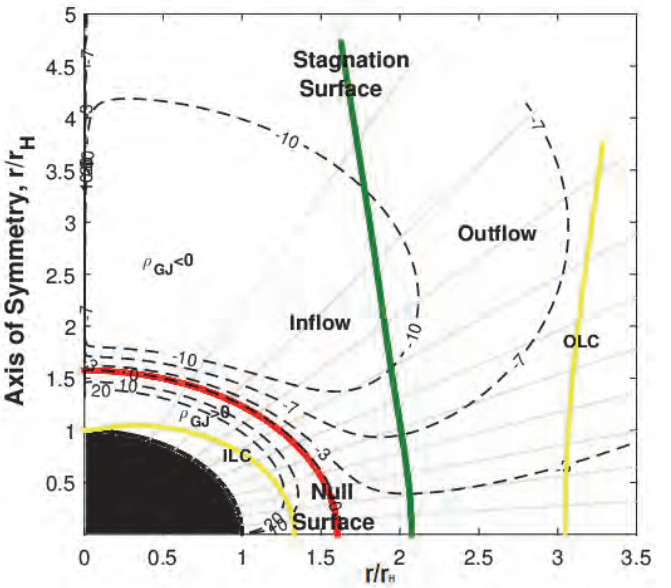

Fig. 1. Structure of the BH magnetosphere for a split-monopole and field line rotation frequency $\Omega_F = c/4r_g$. Gray solid lines represent field lines and dashed black lines denote contour levels of Goldreich-Julian density. Between the inner and outer light cylinder (yellow lines) the null (red) and stagnation (green) surfaces are located. Across the null surface the charge density changes sign, while the stagnation surface separates matter inflow and outflow, respectively.

$\rho_e$ can be determined from Gauss law

$$\frac{dE_{||}}{ds} = 4\pi(\rho_e - \rho_{GJ}) \quad \text{with} \quad \frac{d\Phi_e}{ds} = -E_{||}\,, \tag{1}$$

so that the relevant voltage drop becomes $\Delta V_{gap} = \Phi_e(s = h) - \Phi_e(s = 0)$, where $h$ denotes the characteristic gap height. It is easily seen that a "gap" emerges only if the real charge density $\rho_e$ diverges from the expected $\rho_{GJ}$.

Different solutions are obtained however, dependent on what type of boundary conditions (e.g., highly or weakly under-dense) are considered to be realised, as we show in Ref. 8. In general, the resultant voltage drop can be written as $\Delta V_{gap} = \Phi_o(h/r_g)^\nu$, with $\Phi_o \approx \Omega_F r_g^2 B_H/c$, where $B_H$ corresponds to the strength of the normal magnetic field component threading the horizon, and the coefficient $\nu$ is dependent on the chosen "gap" scenario:

(a) if $\rho_e << \rho_{GJ}$, for example, then

$$\Delta V_{gap} = \Phi_o \left(\frac{h}{r_g}\right)^2, \tag{2}$$

(b) while for $\rho_e \sim \rho_{GJ}$ one instead finds

$$\Delta V_{gap} = \Phi_o \left(\frac{h}{r_g}\right)^3, \tag{3}$$

i.e., a scaling $\propto h^3$ where the power index is now increased by one.

## 5. VHE gamma-ray emission from magnetospheric "gaps"

If the potential is sufficiently strong as expected around supermassive BHs, a single particle entering the gap can be accelerated to very high energies (up to Lorentz factors $\gamma \sim 10^{10}$), emitting curvature and inverse Compton gamma-ray photons on its way.[8] In the presence of an ambient photon field, a pair cascade ($\gamma + \gamma \rightarrow e^+ + e^-$) is triggered, that can lead to vacuum breakdown and the formation of highly conducting pair plasma, i.e., to enough charges ($\rho_e \geq \rho_{GJ}$) to annihilate the parallel electric field and ensure gap closure $\mathbf{E} \cdot \mathbf{B} = 0$.[6] As a consequence, the magnetic field lines can be considered as nearly orthogonal to the $\mathbf{E}$ field, with just enough $\mathbf{E} \cdot \mathbf{B}$ remaining to produce sparks of $e^+e^-$-pairs and keep the magnetosphere filled with plasma. An electromagnetic force-free solution could then provide a reasonable approximation to the time-averaged structure of such a magnetosphere.[3]

## 6. Associated "gap" luminosities

Given the anticipated potential strengths around supermassive BHs a significant amount of the non-thermal emission of magnetospheric "gaps" is expected to occur in the high and very high energy $\gamma$-ray domain (Refs. 11, 6, 5, 9). The different "gap" potential noted above, however, lead to different expectations for the maximum "gap" luminosity $L_{gap} \approx n_e V_{gap} dE_e/dt$ (with characteristic gap volume $V_{gap} \propto r_g^2 h$) for a gap of height $h$. As we show in (Ref. 8) the maximum extractable "gap" power is in general proportional to the classical Blandford-Znajek jet power, $L_{BZ} \propto r_g^2 B_H^2 \propto \dot{m} M_{BH}$ (with $B_H \propto \dot{m}^{1/2}$, $\dot{m}$ being the accretion rate), and a sensitive function of the gap height $h$, i.e.,

$$L_{gap} \sim \eta_\beta L_{BZ} \left(\frac{h}{r_g}\right)^\beta , \tag{4}$$

where the index $\beta \geq 1$ depends on the respective "gap"-setup: for case (a) noted above (Eq. (2)) one has $\beta = 2$ with $\eta_2 = 1$, while for case (b) $\beta = 4$ with $\eta_4 = 1/6$.

## 7. The phenomenological relevance of magnetospheric "gaps"

The anticipated occurrence of magnetospheric gamma-ray emission in AGN in principle allows for a fundamental probe of their near BH environment including accretion physics and jet formation. For this to be feasible, however, several constraints need to be met. On the one hand, the escape and detectability of VHE gamma-rays up to a few TeV at least requires the presence of a radiatively inefficient accretion flow (RIAF) close to the BH as otherwise severe $\gamma\gamma$-absorption in the disk photon field will occur (Ref. 8). On the other hand, in classical blazar-type sources (with jets viewed at small inclination) the observed VHE gamma-ray emission is expected to be dominated by the strongly Doppler-boosted emission of their jets. Hence

only in sources where the jet is sufficiently misaligned, such that Doppler effects are modest, might magnetospheric emission become detectable. This has made misaligned and under-luminous AGN, in particular nearby radio galaxies, to the most promising targets (see e.g. Ref. 10 for review and further references). The occur-

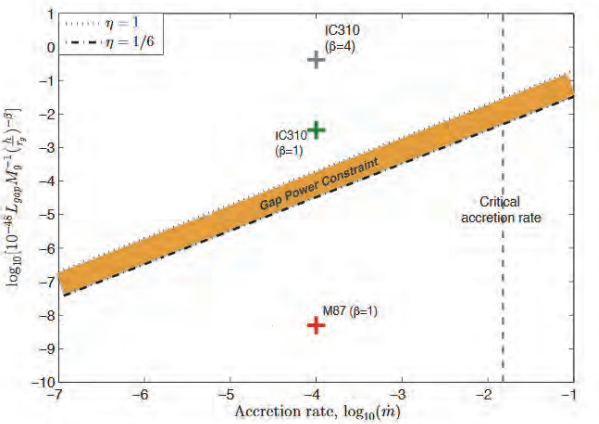

Fig. 2. Maximum possible $\gamma$-ray power (orange band) of a magnetospheric "gap" as a function of accretion rate $\dot{m}$, cf. Eq. (4). Different assumptions for the gap potential, Eqs. (2) and (3), lead to differences in extractable powers. The required transparency of the accretion environment to VHE photons introduces an upper limit $\dot{m}_c \leq 0.01$ on possible rates. If the observed VHE variability is used to constrain the gap height $h$, the extractable power is in principle sufficient to account for the gamma-ray emission seen from M87, yet under-predicts the VHE emission seen from IC 310.

rence of magnetospheric emission in these sources could contribute to the spectral hardening at GeV energies seen in some sources[12] and possibly account for rapid VHE variability on horizon crossing-times and shorter.[2,5] As the extractable power depends on the gap size $h$, Eq. (4), the plausibility of a magnetospheric origin can be investigated for sources in which significant VHE variability is detected.

In the radio galaxy M87 (distance $d = 16.7$ Mpc), for example, day-scale VHE variability has been detected during several TeV high states (with $L_{VHE} \simeq 10^{41} erg/s$). There are also indications that the TeV emission is accompanied by delayed radio core flux enhancements supporting the conclusion that the VHE emission may originate at the jet base very close to the BH (Ref. 1). One typically expects magnetospheric "gaps" to possess maximum heights of $h \lesssim r_g$ (if efficient pair production takes place, screening may well occur earlier, see Ref. 6). M87 has a BH mass of $M_{BH} = (2-6) \times 10^9 M_\odot$, corresponding to light crossing times of $\Delta t_H = r_g/c \simeq (3-9)$ hr. The VHE variability observed to date does not impose a stronger constraint on $h$. To ensure transparency to VHE photons the accretion flow would need to be radiatively inefficient (as indeed expected in M87) and this on average constrains inner accretion rates to satisfy $\dot{m}_c \leq 0.01$, see e.g. Ref. 8 for details. When this is put in context, extractable gap powers are such as to allow accommodation of the $\gamma$-ray emission seen from M87, see Figure 2.

The situation is different for the Perseus Cluster radio galaxy IC 310 (at $d = 80$ Mpc), believed to host a BH of $M_{BH} = 3 \times 10^8 M_\odot$. The minute-scale VHE variability seen during a strong VHE flare in Nov. 2012 (with isotropic $L_{VHE} = 2 \times 10^{44}\ erg/s$) would imply a gap height $h \leq c\Delta t = 0.2 r_g$ (Ref. 2). When this is employed in Eq. (4) along with the ADAF constraint $\dot{m}_c \leq 0.01$, extractable powers tend to become too small to account for the observed VHE emission (see Figure 2), thus disfavouring conventional magnetospheric scenarios for its origin.

## 8. Conclusions

Non-thermal magnetospheric processes could in principle lead to a non-negligible contribution at gamma-ray energies that could vary on horizon crossing times. As this contribution is non-boosted, potential targets would need to be close enough and possess jets sufficiently misaligned for this emission to become detectable by current instruments. The extractable gap power is a sensitive function of the gap height ($h/r_g$). Detection of rapid variability on timescales smaller than $r_g/c$ thus becomes most constraining and could allow to probe different gap descriptions. When put in context of recent observations, this suggests that the gamma-ray emission seen from M87 may have a magnetospheric origin, while such a scenario appears rather disfavoured in the case of IC 310.

We employ two radio surveys to find young energetic active galactic nuclei (AGN) with flat spectrum, and search for their counterpart in the Second Planck Catalogue of Compact Sources (PCCS2) at 353 GHz. We find 21 and 6 such AGN in the S4 and S5 Strong Source Surveys, respectively. Although none of them are within the error circle about the sky position of the track-type high-energy neutrinos already detected by the IceCube South Pole Neutrino Observatory, their flat spectrum and high-frequency detection imply they might emit neutrinos to be observed in the near future. Extending the list of these sources with the 114 flat spectrum AGN appearing with PCCS2-counterpart we already found in the Parkes Catalogue, we conclude that most of them have flux density between $400 \div 1400$ mJy at 5 GHz. This range is a good selection criterion for the future campaigns at 5 GHz aiming to find the possible sources of high-energy neutrinos.

*Keywords*: Active galactic nuclei; high-energy neutrino; catalogues.

## 1. Introduction

In the last years extensive studies have been carried out aiming at identifying the origin of the cosmic high-energy (HE) neutrinos detected by the IceCube South Pole Neutrino Observatory[1–5]. Active galactic nuclei (AGN), powered by supermassive black holes (SMBHs), are promising candidates, as they are able to produce the dominant isotropic neutrino background between $10^4 \div 10^{10}$ GeV[6].

IceCube is located at the Amundsen-Scott South Pole Station, and the observatory uses one cubic kilometre of the Antarctic ice as detector matter. The detector strings penetrate up to 2500 m deep underground, and are sensitive to the Cherenkovradiation of electrons and muons emerging from the interaction of electron and muon neutrinos with the ice. Electrons induce shower-type, while muons induce track-type event topologies. The arrival direction of the parent neutrino is constrained more precisely for the track-type events (within 2°).

Track-type HE neutrinos pinpoint their specific sources, the blazars, a class of radio-loud AGN pointing their jet towards the Earth. We first demonstrated[7] that in the case of the track-type neutrino ID5 and blazar PKS 0723-008 by cross-

correlating the Parkes Catalogue[8] and the Second Planck Catalogue of Compact Sources (PCCS2)[9] at 353 GHz with the arrival direction of track-type HE neutrino events detected by IceCube[2,10,11].

Recently the IceCube Collaboration with partner observatories on Earth and in space has reported on the multimessenger observations of the blazar TXS 0506+056[12]. The HE neutrino event IC-170922A detected at 22/9/2018 was in temporal and positional coincidence with a prominent $\gamma$-ray flare shown by this source. Subseqently we reported on the radio brightening of the neutrino emitting blazar TXS 0506+056[13], supporting its identification as source of the HE neutrino IC-170922A. The radio brightening of TXS 0506+056 preceding the detection of a HE neutrino is similar to the one we reported for PKS 0723-008 and IceCube event ID5[7], suggesting something similar happened with these blazars. The high energy of these neutrinos imply violent events as progenitors, such as the coalescence of compact objects, as we already suggested[7,13,14]. The published candidates for track-type IceCube neutrinos, with the neutrino ID-s in brackets: PKS 0723-008[7] (ID5), PKS B1206-202[7] (ID8), PKS B2300-254[7] (ID18), PKS B2224+006[7] (ID44), TXS 0506+056[12] (IC-170922A), GB6 J1040+0617[15] (IC-141209A), all six of them are flat spectrum sources at GHz-frequencies.

Here we investigate two other radio catalogues, the S4 Strong Source Survey[16] and the S5 Strong Source Survey[17], to identify further possible sources of track-type HE neutrinos. We report on the results here, also on the integrated flux density of the flat spectrum AGN from these surveys, as well as from the Parkes Catalogue[8], that have counterparts in the PCCS2[9] at 353 GHz.

## 2. Flat-spectrum AGN with Planck-counterpart at 353 GHz

An enormous shock-wave generated in the coalescence of two compact objects accelerates both the light and the heavy particles in their immediate environment. The former process leads to enhanced synchrotron emission and flat spectrum up to high radio frequencies ($\sim$ THz) due to the relativistic electrons, while the latter process leads to the emission of ultra-high energy cosmic rays (UHECRs) and HE neutrinos due to the relativistic protons and nuclei. The gravitational wave (GW) signal of a merger is accompanied by huge flares emerging across all regimes of the EM spectrum, as well as by significant excess in HE particles. Due to their much larger mass the coalescence of two SMBHs produces much more energetic GW signal as compared to the merger of astrophysical black holes or neutron stars. Consequently a more violent shock-wave propagates through the immediate environment of the SMBH merger, capable to induce the highest energy particles, and therefore we focused on AGN.

We searched for flat-spectrum AGN in the S4 Strong Source Survey[16] (flux limit 500 mJy, sky coverage $+35^0 < \delta < +70^0$, where $\delta$ is the decliantion), in the S5 Strong Source Survey[17] (flux limit 250 mJy, sky coverage $+70^0 < \delta < +90^0$), and in the Parkes Catalogue[8] (flux limit 250 mJy, sky coverage all the sky south of

declination $+27^0$, excluding the Galactic Plane and the Magellanic Cloud regions). The spectral index $\alpha$ was defined with the convention $S \sim \nu^{+\alpha}$ between 2.7 GHz and 5 GHz. We cross-correlated the coordinates of flat spectrum AGN from these catalogues with the coordinates from the Second Planck Catalogue of Compact Sources (PCCS2)[9]. We used data from the PCCS2 taken at 353 GHz, which is the highest frequency measurements at which the contamination from the Galactic plane can be safely corrected. The error on the sky position of the point sources at this frequency is 8 arcmin. Then we cross-correlated the coordinates of flat spectrum AGN having PCCS2 counterpart with the coordinates of the 15 track-type HE neutrinos detected by the IceCube, considering the errors on the positions as well. The detection data of these neutrino events are summarized in Table 1.

Table 1. Data of the 15 track-type HE neutrino events detected by the IceCube[2,10,11]. ID: identification, $E_{dep}$: deposited energy, $RA$: right-ascension, $\delta$: declination, $\theta$: median angular error.

| ID | $E_{dep}$ $(TeV)$ | $RA$ $(^0)$ | $\delta$ $(^0)$ | $\theta$ $(^0)$ |
|---|---|---|---|---|
| 3 | $78.7^{+10.8}_{-8.7}$ | 127.9 | -31.2 | $\lesssim 1.4$ |
| 5 | $71.4^{+9.0}_{-9.0}$ | 110.6 | -0.4 | $\lesssim 1.2$ |
| 8 | $32.6^{+10.3}_{-11.1}$ | 182.4 | -21.2 | $\lesssim 1.3$ |
| 13 | $253^{+26}_{-22}$ | 67.9 | 40.3 | $\lesssim 1.2$ |
| 18 | $31.5^{+4.6}_{-3.3}$ | 345.6 | -24.8 | $\lesssim 1.3$ |
| 23 | $82.2^{+8.6}_{-8.4}$ | 208.7 | -13.2 | $\lesssim 1.9$ |
| 28 | $46.1^{+5.7}_{-4.4}$ | 164.8 | -71.5 | $\lesssim 1.3$ |
| 37 | $30.8^{+3.3}_{-3.5}$ | 167.3 | 20.7 | $\lesssim 1.2$ |
| 38 | $200.5^{+16.4}_{-16.4}$ | 93.34 | 13.98 | $\lesssim 1.2$ |
| 43 | $46.5^{+5.9}_{-4.5}$ | 206.63 | -21.98 | $\lesssim 1.3$ |
| 44 | $84.6^{+7.4}_{-7.9}$ | 336.71 | 0.04 | $\lesssim 1.2$ |
| 45 | $429.9^{+57.4}_{-49.1}$ | 218.96 | -86.25 | $\lesssim 1.2$ |
| 47 | $74.3^{+8.3}_{-7.2}$ | 209.36 | 67.38 | $\lesssim 1.2$ |
| 53 | $27.6^{+2.6}_{-2.2}$ | 239.02 | -37.73 | $\lesssim 1.2$ |
| 55 | $2600^{+300}_{-300}$ | 110.34 | 11.48 | $\lesssim 1.0$ |

## 3. Discussion

We found 21/6/114 flat spectrum AGN with PCCS2-counterpart at 353 GHz in the S4-S5 Surveys and in the Parkes Catalogue, respectively. The map of the flat spectrum AGN with PCCS2-counterparts and the track-type HE neutrino events are presented in Figure 1 in galactic coordinates. The number of these sources in 200 mJy-bins is presented in Figure 2, separately at 2.7 GHz and at 5 GHz. Most of these AGN have flux density between $400 \div 1400$ mJy at 5 GHz. This range might be a good selection criterion for future campaigns at 5 GHz, aiming to find the possible sources of HE neutrinos.

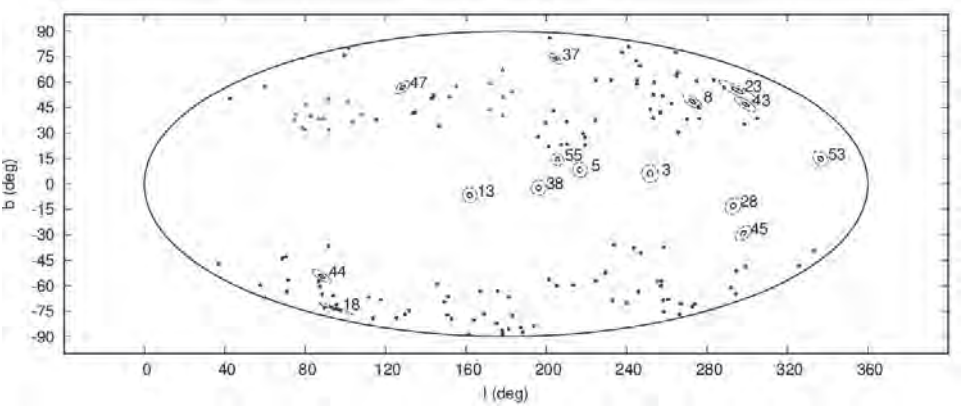

Fig. 1. Map of flat spectrum AGN with Planck-counterpart at 353 GHz in galactic coordinates, employing Mollweide projection. The error circle of the track-type neutrino events (denoted by their ID-number) is presented by continuous black line and three times it's size by a dashed line. The event ID5 is marked by a red cross.

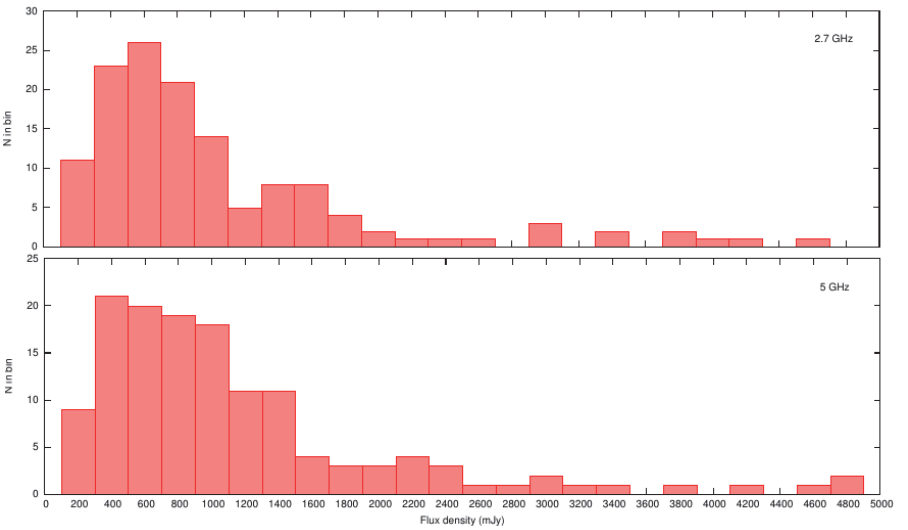

Fig. 2. The number of flat spectrum AGN with Planck-counterpart at 353 GHz, binned by their flux density measured at 2.7 GHz (upper panel) and at 5 GHz (bottom panel). There are 6, respectively 4 AGN that are brighter than 5000 mJy at 2.7 GHz, respectively 5 GHz.

We proposed a scenario of binary SMBH evolution, which naturally explains the observed HE neutrino emission leading to the emission of GWs through a sequence induced by the merger[7,13,14]. We expect that there are three main phases of the emission of HE particles in this scenario. The first one is the process of

spin-flip, when the jets sweep through a large cone (see M82 where this may have been detected,[18,19]). The second one is after the spin-flip, when a new jet is boring into the environment, leading to more injection of the seed particles to create HE nuclei, gammas and neutrinos. The third one is probably in the instant of the coalescence of SMBHs, when a giant shock-wave may be generated by low-frequency GWs (lfGWs) to accelerate particles to high energies, leading to a final burst of HE nuclei, gammas and neutrinos. Only the HE neutrinos are detectable across the universe. Considering TXS 0506+056, the post-merger SMBH binary scenario provides a consistent physical picture explaining the already occurred multimessenger observations (radio, $\gamma$-ray, and HE neutrino).

The next-generation IceCube detector, the future ten-cubic-kilometre detector IceCube-Gen2, is a very promising development regarding this work. This instrument is aimed to detect very high-energy astrophysical neutrinos in the PeV to EeV range, yielding hundreds of neutrinos across all flavours at energies above 100 TeV. This will enable detailed spectral studies, significant point source detections, important for quantifying the HE particle emission of the individual candidate-sources. The IceCube-Gen2 spectra together with the EM-observations will teach as how to find AGN harbouring SMBHs, that will merge within a very short time emitting GWs.

A great challenge will be the direct detection of these lfGWs (of order of microHz to milliHz) by the future Laser Interferometer Space Antenna (LISA) mission. The ultimate proof of the above scenario will be this direct detection of lfGW-signal of the candidate sources.

on behalf of the SVOM collaboration

The Space Variable astronomical Object Monitor (SVOM) is a mission dedicated to the detection and characterization of Gamma-Ray Bursts and other high-energy astrophysical transients. SVOM is jointly developed by the Chinese Academy of Science (CAS), the Chinese National Space Administration (CNSA) and the French space agency (CNES) with a launch date foreseen at the end of 2021. SVOM will enable to observe new sources in a large wavelength domain, from the near infrared to gamma rays, thanks to its unique combination of space and ground based instruments. The space borne instruments include two wide field of view monitors, ECLAIRs and GRM, operating in the hard X-ray to gamma-ray energy band, and two narrow field telescopes, MXT and VT, operating in the X-ray and visible domain. On the ground three dedicated robotic telescopes, F-GFT-Colibri, C-GFT, and GWACs will provide complementary coverage in the near infrared and visible bands. SVOM alerts will be distributed publicly to the scientific community in order to enhance the scientific return of the mission.

*Keywords*: Gamma-Ray Bursts; Space Instrumentation.

## 1. Introduction

The Space Variable astronomical Object Monitor (SVOM) mission is being jointly developed by the Chinese Academy of Science (CAS), the Chinese National Space Administration (CNSA) and the French space agency (CNES), and its launch date is foreseen for the end of 2021. The science goals are shared between a Core Programme (CP), a General Programme (GP), and a Target of Opportunity (ToO) Programme. The goals of the CP include the detection and characterization of Gamma-Ray Bursts (GRBs) with a particular emphasis on the detection of high redshift ($z > 5$) events and their use as probes of the early Universe, the broad band coverage of the GRB prompt emission, and the building of a uniform afterglow data sample from the X-rays to the near infrared. The CP will make use of 25% of the SVOM observation time. During the rest of the time SVOM will be operated as an observatory performing pre-planned (GP, 60% of the SVOM time) and un-anticipated ToO observations (15% of the time). This sharing applies to the

nominal lifetime of the mission (i.e. the first three years on orbit) and will evolve during the extend mission including a higher fraction of ToO time (up to 40% of the SVOM observation time). The reason for it is that SVOM is also suited to play a role in the upcoming era of multi-messenger astronomy, being able to provide follow-up of triggers related to gravitational wave, neutrino, very high energy gamma-ray or synoptical astronomy.

In order to favour the follow-up of SVOM GRBs by ground based observatories, SVOM will be mainly pointing to the anti-solar direction. In addition, in order to maximize the GRB detection sensitivity, at least during the nominal mission lifetime, the SVOM pointing has been defined as to avoid the Galactic plane (which in turn facilitates the follow-up from ground) and other bright X-ray sources (such as Sco X-1). Thanks to this pointing strategy we expect that about 75% of the SVOM GRBs can be followed promptly from ground, increasing the chances of measuring their redshift through spectroscopy.

For a detailed view of the SVOM science objectives we refer the reader to the SVOM white paper [1]. In this paper we will mainly review the SVOM space payload and the associated ground segment.

## 2. The SVOM Space Segment

SVOM will be launched from Xichang in China by a LM-2C rocket and injected into a circular low Earth orbit with an inclination of about 30° at an altitude of ∼625 km. It will carry two wide field monitors and two narrow field telescopes. The wide field monitors are ECLAIRs, a coded mask telescope operating in the 4–250 keV energy range, provided by CNES in collaboration with French laboratories (IRAP, APC, CEA-Irfu), and the GRM, a set of three non-imaging gamma-ray spectrometers, sensitive in the 15 keV–5 MeV energy range, provided by IHEP Beijing. The narrow field telescopes are the MXT, sensitive in the 0.2–10 keV energy range provided by CNES in collaboration with CEA-Irfu, LAL, MPE, and the University of Leicester, and the Visible Telescope (VT), provided by the NAOC in collaboration with XIOPM.

### 2.1. *ECLAIRs*

ECLAIRs is composed by a focal plane of 80×80 CdTe pixels of 4×4×1 $mm^3$ size. A 54×54 $cm^2$ mask with an open fraction of 40% and a pixel size of about 1.1 cm is placed 46 cm above the detection plane. The system provides a ∼2 sr field of view and a point spread function of 52 arc min (FWHM). The ECLAIRs data stream (monitored on time scales from 10 ms to about 20 minutes on 4 energy bands and in 9 detector zones) is analysed in real time on board the satellite by the UGTS electronic box in order to search for new sources appearing in the field on view. Once a new source is detected its coordinates are computed and transmitted to the satellite in order to send the information to ground based observatories and to slew

to place the ECLAIRs error box (<12 arc min) into the field of view of the narrow filed telescopes for more accurate localization and physical characterization in the X-rays and in the visible domain. ECLAIRs will be able to detect all kind of GRBs, see Fig. 1, but thanks to its low energy threshold of only 4 keV it will be more sensitive than previous experiments to X-ray rich GRBs which could represent the population of high distance GRBs due to cosmological energy shift[2]. ECLAIRs is expected to detect about 60 GRBs per year.

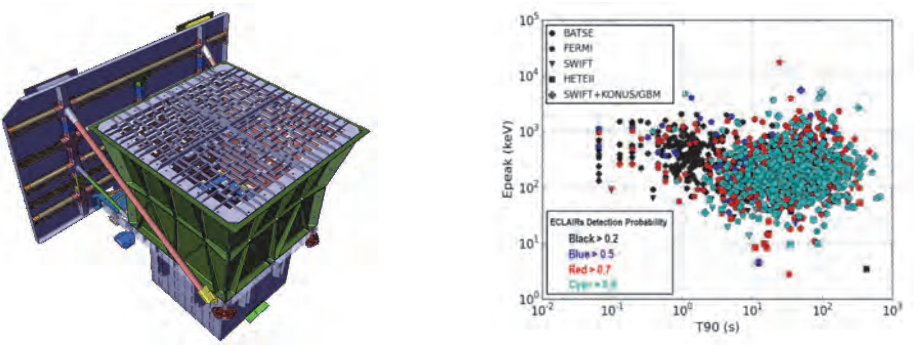

Fig. 1. Left: the ECLAIRs coded mask telescope. Right: the probability of detection by ECLAIRs (color code) of a sample of GRBs observed by previous experiments, plotted as a function of the GRB duration and spectral peak energy.

### 2.2. *GRM*

The Gamma-Ray Monitor (GRM) system is composed by three Gamma-Ray Detectors (GRD) and a particle monitor. Each GRD is made of a NaI(Tl) scintillating crystal, a photomultiplier and its readout electronics, and has a geometrical area of 200 $cm^2$, thickness of 1.5 cm, FoV of $\pm 60$ degrees with respect to its symmetry axis, dead time $<8$ $\mu$s, temporal resolution $<20$ $\mu$s and energy resolution of 16% at 60 keV. A plastic scintillator in front of the NaI(Tl) crystal is used to distinguish low energy electrons from gamma-rays. The 3 GRD-modules point at different directions in order to cover, globally, a field of view which is larger than the ECLAIRs one, see Fig. 2. This will allow to detect a larger number of GRBs ($\sim$90 per year), although most of them will be poorly localized (error box $> 10°$). For the GRBs detected both in the field of view of ECLAIRs and in the one of one or more GRD a combined spectral analysis will be possible from a few keV to a few MeV, allowing a complete physical description of the SVOM GRBs, as shown in the right panel of Fig. 2.

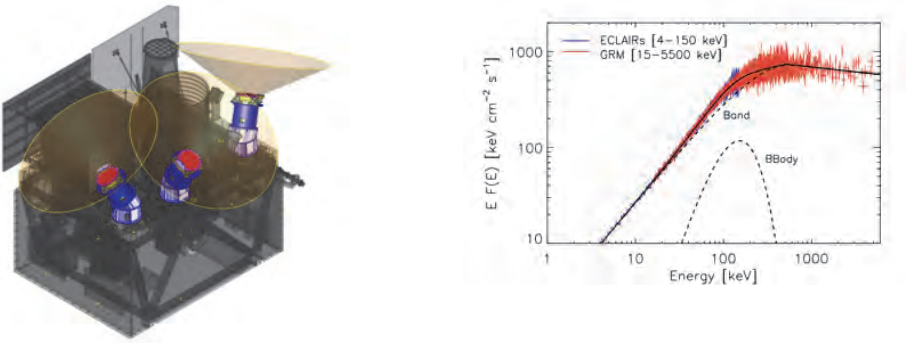

Fig. 2. Left: the GRDs and their individual field of views. Right: a simulation showing a simultaneous spectral fit of GRB 100724B. GRB 100724B was observed by Fermi/GBM and a thermal component (BBody in the figure) has been reported: this component can be detected in the simulated data with the same statistical significance with respect to the GBM data. For more details, see the SVOM white paper [1].

### 2.3. *MXT*

The Microchannel X-ray Telescope (MXT) [3] is an X-ray focussing telescope with a field of view of 57×57 arc min, whose innovative optical concept is based on the so-called *Lobster Eye* optics [4]. This optical concept is realized making use of square pore lead glass micro pore optics (MPOs) plates with 40 $\mu$m pore side and 1-2 mm thickness (with inner Ir coating to enhance the reflectivity), produced by Photonis. 25 plates of 40 mm side are used to build the complete MXT optics, which is coupled to a camera sensitive in the 0.2–10 keV energy range, based on a pnCCD [5] composed of 256×256 pixels of 75 $\mu$m side. The pnCCD and is read-out rate every 100 ms and actively cooled to –65°C. A filter wheel allows to put a calibration source or additional optical/UV filters in front of the detector when needed.

The MPO Point Spread Function (PSF) is composed by a central spot and two cross arms: about 50% of the incident X-rays are reflected twice and focused in the central PSF spot, X-rays reflected just once and focused in both PSF arms (2×22%), and the rest produces a diffuse patch. In the *Lobster Eye* geometry the vignetting is very low, reaching 10–15% at the edge of the FoV. Simulations indicate that the PSF of such system could reach 4.5 arcmin FWHM at 1.5 keV (central peak). In reality, due to defects in the alignment of the channels, distortions of the channel walls, and misalignment of the plates, such system may finally provide a ∼10 arc min FWHM PSF. The GRB afterglow position is computed on-board in near real-time by the MXT Data Processing Unit. The expected MXT effective area is about 23 cm$^2$ at 1 keV for the central spot, and expected GRB afterglow localization performance, obtained by folding the entire Swift/XRT afterglow dataset through the MXT response, shows that MXT is well adapted to study GRB afterglows, see Fig. 3. Indeed, 50% of the bursts will be localized to better than

1 arc min (90% c.l. radius; statistical uncertainties only) within 5 min from the MXT stabilization time.

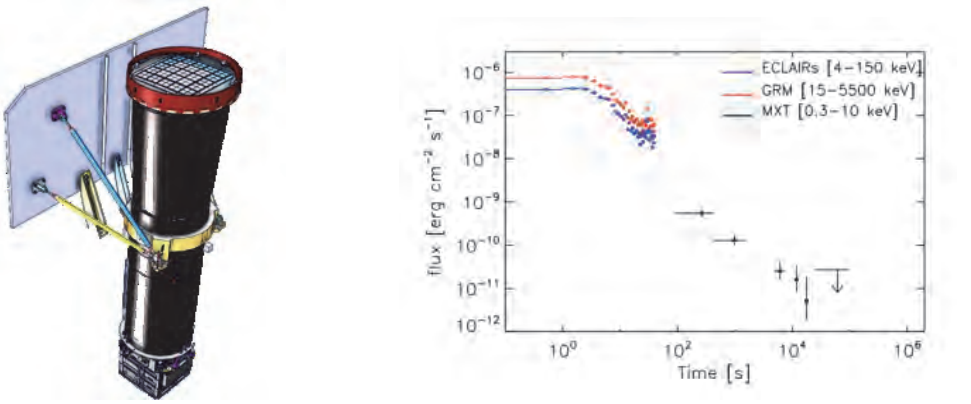

Fig. 3. Left: the MXT telescope. Right: Simulation of the prompt and afterglow emission of GRB 091020 in SVOM instruments. In MXT the afterglow is detected up to $\sim 10^4$ s. For more details, see the SVOM white paper [1].

### 2.4. *VT*

The Visible Telescope (VT) main purpose is to detect and observe the optical afterglows of GRBs localized by ECLAIRs. It is a Ritchey-Chretien telescope with a 40 cm diameter and its limiting magnitude is about $M_V$=22.5 for a 300 s integration time. The VT is designed to maximize the detection efficiency of GRB's optical afterglows. A dichroic beam splitter divides the light into two channels, in which the GRB afterglow is observed simultaneously, a blue channel with a wavelength from 0.4 to 0.65 $\mu$m and a red channel from 0.65 to 1 $\mu$m. Each channel is equipped with a 2K×2K CCD detector. The Quantum Efficiency (QE) of the red-channel CCD is over 50% at 0.9 $\mu$m, which gives VT the capability of detecting GRBs with redshifts larger than 6.5. The VT FoV is about 26×26 arc min$^2$, covering the ECLAIRs error box in most cases.

## 3. The SVOM Ground Segment

Three optical/infrared instruments compose the ground-based SVOM system. The first unit of the Ground-based Wide Angle Cameras (GWACs), currently located Xinglong (China), and is already operational. Another unit may be installed later at a different site. The GWACs located in China consist of 40 cameras of 180 mm diameter, covering $\sim$6000 deg$^2$ in total in the wavelength range 500-850 nm. The GWAC system can reach a magnitude limit of V=16 in 10 s. In addition to the GWACs, whose main goal is to try to catch the prompt optical emission of SVOM

GRBs, two robotic 1-m class telescopes are being included in the SVOM system. The Chinese Ground Follow-up Telescope (C-GFT) has a 1.2 m diameter primary mirror, is located at the Jilin observatory, has a field of view of 21×21 arc min$^2$ and is sensitive in the 400-950 nm wavelength range. The French Ground Follow-up Telescope (F-GFT/Colibri) will have a 1.3 m diameter primary mirror and will be installed in San Pedro Martir (Mexico). It offers a field of view of 26×26 arc min$^2$ and operates simultaneously in 3 bands from 400 to 1700 nm.

The SVOM ground segment includes a set of VHF antennas (about 40), which will be deployed on the projected track of the satellite in order to collect in real time the alerts produced by the platform. These VHF ground stations will be connected to the French Science Centre (FSC), which will immediately dispatch the alerts produced by all the SVOM instruments to the scientific community. We expect that 65% of the SVOM alert messages are delivered within less than 30 s, and that 95% of them reach the observers within less than 20 minutes.

## 4. Conclusions

SVOM will play a key role in the upcoming era of time domain and multi-messenger astronomy. At the time of SVOM launch, new large sky area time domain oriented instruments, like the LSST in the optical or the SKA at radio wavelengths, will deliver an unprecedented number of well localized ToOs that may be worth following up with the space-borne and ground-based SVOM instruments. Gravitational wave detectors (advanced LIGO, VIRGO, LIGO-India, KAGRA, etc.) will provide more alerts than now with improved localisation accuracies. Neutrino detectors IceCube-Gen2, KM3NeT (extension of ANTARES), etc. will also trigger a significant number of alerts. In this respect, the SVOM/MXT grasp appears to be well adapted to the large error boxes delivered by gravitational wave and neutrino detectors.

# Mercury perihelion advance in perspective (1906–1915)

Christian Bracco

*Syrte, Observatoire de Paris, Université PSL, CNRS, Sorbonne Université, LNE, Paris, 75014, France*
*E-mail: Christian.Bracco@obspm.fr*

Jean-Pierre Provost

*720 route de la Turbie*
*Eze, 06360, France*
*E-mail: provost@oca.eu*

Thanks to the introduction of a general Lagrangian, we derive a simple expression for Mercury perihelion advance (MPA) which can be applied to many historical examples, such as Poincaré's 1906 application of his relativistic action, Einstein's probable test of his 1912 metric, Einstein-Besso's 1914 application of the *Entwurf*... as well as to modern presentations. We argue that Einstein's failure to derive in his Zurich Notebook the right equations of general relativity has a physical rather than mathematical origin, which amounts to an incomplete application of the 1895 Lorentz Transformations to his 1911 formulation of the Equivalence Principle. MPA could have been already in his hands in 1912.

*Keywords*: Mercury; Lagrangian; Lorentz; Poincaré; Einstein.

## 1. Introduction: Between history and teaching

In this presentation, we discuss Mercury perihelion advance (MPA) in relation to relativity both from an historical and a pedagogical point of view [1]. Implementing efficiently historical issues in the teaching of physics (instead of referring to them either anecdotally, critically or emphatically) is in our opinion an important goal both for the history and the teaching of science. Of course, this necessitates to formulate them in a modern perspective, which implies that one acknowledges that historical issues are often close to modern ones, a point of view generally shared by mathematicians in the tradition of Henri Poincaré, but not by physicists who are rather inclined to adopt the Bachelardian epistemological point of view of scientific revolutions (or a Kuhnian one in terms of change of paradigm). In return, such an approach may shed a new light on these issues. As an example, which concerns MPA, we explained in [2] how Lorentz 1895 transformations $x' = x - Vt$, $t' = t - Vx$ (with $c = 1$) (thereafter 1895 LT) can be used to introduce Special Relativity (SR) early in teaching and discuss relativistic physics without calling for the exact 1904 LT;[a] then applying these LT to Einstein's approach of gravitation through the

[a]Other examples of the interest of historical issues for present teaching are our discussions of Kepler's equant model [3] and Newton's geometrical derivation of Kepler laws [4].

equivalence principle (EP) in 1907 and 1911, we realized that Einstein's "bumpy road" to General Relativity (GR) mainly originated from an incomplete use of them (see section 3 below).

As well documented [5], the observation of Mercury's orbital perihelion (Le Verrier 1859, Newcomb 1882 and 1895, etc.) has left a residue of about 43" per century unexplained by perturbations due to other planets within the framework of Newton's theory of gravitation, or by attempts to modify the gravitational force.[b] Less known is that the calculation of this residue, proposed as an exercise in some text books, from the Lagrangian (with $c = 1$)

$$L_{HP} = -\sqrt{1 - v^2} + \alpha u \quad (\alpha = GM, u = 1/r), \tag{1}$$

has been taken as a test of relativistic mechanics as soon as 1906 by Poincaré in his Sorbonne lectures on Mercury perihelion[c] [6]. History of the MPA has remembered that SR with the above Lagrangian only accounts for $1/6^{\text{th}}$ of the correct value, forgetting to consider

$$L_{SR} = -\sqrt{1 - v^2} + \alpha\gamma u, \quad (\gamma = (1 - v^2)^{-1/2}), \tag{2}$$

which introduces the physical idea of "inertia of energy". It has essentially memorized the final explanation of MPA by Einstein in November 1915 [8] from the metric

$$ds^2 = (1 - 2\alpha u)dt^2 - (1 + 2\alpha u)dr^2 - r^2 d\Omega^2, \tag{3}$$

(based on the solution of $R_{\mu\nu} = 0$ at first order) as one of his most famous discoveries. History generally ignores Einstein-Besso calculation[d] of MPA from

$$ds^2 = \left(1 - 2\alpha u + \frac{3}{2}(\alpha u)^2\right) dt^2 - d\vec{r}^2, \tag{4}$$

based on Einstein-Grossman's *Entwurf* [10] and the hypothesis that gravitational energy (the quadratic term in Eq. (4)) be also source of gravitation, or Einstein 1912 [11] likely one from

$$ds^2 = (1 - 2\alpha u)dt^2 - d\vec{r}^2, \tag{5}$$

after his incomplete application of the EP (see section 3), or Einstein-Fokker 1914 possible one from

$$ds^2 = e^{-2\alpha u}(dt^2 - d\vec{r}^2) \tag{6}$$

[b] We recall that in Newton's theory, an inverse square law for the acceleration $-\alpha\hat{r}/r^2$ accounts for the elliptical trajectory $r = (l^2/\alpha)(1 + e\cos K\varphi)^{-1}$ ($l$ area constant or angular momentum per unit mass), which for small eccentricity $e \ll 1$ corresponds to Kepler's equant model.

[c] We recall that in 1905 Poincaré deduced the relativistic free Lagrangian (he took already $c = 1$!) from the Lorentz contraction and justified it by the invariance of action under the Lorentz group [7]. In 1906, he compared his result for MPA with those derived from Abraham's and Langevin's Lagrangians (based on different hypotheses concerning the shape of a moving electron).

[d] A noticeable exception is [9].

(equivalent to Nordström scalar theory).[e] Historical discussions also generally put aside the question of why Einstein 1915 metric is equivalent for MPA to Schwarzschild's exact solution

$$ds^2 = (1-2\alpha u)dt^2 - (1-2\alpha u)^{-1}dr^2 - r^2 d\Omega^2 \tag{7}$$

or why it is not equivalent to

$$ds^2 = (1-\alpha u)^2 dt^2 - (1+\alpha u)^2 dr^2 - r^2 d\Omega^2 \tag{8}$$

although like Eq. (3) it also fully takes into account the EP. In section 2, we present a simple formalism which allows to address all these proposals and to test the different physical ideas which have anticipated GR.[f]

## 2. A general Lagrangian approach to Mercury perihelion advance

Quite remarkably, the eight above metrics, with the identification $ds^2 = L^2 dt^2$ and the Lagrangians given by Eqs. (1) and (2), correspond to a squared Lagrangian of the type (for plane trajectories)

$$L^2 = A(\alpha u) - B(\alpha u)\dot{r}^2 - C(\alpha u) r^2 \dot{\varphi}^2, \tag{9}$$

$A$, $B$ and$C$ being functions of $\alpha u$, with $A(0) = B(0) = C(0) = 1$ and the dot meaning a derivation with respect to time. These functions are e.g. respectively $(1-\alpha u)^2$, $(1-\alpha u)$ and $(1-\alpha u)$ for Eq. (1) and $(1-2\alpha u)$, $(1+2\alpha u)$ and 1 for Eq. (3). Finding the equation of the trajectory from $L$, with the use of angular momentum $l$ and energy $E$ conservations, is then a standard exercise of Lagrangian calculus (see [1] for details). It leads to (prime denoting a derivation with respect to $\varphi$):

$$A = E^2 - l^2(au^2 + bu'^2), \quad \left(a = \frac{A}{C},\ b = \frac{AB}{C^2}\right). \tag{10}$$

Because of Mercury's small orbital eccentricity, one can set $u = u_0 + \delta u$, where $\delta u$ is a small deviation with respect to a circular trajectory centered at origin. Then introducing the a-dimensional distance parameter $\varepsilon = \alpha u_0 \simeq \alpha^2/l^2 \ll 1$ (*cf.* note 2) and writing $a(\varepsilon) = 1 + \varepsilon a'(0)$ (idem for $b(\varepsilon)$ and $A'(\varepsilon)$), the perturbation calculus at order $\varepsilon$ yields:

$$\delta u'' + K^2 \delta u = 0; \quad K^2 = 1 + \varepsilon\left(3a'(0) - b'(0) + \frac{A''(0)}{2}\right). \tag{11}$$

[e]The calculations from Eqs. (5) and (6) are merely historical assumptions based on Einstein's acknowledgement that he thought about MPA since 1907. Einstein has also probably tested the relativistic equations of motion in a gravitational field which he puts forward at the top end of his extensive review paper of November 1914.

[f]In present teaching [12], this formalism can also be applied to the PPN metric $ds^2 = (1-2\alpha u + 2\beta\alpha^2 u^2)dt^2 - (1+2\gamma\alpha u)d\vec{r}^{\,2}$ or to the isotropic form $ds^2 = (1-\alpha u)^2(1+\alpha u)^{-2}dt^2 - (1+\frac{\alpha}{2}u)^4 d\vec{r}^{\,2}$ of the Schwarzschild metric.

So the trajectory reads $u = u_0(1 + e\cos K\varphi)$, and the perihelion advance per revolution is:

$$\Delta\varphi = \pi(1 - K^2) = \pi\varepsilon\left(-3a'(0) + b'(0) - \frac{A''(0)}{2}\right). \tag{12}$$

In particular, applications to Eqs. (1) ($\Delta\varphi = \pi\varepsilon$), (2) ($\Delta\varphi = 3\pi\varepsilon$), (4) ($\Delta\varphi = 4\pi\varepsilon$) and (8) ($\Delta\varphi = 5\pi\varepsilon$) allow to appreciate how much[g] the associated physical hypotheses mentionned in section 1 bring the solution close to the exact one obtained from Eq. (7) as well as from Eq. (3) ($\Delta\varphi = 6\pi\varepsilon$). One may also note that a quadratic term in A (*cf.* Eqs. (1), (2), (4), (6) and (8)) interpreted in section 1 as "gravitation due to gravitational energy" systematically contributes negatively to $\Delta\varphi$[8].[h] Finally, we emphasize that the EP often discussed in the context of GR is clearly insufficient since it gives information on $A$, $B$ and $C$ only up to first order in $\alpha u$ and says nothing for $A''(0)$. In conclusion, whereas the EP can account for the gravitational redshift and the deviation of light, one cannot escape $R_{\mu\nu} = 0$ in order to explain MPA; so MPA is a nice introduction to the teaching of GR.[i]

## 3. How far was Einstein from explaining Mercury perihelion advance in 1912?

Following Einstein, it has been claimed that him and Grossmann (in the 1912 Zurich Notebook [13]) where close to the equations of GR (at least in vacuum) since in particular the Ricci tensor $R_{\mu\nu}$ was clearly for them the geometrical counterpart of the energy momentum tensor. The problem was that Einstein 1912 metric deduced from his application of the EP did not satisfy $R_{\mu\nu} = 0$ even at first order in the gravitational potential. The metric was right for time coordinates but false for spatial ones. Up to our knowledge, the question has not been previously raised as to whether 1895 LT $x' = x - Vt$, $t' = t - Vx\,(c = 1)$, which come into play when one conceives, as Einstein, an accelerated system $\Sigma$ moving along the $x$-axis as a succession of inertial frames $R_t = R$, $R_{t+\delta t} = R'$ with relative velocities $V = a\delta t$, imply or not a non trivial $x$-metric for $\Sigma$. We now briefly show that the answer is affirmative.[j]

Let us indeed consider a rod of apparent length $l$ in uniform motion at velocity $v$ in $R_t$, defined by the events $0 < x - vt < l$. It is straightforward to verify that it is defined in $R_{t+\delta t}$ by $0 < x' - v't' < l'$ with in particular $l' = l(1 + Vv)$.[k] This calculation is the same as that of Poincaré in 1900 for a light wave packet ($v = 1$),

[g] $\Delta\varphi = 2\pi\varepsilon$ can be obtained from the non-Lagrangian equation $d\vec{p}/dt = -\alpha\gamma\hat{r}/r^2$ [1].
[h] $A''(0)$ is the only contribution for the scalar theory (Eq. (6)).
[i] Instructive for teaching are also the PPN metric result $\Delta\varphi = \pi\varepsilon\,(4 - 2\beta + 2\gamma)$, and the result issued from the isotropic metric $\Delta\varphi = \pi\varepsilon\,(12 - 4 - 2)$ which shows that $6\pi\varepsilon$ may be obtained in very different ways according to the choice of coordinates.
[j] See [1–2] for more issues and details.
[k] The same analysis for a moving clock (*i.e.* writing $\Delta x = v\Delta t$ with prime coordinates) gives the inverse relation $\Delta t' = \Delta t\,(1 - vV)$.

and the fact that the result is identical to the Doppler effect $\lambda' = \lambda(1+V)$ is simply a consequence of the invariance of the phase already considered by Lorentz in 1895. So, a light wave packet is nothing else but a rod moving at $v = 1$! In 1911, Einstein applied, as is well known, the EP to a light signal sent from the altitude $h$ to the ground and showed, with the help of the Doppler effect, that the received signal has a frequency $\nu_0 = \nu_h(1+gh)$ [14]. He then deduced that the proper times of identical clocks at rest at $z = 0$ and $z = h$ were related by $\tau_h = \tau_0(1+gh)$ and he extended this relation to $\tau = t(1 - GM/r)$ for clocks in the gravitational potential of a spherical mass $M$, thanks to the EP. Had he realized that $\lambda_0 = \lambda_h(1-gh)$ implied for the proper lengths the inverse relation $\Delta l_h = \Delta l_0(1+gh)$, he would probably have been led to the metric given by Eq. (3) instead of Eq. (4). Then he would have explained the MPA and be confident in Grossmann's hypothesis $R_{\mu\nu} = 0$ outside matter as soon as 1912.

In, conclusion, whereas Einstein has found in 1907 and in 1911 subtle ways to apply the Equivalence Principle and relativity at first order to the issue of time, he completely missed the opportunity to address an analogous issue for lengths. He turned to other considerations which have contributed to his "bumpy road" to General Relativity.

# May 29, 1919 total solar eclipse: Brazilian, British and North-American expeditions to Sobral, Brazil

Luís C. B. Crispino*

*Faculdade de Física, Universidade Federal do Pará, 66075-110, Belém, Pará, Brazil*
**E-mail: crispino@ufpa.br*
*www.ufpa.br*

I comment on the three (Brazilian, British and North-American) expeditions organized to observe in Sobral, Brazil, the May 29, 1919 total solar eclipse.

*Keywords*: Total Solar Eclipse; 1919; Expeditions; General Relativity.

Among the most famous eclipses in History of Science, stands out the May 29, 1919 total solar eclipse, during which observations led to the first experimental confirmation of General Relativity.[1]

The photographs which confirmed Einstein's Theory, in 1919, were taken by two expeditions organized by the Royal Greenwich Observatory: one sent to Príncipe Island, in Africa (team composed by Arthur Stanley Eddington and Edwin Turner Cottingham); and the other sent to the city of Sobral, in Brazil (team composed by Andrew Claude de la Cherois Crommelin and Charles Rundle Davidson).[2]

Less known is the fact that, apart from the Cambridge expedition, two other scientific commissions (cf. Fig. 1) were sent to Sobral in 1919.[3] One was the Carnegie commission, composed by Daniel Maynard Wise and Andrew Thomson;[4] and the other was the Brazilian National Observatory commission, leaded by Charles Henry Morize.[5–7] The Carnegie expedition had the purpose to investigate Earth's magnetism and atmospheric electricity, while the Brazilian Observatory team main goal was to investigate the solar corona.

The British and the North-American teams installed their equipment at the racecourse of the Jockey Club at Sobral (cf. Fig. 2), while the Brazilian team set their installation in Patrocinio square (cf. Fig. 3).

Both the British and the Brazilian teams obtained very nice pictures of the eclipsed Sun (cf. Figs. 4 and 5). In those pictures, an impressive solar prominence appears. The measurements of the relative positions of the stars appearing in the British photographic glass plates led to the confirmation of Einstein's theory.

The results obtained by the British expeditions sent to Africa and Brazil were published in Ref. 1. The results of the North-American expedition were published in Refs. 8, 9, 10, 11; and the results of the Brazilian expedition were published in Ref. 12.

# The large numbers hypothesis in cosmology

Eve-Aline Dubois* and André Füzfa and Dominique Lambert

*Namur Institute for Complex Systems and Espace philosophique de Namur*
*University of Namur - Belgium*
**E-mail: eve-aline.dubois@unamur.be*

In 1937, P.A.M. Dirac suggested the idea that the dimensionless constants of physics must be in relation with the epoch (age of the universe expressed in atomic units). From this hypothesis, known as Large Numbers Hypothesis or Dirac's Principle, he built a cosmological model in 1938 and abandoned it.

Following this principle, P. Jordan developed a series of articles, translated by us, based on the conservation of the dimensionless numbers coincidence. He suggested a model of matter creation to counterbalance the expansion of the universe.

Surprisingly, in the seventies, Dirac came back to his Large Numbers Hypothesis and published a new cosmological model, based on a description of the universe using two metrics.

We intend to review and present the historical development of the Large Numbers Hypothesis and its consequences in cosmology through the works of these two famous authors.

*Keywords*: Cosmology - Large number hypothesis - History of science.

## 1. Dirac's Principle

In a short letter to the editor in *Nature*[1], P.A.M. Dirac, following Eddington's work on dimensionless numbers[2], noticed a coincidence between the constants used in cosmology and enunciated his Large Number Hypothesis. Indeed, it could be observed that the ratio between the Coulombian and the Newtonian gravitational forces between an electron and a proton is about $10^{39}$; the ratio between the masses of the universe and of a proton is about $10^{78}$. These two large numbers need different types of explanations because they are not physically linked. But, if you add the coincidence that the age of the universe, according to the contemporary cosmological models, expressed in atomic units, so-called the epoch, is $10^{39}$; it seems logical to put the two previous large numbers in relation with the epoch. It is what Dirac did: "*This suggests that the above-mentioned large numbers are to be regarded not as constants, but as simple functions of our present epoch, expressed in atomic units.*" [1]

This principle has two direct consequences. First, the number of protons and electrons has to increase like the square of the epoch, conserving the null electrical charge of the universe. Secondly, the gravitational constant can not be constant anymore and must decrease with time.

Dirac concluded his letter by a brief paragraph about cosmological applications of his principle, which he studied in a later article, as it will be shown in the next section.

## 2. Dirac's Cosmology of 1938

In 1938, Dirac published a paper in which he suggested a cosmological model based on the Large Numbers Hypothesis[3]. He rewrote his principle as "*Any two of the very large dimensionless numbers occurring in Nature are connected by a simple mathematical relation, in which the coefficients are of the order of magnitude unity.*" [3]

With this hypothesis, he tackled one of the main problems of cosmology, the determination of the form of $f(t)$, similar to the current scale factor, giving the recession law of galaxies, since any cosmological model must explain Hubble's observations. Doing so, he arrived at the possibility of creation or annihilation of protons and neutrons assuming that the effect will be so faint that it could not be detected in laboratory. However, Dirac noted that "*However, such a spontaneous creation or annihilation of matter is so difficult to fit in with our present theoretical ideas in physics as not to be worth considering, unless a definite need for it should appear, which has not happened so far, since we can build up a quite consistent theory of cosmology without it.*" [3]

Dirac also studied the curvature of the slice of three-dimensional surfaces given for each value of the epoch, or $t$-space. The curvature cannot be positive, because, in this case, the mass of the universe is a very large number and will be constant, thanks to the assumption of mass conservation. This is in contradiction with his fundamental principle so it should be ruled out. The case of a negative curvature can also be excluded: working in a sphere of radius equal to the radius of curvature of the $t$-space, the mass contained in this sphere will not evolve with time which contradicts Dirac's principle. Dirac concluded that "*We are thus left with the case of zero-curvature, or flat t-space, as the only one consistent with our fundamental principle and with conservation of mass.*" [3]

The article finished with this summary: "*It is proposed that all the very large dimensionless numbers which can be constructed from the important natural constants of cosmology and atomic theory are connected by simple mathematical relations involving coefficients of the order of magnitude unity. The main consequences of this assumption are investigated and it is found that a satisfactory theory of cosmology can be built up from it.*" [3]

## 3. Jordan's work

From 1937, Pascual Jordan developed a parallel work based on Eddington's study of dimensionless numbers[2] and Dirac's idea that very large numbers could be expressed in relation with the epoch. Jordan's work has been published in a series of articles[4, 5, 6]. We worked on our own translation of them.

Like Eddington, Jordan hoped to find the way to unify quantum mechanics and genral relativity by finding the relation between their two characteristic constants $\hbar$ and $c$. Following Dirac's reasoning, Jordan reached the conclusion that the gravitational constant cannot be constant with respect to the time and that matter must be created.

To have a continuous and spontaneous matter creation process, Jordan considered the possible creation of stars. These stars must have the good radius and mass ratio to counterbalance their mass energy with their own gravitational energy. So that, according to him, the energy cost of this creation is null. Jordan found an argument in favour of his theory of star creation in the observation of younger and older stars.

## 4. Jordan and Hoyle

The history has very often ignored Jordan's German pre-World War II model. In 1948, two articles, due to Hermann Bondi and Thomas Gold for the first[7] and to Fred Hoyle for the second[8], founded the Steady State Theory. Max Born seemed to see some similarities between Jordan's work and Hoyle's model[8]. Therefore, he invited Pascual Jordan to publish in English in the prestigious review *Nature*[9].

However, Hoyle's and Jordan's models are really different. If both of them referred to Dirac's work, they did not develop it in the same way. Jordan worked with the dimensionless constants and their variations when Hoyle modified Einstein's equations to describe a universe with a constant density of matter. And, to create matter, the former considered spontaneous appearance of stars while the latter suggested creation of hydrogen atoms.

That is why Jordan finished his comparison between their models with: "*Several decisive ideas of Hoyle's are in full harmony with my own theory [...] But there are also considerable differences between Hoyle's theory and my own.*"[9]

## 5. Dirac's Cosmology of 1973

Surprisingly, Dirac used a communication at the Pontifical Academy of Science on evolutionary cosmology[10] to come back to his cosmological model with a matter creation process. He published two other articles[11][12] on this subject.

In this series of papers, Dirac studied two ways to create matter: "*A: Matter is created uniformly throughout space, and hence mainly in intergalactic space. B: Matter is created where it already exists, in proportion to the amount existing.*"[10] Thereafter, he called them *additive and multiplicative creation*[12].

According to his Large Numbers Hypothesis, the gravitational constant must vary. To reconcile this idea with the successful Einstein's theory of gravitation, Dirac suggested the use of two metrics: Einstein's one $ds_E$ and $ds_A$, measured by atomic apparatus. From that, he built two cosmological models waiting observations to come to make the distinction between the two, as Shapiro's time delay experiment.

In the conclusion, Dirac wrote: "*The foregoing work is all founded on the Large Numbers Hypothesis, in which I have great confidence.*"[12]

## Conclusion

The present paper described the historical development of cosmological models based on Large Numbers Hypothesis and reviewed the work of two renowned physicists who built cosmological models on this hypothesis. If this hypothesis is now considered as mere numerology and close to pseudo-science, it is interesting to study its past applications in physics. For a review on controversies about the Big Bang theory and the Steady State theory, we refer, among others, to Helge Kragh's work[13]. Our work gives us the opportunity to illustrate the fact that the Steady State theory was not the only one in competition with the Big Bang Theory and, moreover, not the only one to suggest a process of continuous creation of matter.

## Acknowledgement

# Mapping gravity with hierarchical networks

M. Espinosa-Aldama*

*Universidad Autonoma Metropolitana, Unidad Cuajimalpa, Vasco de Quiroga 4871, Contadero, 05370, Ciudad de Mexico, Mexico*

In order to map and clarify the field of gravitation and dozens of alternative theories to General Relativity developed during the past century, I propose several visualizations of networks that illustrate the complexity of theoretical relations, hierarchy of concepts, historical evolution and authorship relations. Conceptual lattices are data driven, and formal concepts are analyzed using *Concept Explorer* and visualized in *D3*.

The interactive web display allows exploration of the network elements that contain information about the theories and their attributes. It also highlights super-concepts and sub-concepts, serving as a tool for the study of physical theories, their models and foundations. A tree type visualization, called the *Gravity Apple Tree*, relates common terms, authors and publications in time series for 12 branches of gravitation. Portraits of authors and links to more than 100 seminal articles are provided. Crucial experiments and observations, located in the time-line space, contrast with the theoretical branches. A citation network based on the seminal articles shows another view to the development of this theoretical field. Visualizations are available for exploration at (http://remo.cua.uam.mx/vis/Exploratorium/).

*Keywords*: Networks, Visualizations, Alternative Theories of Gravity, Concept Lattices, Citation Network, Foundations of Space-Time Theories.

## 1. Introduction

Every now and then a new theory of gravity is proposed. Keeping track of hundreds of proposals and communicating a synthesis to the general public very often results in long dissertations that loose the objective of giving a wide view. One can easily get lost in such attempts. An elegant way of presenting a thorough panorama of the state of the art has been the graphic approach. Maps of knowledge place in order references and milestones that allow us to navigate in a sea of data, such as publication dates, authors and significant terms. Visualizations may emphasize some structures of science, such as networks, clusters and tendencies. Multiple examples can be found in the *Atlas of Science*.[1] The employed methodology involves multidisciplinary skills, such as data mining, data analysis, programming, design, visualization, notions of structuralism in philosophy of science, network theory, lattice theory and some understanding of the discussed subject, in this case, physics and mathematics. Such skills and approaches are usually not found together in the scope of philosophers of science, nor physicists, even communicators. I hope this interdisciplinary approach, inserted in what is called *Science of science*, may contribute with a refreshing perspective to the field of gravitation and serve as a tool for education and philosophical discussion. Here I present three kinds of hierarchical networks for gravitation theories: the *Gravity Apple Tree*, that illustrates figuratively the development in time of 12 theoretical branches, anchored by publication dates of seminal articles from 1905 to 2016; concept lattices that illustrate the

complex structure of theories in a synchronic way, using a formal concept analysis (FCA) of renowned classifications of theories of gravity; and a citation network from 200 seminal articles arranged within 18 clusters. These visualizations have interactive properties that can be explored in a web, coded with *Data Driven Documents* (*D3*), *java script*, *css* and *html*.[a]

## 2. The Gravity Apple Tree

*The Gravity Apple Tree* was born with the intent of giving some order to an overwhelming number of alternative proposals in a synthetic, graphic manner.[2] The tree type network connects authors and publication dates of seminal articles anchored by the year of publication (green colored), classifying theories (in red) in 12 branches. A curved time-line serves as the space where crucial experiments and observations feature. The lower part of the trunk symbolizes some 200 years of newtonian gravitation. In the center of the branches, main principles and applications drive their growth.

Metric theories, that is, theories where bodies follow geodesics of space-time in free fall, as defined in Ref. 3, occupy the lower right side of the tree. The upper right side is occupied by MoNDian theories and f(R) theories, following the classification in Ref. 4. The left side is occupied by non-metric theories that suppose torsion, conformal geometries, physical fields, extra dimensions and other exotic proposals (see Refs. 5–9 for more on the history of alternative theories of gravity). Even though it represents a vast plurality of proposals, it does not include many others such as Numerical Gravity, Weyl-Dirac's theory, Plevansky's Complex Gravity, Franklin's Relativist Rotation or the Exponential Gravity of Milne.

The *Gravity Apple Tree* helps us pinpoint interesting events, such as when theoretical branches grow or stop growing in correlation with the experimental developments. It also orders the data in a mnemonic manner, which enables to go further into the mapping enterprise. Its 200 selected seminal articles compose a data base of which we can extract their cites and references (see Section 4). It is accessible to the public in a PREZI format with links to *doi* addresses of seminal articles and includes portraits of main authors and a programmed tour through the tree.[b]

## 3. Concept Lattices of Gravitation Theories

To represent the conceptual structure of gravitation theories we'll turn to the set-semantic model based view of philosophy of science, and focus on the set of *attributes* (axioms) of theories. Here, authors, dates and famous theorems do not feature, but the foundations from which we can deduce a theory. In *Foundations of Space-time Theories*,[11] Michael Friedman represents a theory $T$ by a model set comprised by geometric objects $GO$ in a manifold $M$ of 4 dimensions and a set of relations $R$. The

[a] http://remo.cua.uam.mx/vis/Exploratorium/.
[b] https://prezi.com/rdkivznlhgga/the-gravity-apple-tree/.

structuralist view of Bunge et al.,[12] is one of the most detailed approaches among philosophers of science. It takes $T$ (or more precisely the theoretical element $ET$) to be composed by a formal nucleus $K$, a set of Intentional Aplications $IA$, a Scientific Community $CC$, and of historical data $h$. $ET =< K, IA, CC, h >$ Here, we are focusing only on $K$, which is formed by classes of models $M$, $Mp$, $Mpp$ and Links between models $L$ such as the Lorentz transformations. $K = \langle D, Tip, Cond, R, E, L\rangle$ Classes of models are formed by combinations of domains $D_i$, with certain tipifications $Tip_j$, under certain conditions $Cond_n$, that follow certain relations $R_m$ and where we can distinguish certain distinguished elements $E$.

*Previous partial models*: $M_{pp} = \langle D_i, Tip_j, Cond_n\rangle$ refere to the *non-theoretical* terms, such as *Protophysics*,[13,14] where pure geometrical space-time theories lie, with respect to gravitation theories.

*Partial models*: $M_p = \langle M_{pp}, D_{i+l}, Cond_q\rangle$ include the elements of $M_{pp}$ plus some new domains expressed under *T-theroetical* terms and conditions.

*Actual models*: $M = \langle M_{pp}, M_p, R_m, E_q\rangle$ includes all of the above, plus some relations (field equations and equations of motion), as well as the distinguished elements such as the gravitational constant or the speed of light.

In this study, $ET$ will only contain the formal nucleus $K$, with out the links between models: $ET = \langle D, Tip, Cond, R, E\rangle$. As several theories are included, partial and previous models are expected to appear in the lattices.

### 3.1. *Methodology: Formal Concept Analysis*

After the selection of different classifications or theoretical reconstructions, a binary data set called *context* $(G, M, I)$ relates a set of objects $G$ (theories or models) with a set of attributes $M$ (axioms) of all objects. Using Formal Concept Analysis (FCA) — a theory and analysis methodology developed by Rudolf Willy[10] in the 1970s, based on lattice and set theory — we can extract a set of concepts and order them in a hierarchical fashion through a coverture relation, composing a concept lattice.[15,16] That is, a network where nodes represent concepts of a context, and any two nodes must have an infimum and a supremum node. These networks are read in a vertical way. A formal concept is a pair of sets *(B,A)*, where $B \subseteq G$ and $A \subseteq M$, such that $B'' = B$ and $A = A''$ where $\ll''\gg$ is a closure operator. An extra title row corresponds to the classes of attributes, which enables extra encoding. It also occupies multiple algorithms to draw and analyze lattices. The free software *Concept Explorer* (conexp 1-3), written in *java* may do the work, providing the corresponding lattices, but it requires to enter the context by hand and does not provide good importing or exporting options, such as *json* files (Java Script Object Notation). In order to solve this rough patch, and to include in the analysis other categories such as classes of attributes, the FCA is done through a code in *Wolfram Mathematica* that imports the *csv* file, uses *conexp* as a library from which we extract the necessary algorithms that provide information corresponding to the

context, nodes, attributes, objects, tags and node levels among others.[c] The *json* file is then occupied in a web that uses *D3*[d] to visualize the lattice. Visualization in *D3* allows interactivity in the web, as nodes can be moved by the user, double clicks on nodes highlights upper and lower connected nodes, and single clicks shows additional information related to attributes and theories. For this, extra *csv* files are needed, as well as the *MathJax* library.[e]

Finite ordered sets as the ones used here have a supreme and a minimum element for they are called lattices. The supreme node, generally called *Meet*, represents the concept that is possessed by all of the theories and should be presented at the top of the diagram. In our case, all theories are based on a four dimension manifold. The minimum node, also called *Join*, or *null node* that posses all of the attributes, but generally does not belong to any object is located at the bottom of the diagram. Diagrams should be as symmetric as possible, keeping nodes in their hierarchical level. Lattices are much more informative when they are presented in such a way and for small contexts. For big contexts, diagrams may appear messy or confusing for it is convenient to present them with interactive properties that allow the highlighting of certain parts in order to allow readability.

The *Space-Time Theories Eploratorium* shows six interactive concept lattices, besides other visualizations on gravitation. A lattice for physical geometry, that relates the Leibnitzian, Galilean, Newtonian, Affine, Metric Affine, Riemannian, Lorentzian and Minkowski space-times; and a lattice for classical physical theories that includes Newton's gravitation, Newton-Cartan Gravitation, Special Relativity and General Relativity were both based on Fiedman's classification of space-time theories.[11,17] The lattice for f(R) theories is based on Ref. 18, while the lattice for non-local theories is based on Refs. 19–22. In *Theory and Experiment in Gravitational Physics*[3] we can find Clifford Will's cookbook to obtain the post newtonian parameters of any metric, Lagrangian based theory. Also, several tables that provide classes of attributes such as variables (*Domains*), field equations and motion equations (*Relations*), constrictions and cosmological parameters, as well as special functions and constants (*distinguished Elements*). From this cookbook, we can extract two data bases for 14 viable theories: one for the Lagrangian formulation and a second one for the PPN formulation.

The concept lattices clearly show their theoretical foundations and structure: a Manifold, a connection, a metric tensor, as well as their conditions, typifications and relations. Previous partial models, such as a Lorentzian space-time for GR rests in higher levels, while specific models of a theory, such as SR for GR would rest under the object-concept node. So foundations rest above the object-concepts, while specific models of T under the object-concept.

[c]Similarly, this can also be done with the free software Jupyter.
[d]D3: a java script library developed by Mike Bostock. Explore d3js.org and https://bl.ocks.org/mbostock.
[e]Explore the resulting visualizations at: http://remo.cua.uam.mx/vis/Exploratorium/.

The *Space-Time Theories Exploratorium* shows also a *holon* of theories, that is, a big lattice obtained by the addition of all contexts explored so far. Such addition requires carefulness, as some attributes are not considered in the original theoretical element *ET*, but are necessary in a wider context and may need specific conditions too. That is the case of the affine connection, common to all connections, that may posses torsion or non metricity, with the condition that it is zero for all points of the manifold for some theories. As exploring these lattices, one can easily point out the different notions for metric theories (those that follow geodesics, those that depend only on curvature with no torsion, etc.); point those that follow Einstein's equation, those that are local or non-local, those that have a flat metric, or the attributes of some specific theory, among other features.

## 4. Citation Network

Order between citations and references of seminal articles provides also insight into the path and tendencies of research. Papers provide cited references that tell us where their ideas come from, and citations that tell us about their resonance. The *Exploratorium* includes a citation network for the 200 seminal articles of the *Gravity Apple Tree* in order to represent the popularity of some ideas and their distances. One can pinpoint seminal articles and locate thematic clusters for more than eighty thousand citations and references. Data was downloaded from the Science Citation Index (SCI) of Thomson Reuters; the electronic archive for pre-publications of scientific articles and automatized distribution server ArXiv.org, operated by the University of Cornell; the Astrophysics Data System (ADS), a portal and digital library of NASA that keeps three bibliographic data bases with more than 11.3 million registrations of bibliographic data on physics, astronomy and astrophysics. Larger nodes correspond to seminal articles as their in-degree is sized compared. It is a force directed layout visualized with Gephi 0.9.2, using Sci2 tool.[f] Process is explained in Ref. 23.

## 5. Insights and Future Work

I have presented several examples of hierarchical networks for gravitation theories: a temporal network, concept lattices and a citation network, expecting to bring some insight on the plurality, composition and evolution of the field of gravitation. These networks can be found in an interactive display in the web, facilitating exploration. It is clear that there is a hierarchy that dominates the structure and development of scientific theories, and that such orders can be well represented in directed networks, and that complex networks are easily explored in interactive displays. These are very rich representations full of valuable information and interactive links. Design

[f]Sci2 Team. (2009). Science of Science (Sci2) Tool. Indiana University and SciTech Strategies, https://sci2.cns.iu.edu.

in several immersing levels, color coding, and extra information displays are important to visualize the distribution of attributes and not to overcrowd the image. One can color code theories according to their viability or experimental adequacy, and distinguish classes of attributes and their level of appearance. Aesthetic designs such as the tree-like shape may likely be hanged as pleasant posters while displaying a synthesis full of information. Meanwhile, interactive displays may turn an abstract and hard matter into a ludic, mnemonic experience. The concept lattices show topologic and geometric considerations standing at the top levels, following a downward construction of theories, leaving physical considerations in the lower levels. Classes of theories and classes of models, such as potential and actual models may be shown explicitly. As expected, the criteria used in most classifications is variable. We can find different formalisms (Lagrangian, PPN, non-Lagrangian), formulations (holonomic and anholonomic), direction of reconstruction (upwards and downwards), classes of attributes, global and local considerations, relativist or absolutist views, etc. So combining or adding up contexts becomes quite a delicate enterprise, but a clarifying one.

This work in progress attempts to include non-metric theories, MoNDian theories and M theories in order to be more inclusive, and finding a common classification that allows to join all conceptual networks. Other classifications being currently analyzed and visualized are included in Refs. 4, 5, 17, 24. All these complementary graphic representations should give us a fair idea of the paths taken by scientists as they explore the obscurities of gravitation and the general mathematical suppositions of the geometric approach to gravitation. Future work on the citation network will include the temporal component that will order the publications in terms of their timestamp and the reference network, as well as extending the seminal data base.

# The Struble–Einstein correspondence

Marcus C. Werner

*Center for Gravitational Physics, Yukawa Institute for Theoretical Physics,*
*Hakubi Center for Advanced Research,*
*Kyoto University,*
*Kitashirakawa Oiwakecho Sakyoku, Kyoto 606-8502, Japan*
*E-mail: werner@yukawa.kyoto-u.ac.jp*

This article presents hitherto unpublished correspondence of Struble in 1947 with Menger, Chandrasekhar, and eventually Einstein, about a possible observational test supporting Einstein's special relativity against Ritz's emission theory using binary stars. This 'Struble effect,' an acceleration Doppler effect in emission theory, appears to have been overlooked, and the historical context, including de Sitter's binary star test of special relativity, is also discussed.

*Keywords*: History of relativity; special relativity; emission theory.

## 1. Introduction

The nature of light propagation is central to the history of relativity theory. An early rival of Einstein's special relativity was emission theory, which was also consistent with the negative result of the Michelson-Morley experiment. In 1947, Raimond Struble (1924–2013), then a student at the University of Notre Dame and later a professor of mathematics at North Carolina State University in Raleigh, corresponded with Chandrasekhar at Yerkes Observatory and Einstein at the Institute for Advanced Study about an observational test of emission theory using binary stars. While de Sitter, among others, had shown earlier that binary star observations do, indeed, support special relativity against emission theory, Struble pointed out a new Doppler effect due to the binary's orbital acceleration, which appeared to have been overlooked.

These letters and related documents, hereinafter denoted *Struble-Einstein correspondence* (SEC), are held privately and are listed in the Appendix. The purpose of this article is twofold: on the one hand, to present this unpublished correspondence with Einstein and, on the other hand, to draw attention to Struble's effect and place it in its historical context of binary star tests of emission theory.

## 2. Historical background

### 2.1. *Emission theory*

After Einstein's paper on special relativity[1] was published in 1905, emission theory was considered as a viable alternative to understand the negative result[2] of the Michelson-Morley interferometer experiment without the need to adopt special relativistic kinematics. This theory was developed in particular by Walter Ritz (1878–1909), Einstein's junior by one year at the Zurich Polytechnic Institute (presently the ETH), who proposed such a framework[3] in 1908 (see, e.g., Ref. 4 for historical

aspects): light is emitted at a constant speed $c$ in any direction $\mathbf{u}$, $|\mathbf{u}| = 1$, relative to a source moving at velocity $\mathbf{v}$ relative to an observer. Thus, the velocity of light relative to the observer becomes

$$\mathbf{c}_r = c\mathbf{u} + \mathbf{v}\,. \tag{1}$$

Just as Einstein's theory, this is consistent with Michelson-Morley because light has a constant speed relative to the interferometer in this case (without being *universally* constant), so there is no diurnal variation of the light travel time.

To test the emission theory with a similar interferometer experiment, one would either require suitably moving mirrors, as was indeed considered by Michelson[5] himself in 1913, or a light source moving fast with respect to the interferometer, such as a celestial light source. This point was made by Tolman in 1912:

> "Hence if the Ritz theory should be true, using the sun as source of light we should find on rotating the apparatus a shift in the [interference] fringes of the same magnitude as originally predicted for the Michelson-Morley apparatus where a terrestrial source was used. If the Einstein theory should be true, we should find no shift in the fringes using any source of light." (Ref. 6)

A negative result using star light was finally achieved by Tomaschek[7] in 1924, providing strong evidence against emission theory and corroborating special relativity. Meanwhile, other experimental tests of emission theory were sought, and it is here that binary stars enter the picture.

### 2.2. *Binary star tests*

Consider an idealized Newtonian binary star system consisting of a small component $S$ orbiting a large component with speed $v$ in a circular orbit of radius $a$, whose centre is effectively the barycentre of the system. We assume also that the observer $E$ is coplanar with the orbit at large distance $d$, $d \gg a$, and that light is emitted isotropically by $S$ at the emission time $t_0$. Denoting the constant orbital angular velocity of $S$ by $\omega$, we have $v = a\omega$. This setup is illustrated in Fig. 1.

Suppose, now, that emission theory holds. Then at emission time $t_0$,

$$c_r(t_0) = c - v_r(t_0) \simeq c - v\cos\theta(t_0) = c - a\omega\cos\omega t_0\,, \tag{2}$$

Fig. 1. Schematic binary star system as considered by Struble in SEC 3.

from (1). This speed is constant from $S$ to $E$, which are separated by the distance $d(t_0) \simeq d + a \sin \omega t_0$, so a light signal emitted by $S$ at $t_0$ is received by $E$ at the observation time

$$\begin{aligned} t &= t_0 + \frac{d(t_0)}{c_r(t_0)} \simeq t_0 + \frac{d + a \sin \omega t_0}{c - a\omega \cos \omega t_0} \\ &= \frac{d}{c} + t_0 + \frac{a}{c} \sin \omega t_0 + \frac{ad\omega}{c^2} \cos \omega t_0 + \mathcal{O}\left(\frac{a^2\omega^2}{c^2}\right) \end{aligned} \tag{3}$$

at leading order, with $v \ll c$. Hence, the observation time $t$ is a linear function of the emission time $t_0$ plus a small oscillation, as would be the case in Einstein's theory with $c_r(t_0) = c = \text{const}$. However, note that $d\omega/c$ can be large, so the fourth term in (3) need not be negligible, and this gives rise to characterstic optical effects of emission theory: if $d\omega/c$ is sufficiently large, the map $t \mapsto t_0$ is no longer one-to-one, and a given observation time corresponds to multiple emission times. In other words, $E$ would observe $S$ at the same time in multiple points of its orbit. In his *Introduction to the Theory of Relativity*, Bergmann referred to this phenomenon of multiple star images as "ghost stars", whose absence provided strong evidence against the emission theory of Ritz and for the constancy of the speed of light in the sense of Einstein's special relativity theory:

> "In some cases, we should observe the same component of the double star system simultaneously at different places, and these 'ghost stars' would disappear and reappear in the course of their periodic motions. [...] However, no trace of any such effect has ever been observed. This is sufficiently conclusive to rule out further consideration of this hypothesis." (Ref. 8, pp. 19–20)

Daniel Comstock (1883–1970), who visited J. J. Thomson at Cambridge during 1906–1907 before returning to MIT where he later became a co-founder of *Technicolor*[9], seems to have been the first to seriously consider astronomical tests of emission theory, in particular its implications for binary stars. At a meeting of the American Physical Society in October 1909 at Princeton, he noted that

> "The assumption that the velocity of light depends on that of the source has, so far as the author is aware, never been properly examined. This is strange, but is probably explainable as a natural result of the complete trust which has been put for years in the conception of an ether." (Ref. 10)

In 1910, Comstock devised a criterion[11] to check whether the orbit of an observed binary obeys Keplerian motion, thus revealing anomalies such as a changing speed of light according to emission theory. Apparently unaware of Comstock's work, de Sitter also proposed[12,13] to use binary star orbits to constrain emission theory in February 1913. This seems to have had more impact, and generated considerable

interest within the physics community during that year, e.g. with papers by Guthnick[14] and Freundlich[15]. In his reply[16], de Sitter agreed to a parametric extension generalizing Eq. (1),

$$\mathbf{c}_r = c\mathbf{u} + \kappa\mathbf{v}\,,$$

where $\kappa = 1$ in Ritz's original theory and $\kappa = 0$ in special relativity. The task, then, was to constrain $\kappa$, and by considering the system $\beta$ Aurigae, he found $\kappa < 0.002$ and hence good agreement with special relativity. Einstein himself was, naturally, very interested in these developments. In May 1913, he wrote to Ehrenfest,

> "The matter concerning binary stars is very nice, provided that the [spectral] line movements are really measured accurately enough to check the Keplerian motion to some extent." (Ref. 17, doc. 441, p. 523)[a]

At this time, Einstein was working on the generalization of his theory of relativity to include gravity. Having predicted a gravitational deflection of light in 1911 using an early version of general relativity[18], he was in touch with Freundlich who had proposed an observational test of gravitational lensing[19] (cf. also Ref. 20) in January 1913. In a letter to Freundlich in August 1913, mainly about this issue of gravitational lensing, Einstein also expressed the paramount importance of the binary star tests for relativity theory:

> "I am also very curious about the results of your investigations concerning the binary stars. If the speed of light depends on the speed of the light source even only in the slightest, then my entire theory of relativity, including the theory of gravity, is wrong." (Ref. 17, doc. 472, p. 555)[b]

In addition to orbital properties, Struble thought that binary systems can provide other observational evidence for special relativity, as we shall discuss now.

## 3. Struble's effect

### 3.1. *Motivation and results*

As a student, in the wake of the atomic bombs ending the Second World War, Struble became interested in the underlying physics, the mass defect $\Delta E = \Delta m c^2$ and its origin in special relativity:

[a] Own translation. Original: "Die Sache mit den Doppelsternen ist sehr hübsch, vorausgesetzt, dass die Linienwanderungen wirklich exakt genug gemessen sind, um einigermassen die Keplersche Bewegung nachzuprüfen."

[b] Own translation. Original: "Sehr neugierig bin ich auch auf die Ergebnisse Ihrer Untersuchungen über die Doppelsterne. Wenn die Lichtgeschwindigkeit auch nur im Geringsten von der Geschwindigkeit der Lichtquelle abhängt, dann ist meine ganze Relativitätstheorie inklusive Gravitationstheorie falsch."

> "Since the constancy [of the speed of light] seemed to me unbelievable, I started thinking about other possible evidence and came upon the double-star phenomena [...]." (SEC 11)

Struble's adviser was initially the Viennese mathematician Karl Menger (1902–1985), a pioneer of fractal and probabilistic metric geometry, who had emigated to the USA joining the University of Notre Dame in 1937, where he started the mathematics PhD program and hosted Gödel. Even after moving to the Illinois Institue of Technology in 1946, he stayed in touch with Struble, whom he had encouraged to work on the binary star problem:

> "I asked Mr. Struble to study the geometrical aspects of DeSitter's theory and in pursuing this study he discovered another phenomenon which would be observable if the principle [of the constancy of the speed of light] were wrong, namely, a change in the wave length of the light emitted by the companion. This change would be entirely different from the Doppler effect, and quantitatively much larger than DeSitter's phenomena." (SEC 4)

The argument (SEC 3) can be summarized as follows. Consider again a binary star system in emission theory as discussed in Sec. 2.2, with speed of light $c_r$ relative to the observer $E$ given by Eq. (2). Now the observed frequency of light $\nu$ is related to the frequency $\nu_0$ at the emitter $S$ by

$$\nu = \nu_0 \frac{c_r}{c} \simeq \nu_0 \left(1 - \frac{v}{c} \cos\theta\right).$$

In other words, there is a standard Doppler effect in frequency which is linear in the orbital speed $v$, but it should be noted carefully that the wavelength of light remains unchanged, $\lambda = \lambda_0$, as pointed out by Tolman[21] in 1910. However, Struble observed that the changing of $c_r$ with $\theta$ or emission time $t_0$, that is, the orbital acceleration, gives rise to an actual change in wavelength which can be very large. This is the "change [...] entirely different from the Doppler effect" which Menger referred to in the quotation above.

To see this, note that during the time $\Delta t_0 = \lambda_0/c$ needed to emit a monochromatic wave of length $\lambda_0$ at $S$, the speed of light relative to $E$ has changed by $\Delta c_r \simeq \Delta t_0 a\omega^2 \sin\omega t_0$, from Eq. (2). So after a travel time of approximately $d/c$ to reach $E$, the wavelength has changed by

$$\Delta\lambda = \lambda - \lambda_0 \simeq -\Delta c_r \frac{d}{c} \simeq -\lambda_0 \frac{ad\omega^2}{c^2} \sin\theta \tag{4}$$

at leading order.[c] As before in Eq. (3), the term containing $d$ may give rise to a large observational effect.

In February 1947, Struble expounded his argument in a letter to Chandrasekhar at Yerkes Observatory, who noted in his reply, shown in Fig. 2, that

[c]This is corrected from Struble's derivation (SEC 3), which contains ambiguities in the angle and sign.

> "[...] it does seem that no one has thought of the effect of acceleration on the velocity of light on classical lines." (SEC 1)

However, he cautioned that group velocity rather than phase velocity should be considered, and that

> "[...] one's interest is somewhat dimmed by the consideration that the effect is not present anyway." (SEC 1)

Special relativity was well established and tested by that time, and the latter remark is also echoed by Tate (SEC 2), the editor of *Physical Review*, where Struble had tried to publish his work as a *Letter to the Editor*. Six days after this rejection, Menger tried intercede on behalf of his former student (SEC 4), and received a reply from the assistant editor Hill (SEC 6). While acknowledging that there are theoretical issues with accelerated light sources even in classical electrodynamics,[d] Hill agreed with Tate that special relativity was already sufficiently corroborated and therefore questioned that

> "[...] at the present time Ritz' theory requires a final coup de grâce, [...] [having,] like numerous other trial theories of its period, [...] earned a decent oblivion." (SEC 6)

He also pointed out that it remains unclear in Struble's derivation how the spectral energy distribution changes, a remark that reflects Chandrasekhar's concern about the group velocity.

### 3.2. *Correspondence with Einstein*

Having thus received encouragement as well as rejection, Struble decided to approach Einstein himself as arbiter "for final judgement" (SEC 7) regarding the validity of his derivation. In October 1947, Struble sent a letter to Einstein at the Institute for Advanced Study, emphasizing his new effect:

> "Many spectroscopic binary systems would exhibit these ghost stars due to their geometric characteristics, but as of now I have been unable to find any visible binary systems which would. Mostly because of this I investigated geometrical consequences of Ritz' hypothesis which concerned these visible double stars, in an attempt to agument [*sic*] de Sitter's repudiation." (SEC 7)

The accompanying computation (SEC 8) recapitulated the one sketched above (SEC 3), although Struble expressed his result now in terms of frequency rather than wavelength.

[d] This remark presumably refers to the Abraham-Lorentz backreaction force which is proportional to the *third* time derivative of the trajectory, thus causing problems with inital values.

In his reply of November 1947 (SEC 9), shown in Fig. 3, Einstein agreed that Struble's argument "is essentially right", although he preferred his own derivation. Using again the notation of Sec. 2.2, Einstein obtained an approximation for the observation time as a function of emission time,

$$t \simeq t_0 + \frac{ad\omega}{c^2}\cos\omega t_0\,,$$

as in Eq. (3), ignoring the constant $d/c$ and neglecting the other terms. Infinitesimal intervals are therefore related by

$$\mathrm{d}t \simeq \mathrm{d}t_0\left(1 - \frac{ad\omega^2}{c^2}\sin\omega t_0\right). \tag{5}$$

Assuming that the phase $\varphi$ of the light wave obeys a simple harmonic oscillation, Einstein noted that the frequency is

$$\nu^2 = -\frac{1}{\varphi}\frac{\mathrm{d}^2\varphi}{\mathrm{d}t^2}\,,$$

and the chain rule implies[e]

$$\frac{\mathrm{d}^2\varphi}{\mathrm{d}t^2} = \frac{\mathrm{d}^2\varphi}{\mathrm{d}t_0^2}\left(\frac{\mathrm{d}t_0}{\mathrm{d}t}\right)^2 + \frac{\mathrm{d}\varphi}{\mathrm{d}t_0}\frac{\mathrm{d}^2t_0}{\mathrm{d}t^2}\,,$$

so that, neglecting the last term and using equation (5),

$$\nu \simeq \nu_0\frac{\mathrm{d}t_0}{\mathrm{d}t} \simeq \frac{\nu_0}{1 - \frac{ad\omega^2}{c^2}\sin\omega t_0}\,,$$

which, in the given approximation, is in agreement with Struble's result. Einstein also supported his interpretation, stating that

> "The effect is, of course, in most cases of observation much greater than the ordinary Doppler-effect and without doubt incompatible with the experimental facts" (SEC 9),

but, in closing his letter, reminded Struble that careful checking of the literature is in order since

> "I should be quite astonished if De Sitter would not have made this little calculation. In any case, you should carefully look into his paper before publishing something about it." (SEC 9)

[e]The letter has $\frac{\mathrm{d}^2\varphi}{\mathrm{d}t^2} = \frac{\mathrm{d}^2\varphi}{\mathrm{d}t_0^2}\frac{\mathrm{d}t_0}{\mathrm{d}t} + \frac{\mathrm{d}\varphi}{\mathrm{d}t_0}\frac{\mathrm{d}^2t_0}{\mathrm{d}t^2}$, but the mistake in the first term of the right-hand side does not propagate to the following computations. Despite the approximations made, equality signs are used throughout the letter (SEC 9).

### 3.3. *Aftermath and assessment*

Einstein's letter made it clear that the question of priority for Struble's result had to be settled before any further attempt at publication should proceed. In January 1948, Menger advised Struble to obtain the original papers regarding the binary star effects of emission theory (SEC 10), in particular the 1913 articles in German by de Sitter[12] and Freundlich[15]. As discussed in Sec. 2.2, these are concerned primarily with apparent distortions of the binary orbits – indeed, Struble's effect is treated neither there nor in the other related papers, by Comstock[10,11], de Sitter[13,16], Guthnick[14] and Tolman[6,21].

A heuristic argument which comes close to Struble's is found in Bergmann's *Introduction to the Theory of Relativity*: using the notation of Sec. 2.2 as before, the light travel time to the observer is approximately $d/c$ so that

$$\frac{\Delta t}{\Delta c} \simeq -\frac{d}{c^2}, \quad \text{and since } \Delta c = v, \quad \Delta t \simeq -\frac{vd}{c^2}\,.$$

The amplitude of emission theory effects will then be determined by the ratio $\Delta t/T$, where $T := 2\pi/\omega$ is the orbital period of the binary (Ref. 8, p. 20). Hence,

$$\Delta t\ \omega \simeq -\frac{ad\omega^2}{c^2}\,,$$

as in Eq. (4) for the amplitude of Struble's effect on wavelength.[f] Still, there is no explicit discussion of Struble's effect and how it differs from the ordinary Doppler effect here.

Hence, it does appear that Struble's effect had not been noticed before or, at any rate, was not at all well known, in accordance with the assessment by Chandrasekhar in SEC 1. It is also interesting to note that the effect does not appear in the 1965 paper by Fox[22], which is a detailed critique of all available evidence against emission theories. On the other hand, it must be conceded that Struble's argument is purely kinematical as it stands, and a final assessment of its physical merit should include a deeper investigation of dynamical aspects as well, along the lines suggested by Chandrasekhar (SEC 1) and Hill (SEC 6) mentioned before.

In the end, Struble pursued his interests in mathematics and its applications, and never resumed his attempt to publish this work at the interface of astronomy and theoretical physics:

> "[...] the main reason I couldn't follow through was that I would need to use Einstein's superior version. Though his letter granted me precidence

[f] In fact, it is likely that Struble knew Bergmann's treatment, since the first edition had been published in 1942 and it had become a popular textbook on relativity theory: there had been four printings by 1948, according to the colophon of the Prentice-Hall, New York NY, 1948, edition. Moreover, Struble used the rather imaginative expression "ghost stars" in his letter to Einstein (SEC 7), which is also found in Bergmann (Ref. 8, p. 19) but not in the original papers on binary star effects of emission theory mentioned above.

[*sic*] on the idea, I couldn't publish his modifications as mine. I probably should have discussed it with him at the time." (SEC 11)

## 4. Final remarks

In addition to its scientific interest, the Struble–Einstein Correspondence gives detailed insight into individual motivations and practical aspects of the scientific process, as described in this article. Einstein's reply to the student Struble is also a testament to his often generous attitude towards researchers outside his immediate circle of professional colleagues.[g]

Finally, it may be mentioned that the *Albert Einstein Archives* preserve a copy of Struble's correspondence (SEC 7 in Ref. 24, SEC 8 in Ref. 25) as well as the autograph draft of Einstein's letter written in German[26], although the English version that Einstein eventually sent to Struble (SEC 9) appears to be lacking.

## Acknowledgments

MCW would like to thank Masataka Fukugita, Domenico Giulini and Dennis Lehmkuhl for helpful discussions.

## Appendix

The documents of the Struble-Einstein Correspondence are held by Struble's estate in Raleigh, NC, USA, and consist of the following.

SEC 1. S. Chandrasekhar to R. A. Struble, typed and signed letter, 1 page, 1947 March 28.
SEC 2. J. T. Tate to R. A. Struble, typed and signed letter, 1 page, 1947 July 23.
SEC 3. [R. A. Struble:] An observable consequence of the ballistic hypothesis, typed and annotated document, 1 page (incomplete), no date.

r. Raimond A. Struble
56 River Avenue
outh Bend 6, Indiana

ear Mr. Struble,

I am sorry to be so long over your letter of February 14, ut I have been away from Yerkes for part of the time and inaccessible o my correspondence.

I have not had the chance to scrutinize your paper as carefully as I would like to, but it does seem that no one has thought of he effect of acceleration on the velocity of light on classical lines. ut I feel somewhat uneasy about the details of your argument. You re essentially discussing the analogue of phase velocity. But, hould you not, under the circumstances, consider the group velocity?

I am sorry to be so indefinite, but one's interest is somehat dimmed by the consideration that the effect is not present anyay.

Yours sincerely,
S. Chandrasekhar
S. Chandrasekhar

THE INSTITUTE FOR ADVANCED STUDY
SCHOOL OF MATHEMATICS
PRINCETON, NEW JERSEY

November 5,1947

Mr.Raimond A.Struble
556 River Ave.
South Bend 6,Indiana

Dear Sir:

Your result is essentially right. I was not able to grasp your calculation. I have done it as follows:

Be $t_0$ the time on the emitting body then the time of arrival on the earth is (with sufficient precision):

$$t = t_0 + \frac{R}{c - v}$$

or again with sufficient precision

$$t = t_0 + \frac{R}{c}\left(1 + \frac{v}{c}\right) = t_0 + \frac{R}{c} + \frac{R}{c^2}v$$

The constant time interval $\frac{R}{c}$ is without influence. One has therefore

$$t = t_0 + \frac{R}{c^2}v \qquad \left(v = a\Omega\cos(\Omega t_0)\right)$$

$$t = t_0 + \frac{a\Omega}{c^2}\cos(\Omega t_0) \quad \cdots (1)$$

The spectral oscillation is given by $\varphi = \cos\nu t_0$ (approximately). At the earth this function expresses the corresponding oscillation if one substitutes for $t_0$ its expression in $t$ according to (1). The frequency on earth is $\nu = -\frac{d\psi}{dt}$. We have

$$\frac{d\varphi}{dt} = \frac{d\varphi}{dt_0}\cdot\frac{dt_0}{dt}; \quad \frac{d^2\varphi}{dt^2} = \frac{d}{dt_0}\left(\frac{d\varphi}{dt_0}\right)\frac{dt_0}{dt} + \frac{d\varphi}{dt_0}\cdot\frac{d^2t_0}{dt^2}$$

$$= \frac{d^2\varphi}{dt_0^2}\left(\frac{dt_0}{dt}\right)^2 + \frac{d\varphi}{dt_0}\cdot\frac{d^2t_0}{dt^2}$$

correction

THE INSTITUTE FOR ADVANCED STUDY
SCHOOL OF MATHEMATICS
PRINCETON, NEW JERSEY

-2-

The second term in the last formula is negligible relative to the first. It is therefore

$$\nu^2 = -\frac{\frac{d^2\varphi}{dt_0^2}\left(\frac{dt_0}{dt}\right)^2}{\frac{d\varphi}{dt_0}\left(\frac{dt_0}{dt}\right)^2} = \nu_0^2\left(\frac{dt_0}{dt}\right)^2$$

or

$$\nu = \nu_0\frac{dt_0}{dt}$$

According to (1) is

$$dt = dt_0 - \frac{a\Omega^2}{c^2}\sin(\Omega t_0)\,dt_0$$

therefore

$$\nu = \nu_0\frac{1}{1 - \frac{a\Omega^2}{c^2}\sin(\Omega t_0)}$$

Here $t_0$ has to be expressed as a function of $t$. This is in accordance with your remarks. The effect is, in most cases of observation, of course, much greater than the ordinary Doppler-effect and without doubt incompatible with the experimental facts. (since $\frac{a\Omega^2}{c^2} < 1$)

I should be quite astonished if De Sitter would not have made this little calculation. In any case, you should carefully look into his paper before publishing something about it.

Sincerely yours,
A. Einstein
Albert Einstein.

# Angelo Secchi and beyond: From the beginning of stellar spectroscopy to the expansion of the universe

Matteo Galaverni

*Specola Vaticana,*
*V-00120 Vatican City, Vatican City;*
*INAF/OAS Bologna, Osservatorio di Astrofisica e Scienza dello Spazio,*
*Area della ricerca CNR-INAF, via Gobetti 101, I-40129 Bologna, Italy*
*E-mail: matteo.galaverni@gmail.com*

The spectral classification introduced by Father Angelo Secchi, SJ (1818–1878) opened a new way to study the stars and the universe. We summarize the main achievements of his work and show how the following developments lead to the foundation of modern astrophysics.

*Keywords*: Angelo Secchi; Astrophysics; Spectroscopy; History of Astronomy.

## 1. Beyond astrometry and celestial mechanics

At the beginning of the Nineteenth Century, astronomy was concerned with astrometry and celestial mechanics (calculation of the orbits of planets, compilation of catalogues of position and brightnesses of stars and other celestial objects). In 1835 the French philosopher Auguste Comte (1798–1857) was so confident about the impossibility of obtaining experimental data on the physics of stars that he wrote:

> "Every research in relation to stars not reducible in the end to simple visual observations is perforce barred to us [...] we could never study, by any means, either their chemical composition or their mineral structure [...] our positive knowledge concerning the stars is necessarily restricted just to their geometrical and mechanical phenomena, being it entirely impossible to undertake any physical or chemical research." [1]

Already at the beginning of the Nineteenth Century the German physicist Joseph von Fraunhofer (1787–1826) began to study in detail the myriad of dark lines that appear when sunlight is refracted by a prism. Fraunhofer classified more than 570 dark lines in the solar spectrum. By the middle of the 19th Century Gustav Kirchhoff (1824–1877) explained the presence of those thin dark lines through the presence of particular chemical elements in the atmosphere of the Sun, they absorb the light at a fixed wavelength. It was the beginning of the chemical analysis of the universe through spectroscopy (see Fig. 1).

These new studies provided the necessary motivations to overcome classical astronomy and foster the birth of modern Astrophysics. The observations of the spectrum of the Sun encouraged the study of the spectra of other stars by Giovanni Battista Donati (1836–1873) in Florence, William Huggins (1824–1910) in London, Lewis Morris Rutherfurd (1816–1892) in New York and Angelo Secchi in Rome.

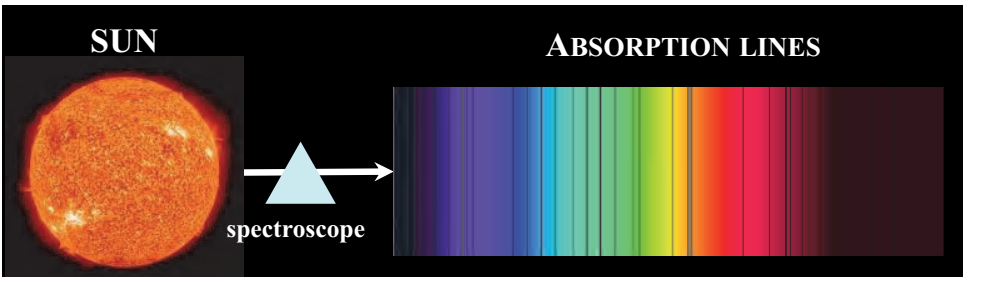

Fig. 1. Spectrum of the Sun. The outermost layers of the Sun's atmosphere absorb the radiation at fixed wavelengths, so are producing dark absorption lines in the continuous spectrum. The spectral lines became precious indicators, like a fingerprint, of the chemical elements present in the atmosphere of the observed star. Moreover, the width of the lines gives information on the abundances and physical conditions (temperature, pressure, magnetic fields) of the various chemical elements in the atmosphere of the star. Using the spectroscope it is possible to study in detail the dark lines sequence: the light coming from the star passes through a slit and then through a prism (or a diffraction grating) that separates the light into various wavelengths.

## 2. The Secchi classification of stellar spectra

The work of Father Angelo Secchi of the Society of Jesus (born Reggio Emilia 1818, died Rome 1878) contributed in a decisive way to the birth of modern Astrophysics. When he was 15 years old he entered the Jesuit order and began his formation. He studied extensively not only theology and philosophy, but also science and, in particular, physics. When in 1850 he was appointed as director of the observatory of the Roman College, he continued to look at astronomy from the point of view of a physicist. He used spectroscopy as a tool to answer a new question: not *where* are the stars (positional astronomy), but *what* are the stars, what is their composition:

> "when the field of astronomical research seemed to be dried-up, and we could only glean where others had richly reaped, here a new discovery opens up an immense horizon, which will reveal us the physical nature of the stars and show us the kind of the matter that compose them. This is the spectroscopy and its applications made by Kirchhoff and Bunsen." [2]

In 1852 he got permission to build a new observatory on the roof of the church of St. Ignatius. He had two main instruments: a Cauchoix refractor telescope (with a 16.9 cm aperture) and — after 1854 — also a Merz refractor telescope (with a 24.4 cm aperture). He also obtained an objective prism, usable on both telescopes, for spectroscopic observations of stars.

Thanks to this advanced instrumentation he started a systematical project on stellar classification based on spectra. In 1863 he published a first study, based on the observations of the spectrum of 35 of the brightest stars: *Sugli spettri prismatici della luce de'corpi celesti* in *Bullettino meteorologico dell'Osservatorio del Collegio Romano*, 31 July 1863. The following ten years were dedicated to improving this

first study, and in 1877 he published the essay *Le Stelle. Saggio di astronomia siderale*, based on the observation of more than four thousand spectra. This last classification included four stellar types based on absorption spectra, plus a fifth type containing prominent emission lines.

We present here a brief description of Secchi's classification following his treatise *Le Soleil* (1st ed: 1870; 2nd ed. vol. I: 1875, vol. II: 1877):

- The first type (see first spectrum of Fig. 2) is characterized by bluish-white stars, like Sirus: "all these stars are commonly called white, although they are slightly blue. They offer a spectrum formed by the ordinary set of the 7 colors, interrupted by four large black lines: the first in the red, the other in the blue-green, the last two in the violet" [3] (predominant hydrogen lines).
- The second group (second spectrum of Fig. 2) includes white-yellowish colored stars like the Sun: "the spectrum of these stars is perfectly similar to that of our Sun, that is, formed of very fine and very tight black lines which occupy the same position as those of the solar spectrum." [3]
- In the third type (third spectrum of Fig. 2) Secchi grouped the stars with color close to "red or orange" as $\alpha$ of Orion; "the spectrum of the third kind in very extraordinary including a double system of nebulous bands and dark lines." [3]
- "The fourth type is even more extraordinary" [3] (fourth spectrum of Fig. 2 these few stars are not necessarily colder than those of the third type, but only chemically different (faint reddish stars, predominant carbon lines).
- Lastly he also added a fifth type (see Fig. 3) characterized by the presence of pronounced emission lines in their spectra: "direct spectrum of hydrogen." [3]

Thanks to his pioneering work, Secchi is rightly considered among the founders of modern astrophysics and the father of the classification of stars based on their spectra. Finally, we would like to emphasize that all the spectra shown in Secchi's books are not photos, but they are all hand-drawn work.

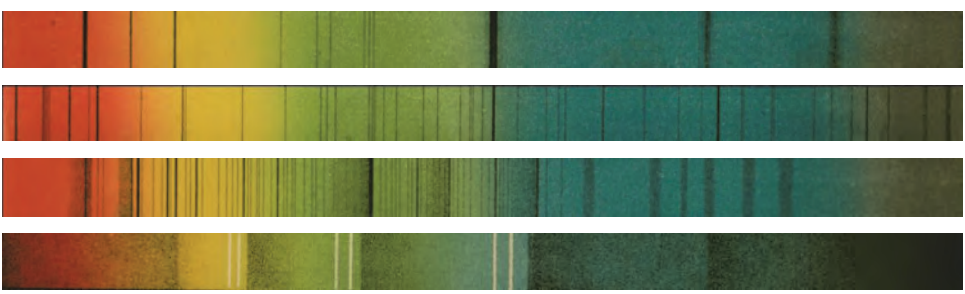

Fig. 2. Absorption spectra of a star of type I (Sirius),type II (Sun), type III (Orion), type IV (152 Schjellerup Catalogue also known as "La Superba" - Y CVn). [4]

Fig. 3. Typical emission spectrum of nebulae (type V).[4]

## 3. After Secchi

Fr. Secchi was fully aware of the new potentialities of spectroscopy: "there remain many things for us to learn: for nature is inexhaustible in its wonders; [when] we think we are arrived at the end, we find that it is only the beginning."[3,5]

### 3.1. *The Harvard classification and the Hertzsprung–Russell diagram*

The work started by Secchi was continued by numerous astronomers. In 1872 Henry Draper (1837–1882) realized the first photographs of a stellar spectrum. At the end of the Nineteenth Century the astronomer Edward Charles Pickering (1846–1919) started a large project focused on stellar classification using photographic techniques. Draper's widow decided to finance this project and in 1890 Pickering published a first catalogue based on the observation of 10.351 stars: *Draper Catalogue of Stellar Spectra*. The work continued in the subsequent years and thanks to the devotion to the project of Annie Jump Cannon (1863–1941) and collaborators it was possible to publish the *Henry Draper Catalog* containing the magnitude, position and stellar classification of 225.300 stars. Later the astronomers Ejnar Hertzsprung (1873–1967) and Henry Norris Russell (1877–1957), starting from the data contained in this catalogue, combined in a diagram the information on the temperature (color) and absolute luminosity of different stars. The H-R diagram is a key step towards understanding stellar evolution. Spectral Classification remains, even today, an important tool to identify peculiar and astrophysically interesting stars.[6]

### 3.2. *Proper motion and expansion of the universe*

Secchi was fully aware of another important information contained in the spectra: "It is the opinion of many talented spectroscopists that spectral measurements can give us a very delicate means to know also the absolute motions in the direction of the visual ray."[4] If the light source is in motion towards the observer, the wavelength will be shortened compared to the wave emitted by a source at rest (*blueshift*), vice versa if the source is moving away from the observer, the wavelength will increase (*redshift*).

Unfortunately, the instruments used by Secchi were not accurate enough to detect this modification of the wavelengths. Only at the end of the Nineteenth Century that it became possible to obtain the first reliable measurements of radial velocities when photographic spectra became available. In the 1920s Edwin Hubble

(1889–1953) and Georges Lemaître (1894–1966) derived the famous law of the expansion of the universe (Hubble-Lemaître law) using this technique.

This discovery marked the passage from a static universe to the model of an universe evolving in time. The expansion of the universe is, together with the Cosmic Microwave Background (CMB) and primordial nucleosynthesis, one of the main pillars of the Big Bang cosmological model.

## 4. The bicentenary of the birth of Angelo Secchi

Angelo Secchi gave an important contribution with his pioneering work to the birth of "New Astronomy", the modern Astrophysics. Therefore many initiatives were organized to remember the bicentenary of his birth.

The Italian Ministry of Cultural Heritage and Activities and Tourism established a National Committee for the celebrations of the bicentenary of the birth of Angelo Secchi. This committee was coordinated by the National Academy of the Sciences and the Italian National Institute for Astrophysics.

Secchi was remembered during the International Astronomical Union XXXth General Assembly in Vienna (August 20–31, 2018).[7]

In Italy conferences and workshops were held both in Rome ("The Legacy of Angelo Secchi SJ 200 years after his birth", September 3–5, 2018; "Angelo Secchi (1818–1878) SJ: the scientist and his time", September 6, 2018) and in his hometown Reggio Emilia ("Father Angelo Secchi, the person, the works, astrophysics", May 11–12, 2018). The Fifteenth Marcel Grossmann Meeting dedicated a parallel session to "Angelo Secchi and Astrophysics" (July 2, 2018). The Italian Astronomical Society (Società Astronomica Italiana) — counting Secchi among its founders when it was still called "Società delgi Spettroscopisti Italiani" — remembered Secchi during its LXII congress (Teramo, May 2–5, 2018). The City Museums of Reggio Emilia organized an exhibition dedicated to him: "All the colors of stars. Father Angelo Secchi and the birth of astrophysics" (October 20, 2018 – February 3, 2019). Also a virtual exhibition "Between Heaven and Earth"[8] was prepared by the National Committee for the celebrations of the bicentenary. A completely new biography "Decoding the Stars" was written by Ileana Chinnici and will be soon published.[9]

We conclude with the words of Secchi himself: "How many other wonders should not be found in the immensity of that space, which we cannot fathom? By taking advantage of art and science, the astronomer reveals to us more and more the greatness of God, and makes us exclaim with the Prophet: *May your works be magnified, O Lord; you did all of them in wisdom* (Psalm 104)."[10]

## Acknowledgments

The author is grateful to Christopher J. Corbally, SJ for valuable comments on this work. Thanks to Vatican Observatory (Castel Gandolfo and Tucson) for hospitality during the development of this project.

The equation of time determines the difference between the mean solar noon and the true one. Graphically it is represented with an analemma, drawn also in the sundials made by Secchi (e.g. the ones of Grottaferrata and Augusta). The relationship between the day of the year and the corresponding equation of time, from Ptolemy to Clavius, is presented, including some medieval cases. Finally the Sundial of Boville Ernica made in 1865 by Secchi for public utility, as in his vision of science, is presented to wish a new restauration.

## 1. Theoretical exposition

The length of each day through the course of the year is variable, it can be longer or shorter than 24 hours of many minutes, about half an hour at most, and this offset is defined as the equation of time. Let us first introduce some basic concepts.

We has to distinguish two different systems of time based respectively on the apparent solar time and the mean one. Obviously a natural unit of time is the rotation of the Earth. It represents the time in which the Sun returns to the local meridian, but it is variable due to two features of our solar system, which we analyze beyond. It is useful introduce also a motion of the Sun without irregularities, namely a uniform motion on the ecliptical plane. On this time is defined the so-called mean solar time system. A comparison of a sundials and a mechanical clock shows that the times are different and the deviation between them can be described by the equation of time. Historically, the term equation was used to tabulate the difference between an observed valued and the expected one, so the equation of time is a quantity that should be added or subtracted to the hour of the passage at the meridian to obtain the mean local noon. So, the precise definition of the equation of time is:

$$E_d = h(S) - h(M) \tag{1}$$

where $h(S)$ is the true solar time in term of hour angle and $h(M)$ is the hour angle of the equatorial mean time.

The features of our solar system are at the basis of the irregularities in the apparent motion of the Sun and the most important contributes are due to the variation of the angular velocity, according to the second Kepler's law, and the obliquity of the ecliptic. The second Kepler's law state: the area swept out per time interval is constant, thus the Sun appears to move faster (relative to the background stars) at perihelion and slower at aphelion. A Sun slower corresponds to an apparent solar day shorter, instead, a Sun faster to a longer solar day. Let us consider Kepler's equation, which allows to connect the position occupied by the planet along the keplerian orbit with the time elapsed from the moment of passage from perihelion

$$E = M + e \sin E \tag{2}$$

where M is the mean anomaly, namely the angle covered by Earth on a circular orbit with constant speed, and E the eccentric anomaly, that is the angle between the position of real Earth projected on the circular orbit and the major axis. For a better comprehension see Fig. 1.

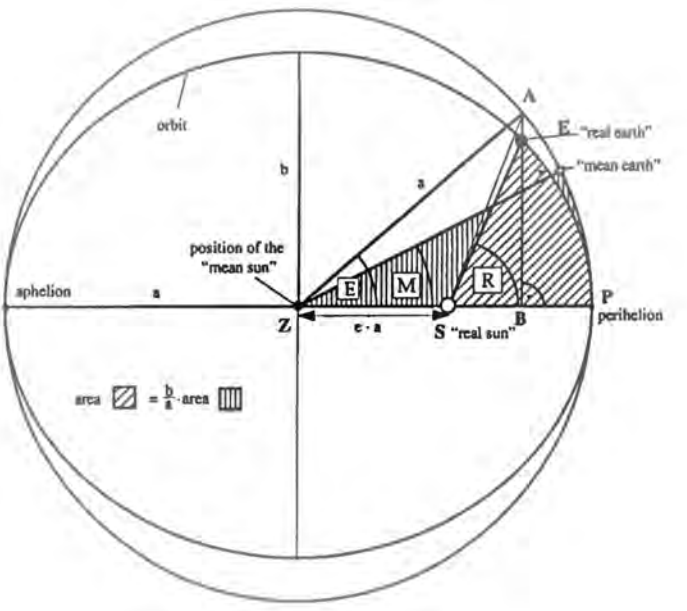

Fig. 1. Angles M and E at a specific time point.

It isn't possible to solve the equation (2) for E in closed form. Therefore, the position of the Earth can only approximated as function of time. More useful is the expansion in series of Eq. (2) in term of R, that is the real angle spanned from the real Earth along the ecliptic orbit, or the true anomaly. In fact if we make the first derivative of the expression of R respect to the time, we obtain the angular velocity and its corrections. The relation is

$$\omega(t) = \frac{2\pi}{T}[1 + 2e\cos M + ...] \tag{3}$$

The deviations amount to about double of eccentricity of the orbit.

The true solar day depends on the declination of the Sun, that is the elevation from the celestial equator. Let us ignore the variation of angular velocity and consider a circular orbit. A uniform circular motion is

$$\theta = 30^\circ(t - t_0) \tag{4}$$

where $t$ is the time passed from vernal equinox in term of months (January has a value from 0 to 1, February from 1 to 2 an do on), and $t_0 = 2,69$ the value which

correspond to 21 March. On the celestial sphere, a circle with inclination $e = 23,5^\circ$ appears as an ellipse, which can be obtained compressing all the coordinates of the circle of a factor $a/b$. In our case $b = 90^\circ$ and $a = e$. So if the coordinate of minor axis has the parametric equation $y = 90^\circ \sin\theta$, for the ellipse becomes the solar declination we are searching. Thus

$$\delta = e \sin\theta \tag{5}$$

So the solar day for a given latitude $\lambda$ and time $t$ is

$$T = 12 + \frac{2}{15} \arcsin\Big[\tan\lambda \cdot \tan\Big(e \sin(30^\circ(t - t_0))\Big)\Big] \tag{6}$$

Obviously this equation is valid for a uniform motion of the Sun. If we consider also the effect of the second Kepler's law, $T$ is affected by a small variation which tends to cumulate during a year. This discrepancy is due to the changing of the declination between two culminations. The projection of an arch of ecliptic value a on the equator gets larger of a factor $1/\cos\delta$, because the relation is $a\cos\alpha/\cos\delta$.

The mean ecliptical arch crossed by the real Sun in a day is about $1^\circ$. Instead the projection of this arch on the celestial equator is

$$\Delta\alpha = 1^\circ \frac{\cos\Big[\arctan\Big(\tan e \cos(30^\circ(t - t_0) + EC)\Big)\Big]}{\cos\Big[e \sin(30^\circ(t - t_0) + EC)\Big]} \tag{7}$$

If we make the product of $\Delta\alpha$ and $v$, an adimensional value of the angular velocity, defined as

$$v = \bar{v}[1 + 2\Delta\cos(30^\circ t)] \tag{8}$$

taking $\bar{v} \simeq 1$ and $\Delta \simeq 0,03$, the semiamplitude of the annual variation of angular velocity, we obtain an expression with dimensions of an angle. Thus the equation of time is the difference

$$ET = v\Delta\alpha - 1^\circ \tag{9}$$

Let us plot the cumulative effect of the discrepancy in time in Fig. 2.

## 2. Historical cases

The ancient name of the equation of time was *a'dilal-'ayynmbi- laydihha*, which can be translated into latin as *aequatio dierum cum noctibus suis*, that is correction of the day and their nights. The difference between apparent solar time and mean time was recognized by astronomers since antiquity, but prior to the invention of accurate mechanical clocks in the mid-17th century, sundials were the only reliable timepieces, and apparent solar time was the generally accepted standard. Ptolemy's Almagest is primarily concerned with the Sun's anomaly, and he tabulated the equation of time in his Handy Tables. Ptolemy discusses the correction needed to convert the meridian crossing of the Sun to mean solar time and takes into

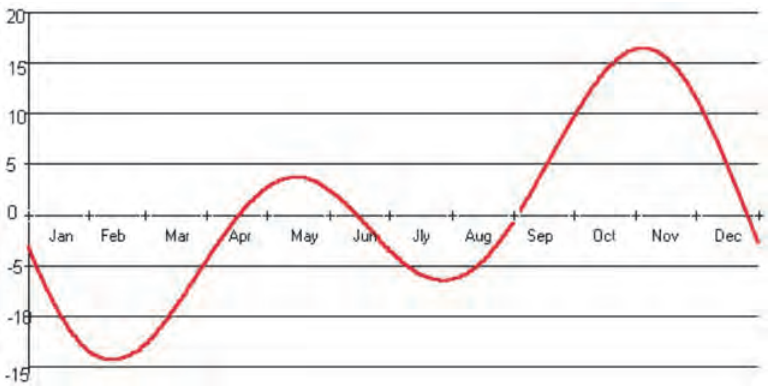

Fig. 2. Graph of true Sun's delay in the passage at the meridian.

consideration the nonuniform motion of the Sun along the ecliptic and the meridian correction for the Sun's ecliptic longitude. Some other medieval islamic astronomers made improvements to the solar tables and published tables of the equation of time. If we study some values taken from this tables, we can see that they were calculated with an high precision. Some of the most important tables we have to quote are of *Al-Battānī*, Arabic astronomer lived in IX century, John of Murs (1321), Levi ben Gerson (1288–1344) and Giovanni Bianchini (1410–1469).

## 3. The analemma

The analemma is a graph which shows the position of the Sun in the sky during a year in the same place and at the same time. A rigorous analemma can be obtained taking a photograph everyday in the same place for a year, but this is obviously impossibile because of cloudy day. The most important feature of the analemma is his form, namely an eight with a lobe bigger than the other (see Fig. 3). Due to the eccentricity of the orbit of Earth and the obliquity of the poloidal axis the form of the analemma can vary with the time and the place. If the Earth's orbit was

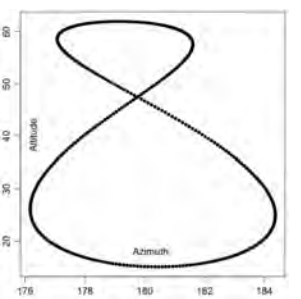

Fig. 3. The analemma, based on observed values of the azimuth and altitude of the Sun at 12.00 GMT at the Royal Observatory, Greenwich for 2006 (see Ref. 2). Note the unequal axes.

circular, two lobes would be equal, instead, if the polar axis hadn't an obliquity, the analemma would be a linear segment.

In some meridians we can find the representation of analemma for each hour of the day, except for the noon. In the meridian showed in photo (Fig. 4) is an example of that. The photo is taken in 7/23 in 2003, for that date the equation of

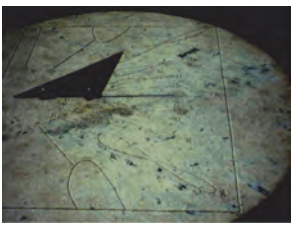

Fig. 4. Meridian with analemma. Photo taken in July 2003, see Ref. 6.

Fig. 5. Sundial of Angelo Secchi in Boville Ernica (FR) as in April 2019 and when restaured in 1996; the gnomon is parallel to the polar axis, the analemma and the equation of time vanished.[7] This sundial was restaured in 1950 by the astronomer Giuseppe Armellini, buried in the nearby Church's crypt, and again by Nicola Severino in 1996.[8] Now it deserves another restauration as it is evidenced with the rectangle. In the left low side its status in 1996.

time was −6 m 24 s. For this longitude the local noon is so at 14:50 UT. Thus, the place is about 42°30′ from Greenwich. In fact the meridian is located in Rio de Janeiro.

# The Sodium D-Lines in Rome from Angelo Secchi to Alessandro Cacciani

Bordoni, Luigi[1] and Sigismondi, Costantino*

[1] *Sapienza University of Rome;* * *ICRA/Sapienza and ITIS G. Ferraris, Roma, Italy*
* *E-mail: sigismondi@icra.it www.icra.it/gerbertus*

Optical spectroscopy developped so much in XIX century that many results required the quantum physics to be fully explained from selection rules to quantum probability. Angelo Secchi designed or modified some instruments like the Hoffman prisms to reach a great resolution, namely better than 1 Angstrom around the Sodium D-Lines. Alessandro Cacciani, who worked in Monte Mario Observatory and Sapienza University of Rome, invented and developped the MOF Magneto-Optical Filter by tuning the magnetic field in a vaporized sodium cell. The MOF is being used in the two MOT telescopes in Anctartica, and has been used in US and EU telescope reaching an extraordinary velocity resolution in the dopplerograms of the Sun. Two inventors in comparison, at a century of temporal distance, with Mount Mario Observatory ideally inherited the Collegio Romano story, because had the Merz telescope of Secchi until the fire of July 15, 1958.

## 1. Father Secchi and Spectral lines

A spectral line is a dark or bright line in an otherwise uniform and continuous spectrum, resulting from emission or absorption of light in a narrow frequency range, compared with the nearby frequencies. Spectral lines are often used to identify atoms and molecules. The spectral lines of a specific element or molecule at rest in a laboratory always occur at the same wavelengths. **For this reason, we are able to identify which element or molecule is causing the spectral lines**[1].

Fig. 1. *Absorption lines are seen as black lines on a coloured background.* © *Swinburne University of Technology.*

Absorption lines appear as dark bands, often superimposed on a coloured continuum, and are the result of specific wavelengths being absorbed along the line-of-sight, and they are produced when photons from a hot, broad spectrum source pass through a cold material.

In 1814 the German Physics Joseph Fraunnhofer repeated the Newton's experiment of breaking the light of the Sun into his colors through a prism[2]. This time he greatly enlarged the resulting colored spectrum, discovering that he was interrupted by more than **600 dark lines**: the spectral lines (today we know about a million!).

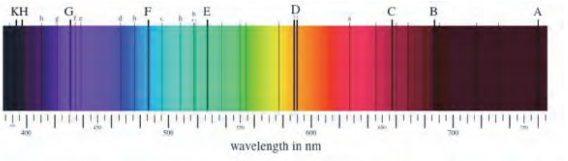

Fig. 2. *Fraunnhofer lines labelled from A to K.* © *2001–2017 The Regents of the University of California. See also*[25,26] *for identifying all the lines.*

Together with Fraunhofer, **Angelo Secchi** was the pioneer of the discovery of essence material of the stars : the stars are not simple point-like objects that move in the cosmos and shine with their own light, but they are big objects made of variegated chemical composition matter that can be investigated quantitatively.

Angelo Secchi **was the first to connect the spectroscope (a prism) to the telescope**. In this way he made an important classification of the stars, which was based on their spectral analysis. This is considered the most significant part of the astronomical work of Father Secchi, enough to make him considered the father of modern astrophysics.

Between 1863 and 1867, he examined more than 4000 stars, trying to identify their resemblances[3]; in this way he cataloged more than 500 stars, subdividing them into four main classes, according to their color and the type of spectral lines. Father Secchi was the first to put in evidence the fact that the color of the stars is related to their spectral lines and that the temperature greatly influences that spectrum. Thus identified the presence of hydrogen, a pioneering discovery of undoubted importance: today we know that the matter of the Sun is made up of 71% of hydrogen, 26% of helium, while the remaining 3% is due to other elements of the scale periodic, heavier.

## 2. Angelo Secchi and prism

In his book Il Sole[4] [pg. 220] Angelo Secchi describes the spectroscope and the prism (the so called triangular glass). A prism is any object that separates white light into the colors of the rainbow (red, orange, yellow, green, blue, indigo, and violet). It works by refracting light, and breaking it according to its wavelength.

The direct vision spectroscope, conceived by the Florentine astronomer Giovanni Battista Amici, consists of **a series of glass prisms** of different refrangibility, glued in succession, through which the beam of light passes to be analyzed[6]. In 1862, Secchi had the oppurtunity to test the performance of a similar instrument used by the French astronomer Jules Janssen. Secchi then ordered the Parisian optician Hoffman a five prism spectroscope which he used in 1863 for his first observations of stellar spectra. Subsequently, Secchi commissioned the Merz company another direct vision spectroscope, of better quality, with which in 1867 he was able to realize his spectral classification of the stars.

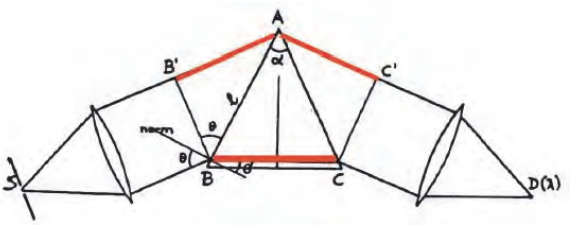

Fig. 3. *How it works a prism: the light coming from a source S is transformed into a parallel beam by an achromatic objective (called collimator), crosses the dispersing prism (ABC) and the resulting spectrum is focused by another achromatic objective (or telescope if observed with the eye) on the detector D.*[5]

Fig. 4. *A) Objective prism, Merz, Munchen, 1864, glass, brass, diameter 162 mm, angle of refraction 12 degrees. INAF museum - Osservatorio Astronomico di Roma; B) TRA CIELO E TERRA Làvventura scientifica di Angelo Secchi a cura di Ileana Chinnici e Mauro Gargano Comitato Nazionale per il Bicentenario della Nascita di Angelo Secchi* © *2018 All Rights Reserved.*

In fact Secchi used the **prism placing it in front of the objectives of the Cauchoix and Merz telescopes** of the Collegio Romano's Observatory and in his book[4] [pg. 222] he wrote that, by adding many prisms, even to small telescope, it is possible to obain a large spectrum: spectral lines become more separate and distinguishable from each other. Using powerful instuments, it is often possible to resolve lines which seem simple at first glance. Sodium D-Line is resolved very easily, but with a powerful spectroscope, it is possible to recognize that in reality it is fivefold, because between the two main lines D1 and D2, there are 3 others at least, not counting those that are outside. You can compare these observations with those of multiple stars: in both cases the result depends on the power of the instruments used. For these researches it is necessary to use 9 prisms and more; and these prisms are made of a very dispersive substance, such as heavy flint or coal sulfide.

Fig. 5. *Sodium D-Lines published in Secchis̀ book Il Sole pg. 223.*

## 3. The Sodium D-lines

Sodium is the seventh most common element in the Universe[7]. On Earth, sodium compounds such as salt give sea water its salty taste and give the white colour of salt pans in deserts. In animal life, sodium is known to regulate heart activity and metabolism. Sodium is also used in technology, e.g. in the sodium-vapour street lights, where it produces yellow-orange light.

A strong doublet at 589.0 nm and 589.6 nm is observed in the Sodium emission spectrum, identifying the D-lines as due to Sodium in the sun[8].

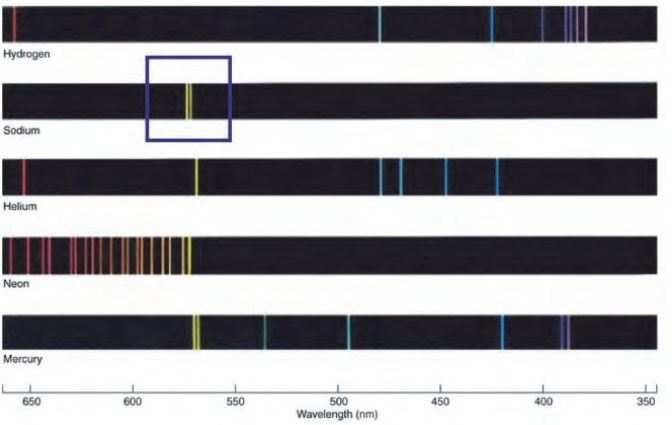

Fig. 6. *Spectral lines observed in Solar specturm.*[8]

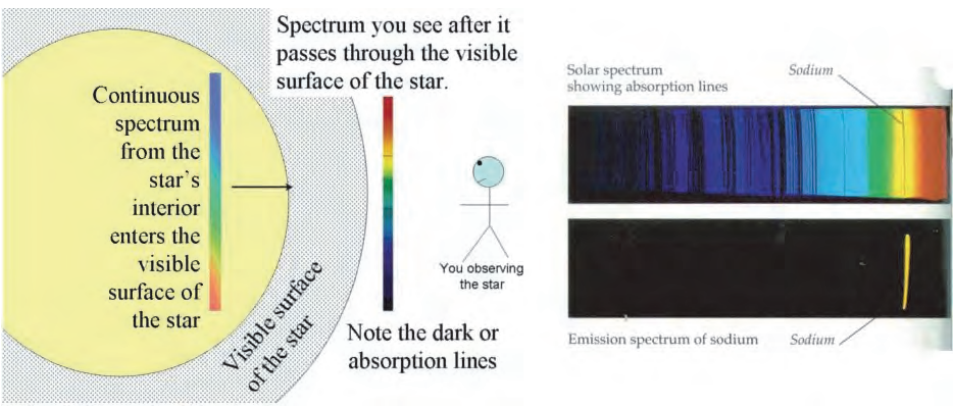

Fig. 7. *Scheme of Solar Spectrum from an observer on Earth.*[8]

## 4. Sodium D-lines and Astrophysical research

The importance of sodium is evident in many astrophysical research. By using a narrow band filter, astronomers can image all sorts of objects for excited Sodium[8]:

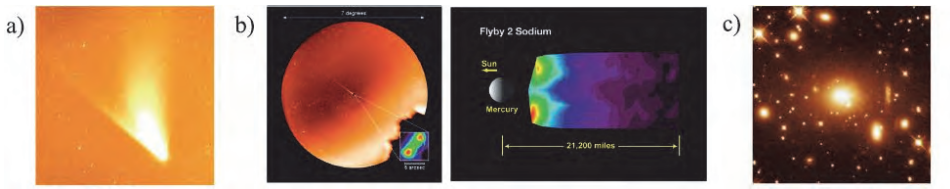

Fig. 8. *a) Sodium D-line image of the tail of the Hale-Bopp comet. b) Sodium D-line images of the comet tail of the planet Mercury. c) Supercluster of Galaxies BAS11.*

**The Sodium D-Lines are also used to measure Doppler shifts and the size of the universe** (Hubble's constant)[8].

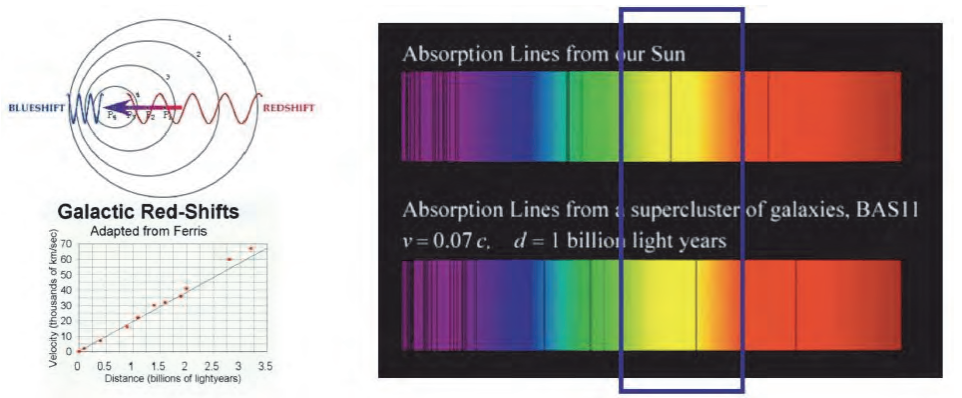

Fig. 9. *Galactic Red-Shifts measured through Sodium D-Lines.*

Sodium is very important in the Physics of Exoplanets. The study of extraterrestrial atmospheres is an active field of research[9]. Several planets outside the Solar System (exoplanets) have been observed to have atmospheres. At the present time, most atmosphere detections are of hot Jupiters or hot Neptunes that orbit very close to their star and thus have heated and extended atmospheres. **The first observed extrasolar planetary atmosphere** was made in 2001[10]. **Sodium in the atmosphere** of the planet HD 209458 b was detected during a set of four transits of the planet across its star. HD 209458 b, also given the nickname Osiris, is an exoplanet that orbits the solar analog HD 209458 in the constellation Pegasus, some 159 light-years from the Solar System.

In a recent article published in Nature An absolute sodium abundance for a cloud-free 'hot Saturn' exoplanet (May 2018)[11], Scientists have detected an

Fig. 10. *Comparison of "hot Jupiter" exoplanets (artist concept). From top left to lower right: WASP-12b, WASP-6b, WASP-31b, WASP-39b, HD 189733b, HAT-P-12b, WASP-17b, WASP-19b, HAT-P-1b and HD 209458b.*[9]

exoplanet atmosphere that is free of clouds, marking a pivotal breakthrough in the quest for greater understanding of the planets beyond our solar system. Just as an individual's fingerprints are unique, atoms and molecules have a unique spectral characteristic that can be used to detect their presence in celestial objects. The spectrum of WASP-96b shows **the complete fingerprint of sodium, which can only be observed for an atmosphere free of clouds**.

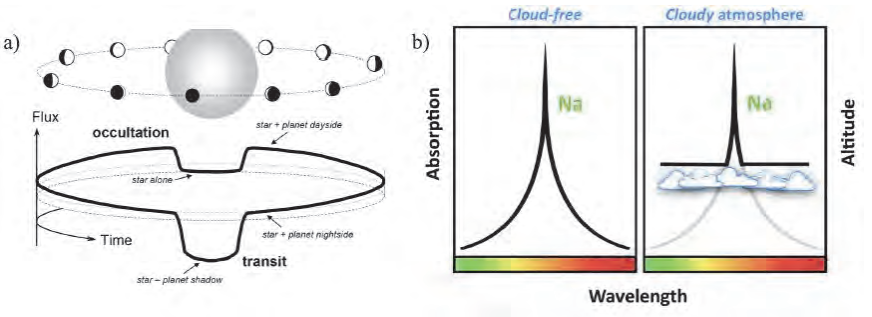

Fig. 11. *a) Exoplanets in orbits close to the line of sight for us on Earth periodically pass in front (transit) and behind (secondary eclipse) of their host stars. Transits and eclipses are a powerful indirect way to study the composition of exoplanet atmospheres*[12]*. b) Sodium fingerprint in an exoplanet spectrum. Shown is the absorption due to sodium at each wavelength. More absorption means that we are looking higher up in the atmosphere,and the vertical axis therefore a measure of altitude in the atmosphere of the planet. An atmosphere free of clouds produces an intact sodium fingerprint (left panel). A cloud deck blocks part of the sodium in the atmosphere, partially removing its spectral signature (right panel). Image credit: N. Nikolov/E. de Mooij.*

Using Europeès 8.2m Very Large Telescope in Chile, the team studied the atmosphere of WASP-96b when the planet passed in front of (transited) its host-star (see figure). This enabled the team to see the starlight shining through the planetary atmosphere, and so determine its composition. It has long been predicted that **sodium exists in the atmospheres of hot gas-giant exoplanets**, and in a cloud-free atmosphere it would produce spectra that are similar in shape to

the profile of a camping tent. Until now, sodium was revealed either as a very narrow peak or found to be completely missing. This is because the characteristic tent-shaped profile can only be produced deep in the atmosphere of the planet and for most planets clouds appear to get in the way. The sodium signature seen in WASP-96b suggests an atmosphere free of clouds. The observation allowed the team to measure how **abundant sodium is in the atmosphere of the planet, finding levels similar to those found in our own Solar System**.

Whether we are talking about exoplanets or our Earth, the role of the atmosphere is crucial in the study of the chemical composition of the sun. In fact the atmosphere of our Earth absorbs the light of the solar photosphere determining the so-called **Telluric lines**[13]. They are those of molecular oxygen and water, which could not exist in the solar atmosphere, much warmer. Furthermore, the atmosphere does not uniformly absorb solar radiation and could contribute to the 10% distortion from solar data.

In his book Il Sole[4] [pg. 235] Angelo Secchi writes *The gases that make up our atmosphere have a considerable absorption force and can therefore, by making some light rays disappear, give rise to some lines that are observed in the spectrum. Since this atmospheric absorption is greater than the layer crossed by light is thicker, the spectrum must vary with the position of the Sun: the lines must be less numerous when it is closer to the zenith, more abundant when it is near the horizon.* Angelo Secchi was referring to what we call today the **Air Mass**. The Air Mass (AM) is the path length which light takes through the atmosphere normalized to the shortest possible path length (that is, when the sun is directly overhead)[14]. The Air Mass quantifies the reduction in the power of light as it passes through the atmosphere and is absorbed by air and dust. The Air Mass is defined as:

$$AM = \frac{1}{\cos(\theta)} \tag{1}$$

where $\theta$ is the angle from the vertical (zenith angle)

The standard spectrum outside the Earth's atmosphere is called AM0, because at no stage does the light pass through the atmosphere.

Angelo Secchi writes in his book[4] [pg. 322] that **water vapor** absorbs solar radiation 100 times greater than atmospheric air.

The measures taken by Angelo Secchi for the Solar Spectrum and consequently for the Sodium D lines, were of course influenced by the Earth's atmosphere. This fact can be seen from the shape of the spectral lines. Many processes tend to broaden these lines so that the lines develop a characteristic shape or profile. When light penetrates the earth atmosphere, the AM0 spectrum is changed due to the following main mechanisms[16]:

- Absorption due to molecules and particles in the earth atmosphere.

- Scattering at molecules and particles in the atmosphere.

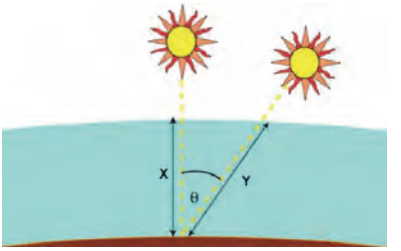

Fig. 12. *The air mass represents the proportion of atmosphere that the light must pass through before striking the Earth relative to its overhead path length, and is equal to Y/X. Copyright 2019 PVeducation.*

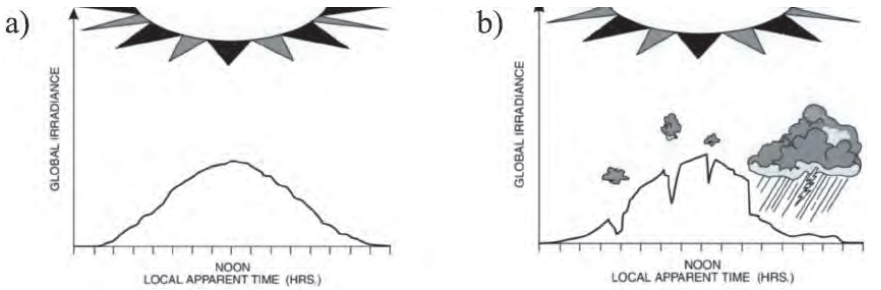

Fig. 13. *a) Diurnal variations of global solar radiative flux on a sunny day. b) Diurnal variations of global solar radiative flux on a cloudy day* ©*2019 Newport Corporation. All rights reserved.* [15]

- Reflection from the earth surface.

- The air mass the light goes through, depending on the elevation of the sun over the horizon.

The Fig. 14 shows the AM0 spectrum as the black line [17] and the terrestrial spectrum without the blue sky (red line) [18], and the transmittance of those atmospheric gases that are the main responsible for absorption [18].

In Fig. 15 we see how the Solar spectrum varies at different AM.

The first experiments made by Father Secchi were done in Rome using a prism with an angle of 10 degrees and 16 cm diameter, in front of a telescope 22 cm achromatic (lost in 1958 in the Monte Mario Observatory fire) [19].

Chromatic resolving power of a prism is given by:

$$R = \frac{\lambda}{\Delta\lambda} = \frac{BCdn(\lambda)}{d\lambda} \tag{2}$$

where $n$ is the refractive index of the prism for the wavelength $\lambda$ and it depends from $\lambda$, $\Delta\lambda$ is the limit of resolution, the difference in wavelength between two lines of equal intensity that can be distinguishedand BC is the maximum thickness of

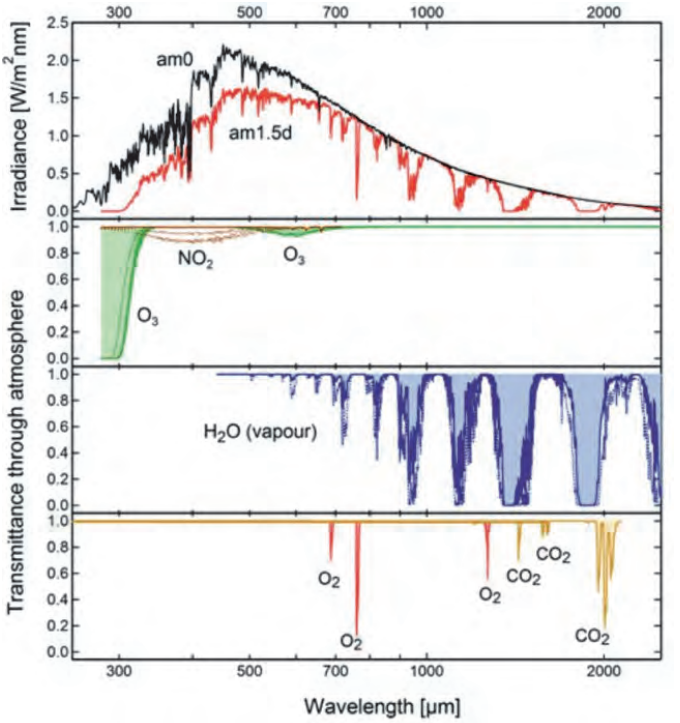

Fig. 14. *Sources of absorption in the AM1.5d spectrum.*[11]

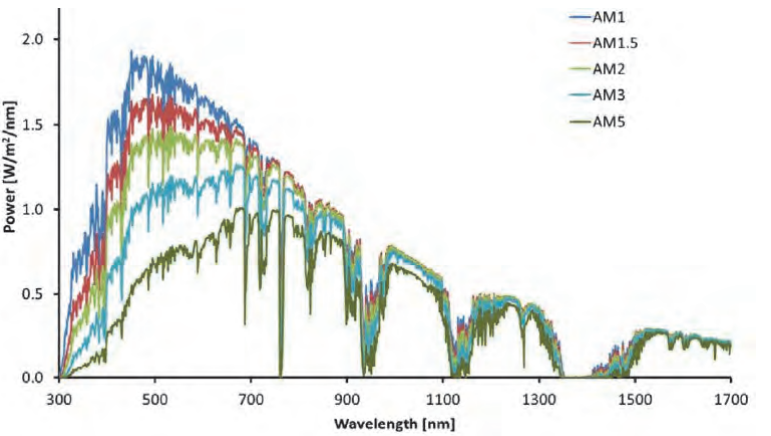

Fig. 15. *The direct incidence solar spectrum at different air mass values.*[11]

the prism traversed by light rays. The quantities $d(n)/d(\lambda)$ and BC often are called the dispersion and baselength of the prism, respectively.

Considering a different value of Air Mass during the day, supposing in the morning an Air Mass = 5, and the usage of seven or more prisms in series, as reported in Angelo Secchiś book[4] [pg. 222], the resolution obtained by Father Secchi was a very good result.

In fact for $n$=1.60 - 1.89 (flint glass), $\lambda(D1) = 589.418$ nm, $\lambda(D2)$ 588.821 nm, $\Delta\lambda = 0.597nm$, R = 986, which is the resolution we can obtain for resolving the the Sodium D-Lines doublet. But Angelo Secchi obtained more: using 9 prisms he was able to see what after will be called the Zeeman effect, discovered 30 years after (1898), more than 30 years after Angelo Secchi's obeservations.

**The Zeeman effect** is the splitting of a spectral line into several components in the presence of a static magnetic field. **Zeeman's original data was exactly on Sodium D lines**.

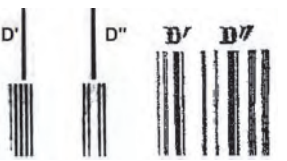

Fig. 16. *Zeeman effect on Sodium D-lines compared with Sodium D-Lines published in Secchiś book Il Sole pg. 223.*[9]

We can deduct that **Angelo Secchi was able to see the effects of the solar magnetic field**, which generates the sunspots. Father Secchi dedicate many pages in his book[4] to these aruguments (sunsposts pg. 8–20, solar magnetic field 335–343).

## 5. Alessandro Cacciani and Sodium Filter

Professor Alessandro Cacciani (1938–2007) has been known world wide for the invention and development of the Magneto-Optical Filter[20]. Hundreds publications present its applications from solar to stellar helioseismology. Astronomer at the Observatory of Roma (1964–1982), he continued his research at the University of Rome La Sapienza where directed the Solar Laboratory and taught Spectroscopy. The Magneto-Optical Filter (MOF) is an instrument that gives a really narrow bandwidth, high transmission (almost 50%) and perfect stability. It can work only in a small range of wavelengths, well defined, like **Sodium (Na)** and K doublets, and can be thought as an high resolution spectrograph within those wavelengths.

It was developed by Alessandro Cacciani at the end of the 1960s Its main use is for the study of the Sun; during the last years it has been adopted also for the analysis of Jupiter oscillations and in Anctartica for long-duration solar observations.

A complete MOF instrumentation is made of two separated unit: the MOF itself and the WS (Wing Selector) that, together, provide accurate Doppler and magnetic measurements. The first unit is composed by two crossed polarizers (P1, P2) and a

metallic vapour (Sodium) between them in a longitudinal magnetic field B between 2000 and 4000 Gauss. A schematic diagram of the filter is shown in the following figure.

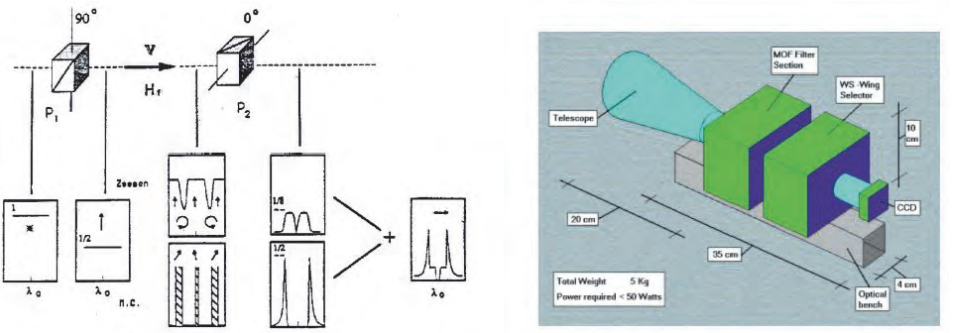

Fig. 17. *Schematic diagram of the MOF filter (top) and spectral behaviour along the optical path. Following the Zeeman rules, the vapour immersed in a magnetic field absorbs two circularly polarized components,leaving the residual light also circularly polarized (in opposite direction). This wavelengths cannot be stopped by the crossed polarizers and are transmitted as a couple narrow bands that can be close at will (depending on the magnetic field strength).*

The working principle of the MOF is based on two concurrent effects, namely the Zeeman effect in absorption and a sort of Faraday rotation close to the lines wings called Macaluso-Corbino effect. Both change the polarization in and around the resonance lines, leading to total transmission profile shown below where the experimental transmissions profile at different temperature and magnetic field values is shown[21].

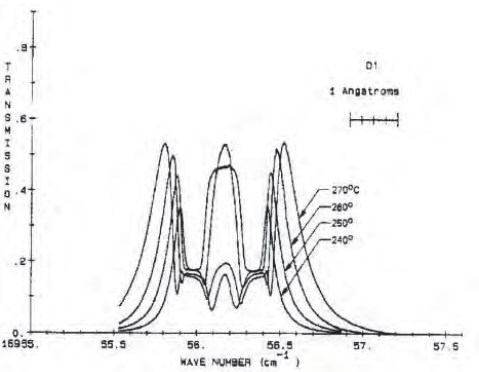

Fig. 18. *transmission profile at different temperature and magnetic field.*

Professor Cacciani develepoed the Sodium Filter even thanks to the "solar tower" present at the Rome Astronomical Observatory. **The invention allowed to "see" the solar surface**. Through the processing of digital images, taken at the

Monte Wilson Astronomical Observatory, it was possible to show to the world the filmed footage of the "flames" movement of the surface of the Sun, lasting 8 hours, summarized in 10 minutes.

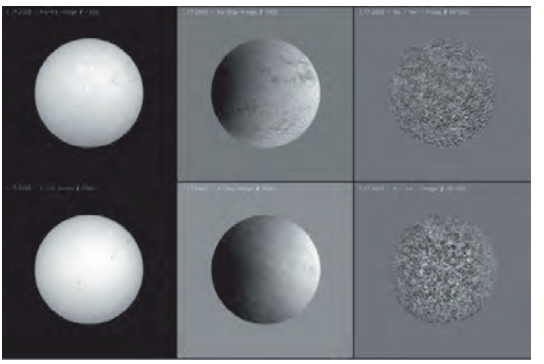

Fig. 19. *Intensity (left), Velocity (middle) and rotation suppressed Velocity (right) sample images in the Sodium Na line (above) and in the K line (below).*

It is possible to find many articles in astrophisical journals which refers to **Professor Caccianiš filter MOF**[22, 23, 24]. Helioseismolgy is a relatively new field of Solar Physics, whereby the internal structure and dynamics of the sun can be studied. This is a field of research that is being actively pursued both from the ground and from the space. Its aim is to derive information about the interior of the sun measuring the waves that travel inside the star and become resonant. From the frequency spectrum of such a resonant waves it is possible to compute the radial profile of relevant physical parameters (temperature, density and chemical composition) as well as its dynamics (internal rotation as a function of radius, large scale convective motions that mix the thermonuclear core etc). To monitor solar oscillations, a series of dopplergrams must be taken over a very long time[24]. At the 60 Foot Solar Tower (Univerisy of Southern California), **dopplergrams are obtained by using a magneto-optical-filter (MOF)**.

**A red/blue pair of sodium images** (see below) is taken once every minute with a separation of 5 seconds between the red and blue images. As a result, one dopplergram is computed once a minute for several hours during the day. The two dopplergrams can be subtracted to obtain a velocity image map of the line-of-sight components of the rising and sinking regions of the sun. A two minute separation is chosen since 2 minutes is roughly half of a solar oscillation. The images below show doppler velocity of the sun at a two minute separation and at a three minute separation, to the left and right respectively. Light regions are rising and dark regions are sinking.

So **a doppler image reveals those individual areas of the sun that are either rising or sinking**. In the images, rotation can be seen. The left hand side of the 2 images is rotating toward the Earth.

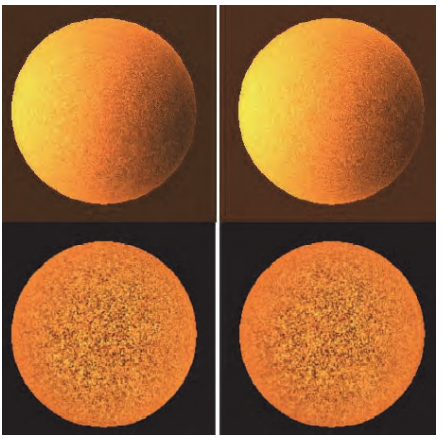

Fig. 20. *Dopplergrams.*

# Dark sky in Rome now and at the time of Angelo Secchi

Sigismondi, Costantino*

*ICRA/Sapienza and ITIS G. Ferraris, Roma, Italy
*E-mail: sigismondi@icra.it www.icra.it/gerbertus

Rome as every modern big city is heavily affected by the light pollution and the observation of the celestial objects is hampered by a luminous background. While a comparison with a rural place is made by observing the Orion nebula at the same heigth above the horizon and in the same meteorological conditions, an historical consideration is made by using the observations of years 1867–68 by Angelo Secchi of the same nebula, and upon the use of the meridian line of santa Maria degli Angeli for measuring the position of the Moon, and the instant of the full Moon used for the computation of the Easter's sunday in Catholic Church. The observation of the Moon on the meridian line nowadays on the meridian line is obstacoled by the external lights of Termini Station and Repubblica Square.

*Keywords*: History of Science, Light Pollution, Urban and Rural site for Astronomy, Pinhole Astronomy.

## 1. Introduction: The luminosity of the night sky in 1700 in Rome

The meridian line of santa Maria degli Angeli was build with the intention of measuring the variation of the obliquity of Earth's orbit for the forthcoming centuries in 1702. Another evident service of this line was to measure the tropical year, in order to check the Calendar's reformation of Gregory XIII. Finally on the meridian line are mentioned the two "Terminus Paschae" between 22 March and 25 April. Being Easter related to the full moon after or equal to 22 March (being 21 March the so called Easter equinox), the observation of the full Moon had to be possible on that meridian line. We tried to observe the Moon on the meridian line during the late evening, and we found it extremely difficult because of the illumination of the church from the external light coming from the great roman windows. The church in 1700s was completely darkened during the noon time for the observations of the Sun and the stars in daylight; during the night the absence of artificial light made unnecessary the use of tents for covering the great windows. So the astronomer Francesco Bianchini (1662–1729) who built this meridian line upon the will of pope Clement XI, did not write expecial notes on lunar observations, probably because they were rather simpler with respect to the observation of the stars in full daylight, as it was done in this meridian line.

## 2. Stars in daytime at Santa Maria degli Angeli

It has been written that Bianchini used very long telescopes in the basilica for observing the stars in daytime. It it true that Bianchini itself used such telescopes of 50 meters of focal lenght and single objective lens (made by Campani and purchased by the Cardinal Melchiorre De Polignac) for observing and mapping Venus from the Palatine Hill, but I exclude he did use the same instruments in the Basilica.

Not because of lack of space, but because they weren't necessary. A star does not show details like the planets, and to him only the position of the star was required, in order to compare the timing of the Solar transit with the one of the fixed star. He used for this purpose the coordinates of the stars reported in the atlas of Philippe de la Hire (1701) made in Paris observatory. The passage of a star on the meridian line can be done by defocusing the star with respect of a crosshair and averaging the first contact of the defocused disk and the second contact, exactly as it was done for the solar image on the floor of the basilica. So the draw of a small telescope used on the meridian line by Bianchini explains fully this procedure.

## 3. Moon in night time

Nothing is left about lunar observation on the floor of the basilica of S. Maria degli Angeli by Bianchini. But evidently he could use the telescope used for the stars in daytime, in the same exact way: he opened the window of about 40 cm wide x 60 cm high above the pinhole and could observe the Moon at the telescope. Our question now is: was it possible to observe the Moon in the same way of the Sun, projected on the floor? Was it useful for calibrating the Easter Computus of the spring full Moons?

## 4. Observed Full Moon and Ecclesiastic Moon

The Computus of Easter was based essentially on the Methonic cycle of 19 years. After this period of time the full Moon occurs in the same day of the year. 19 years contain always 5 bissextile years, unless we are in the surrounding of secular years not multiple of 400. So the problem of ecclesiastic Moon was only a mathematical problem for the astronomers who worked at the reformation upon the will of pope Gregory XIII, Christopher Clavius and Egnazio Danti. They used the mathematical solution of Luigi Giglio. From a physical point of view the solution of Methonic cycle is very stable, and there is the possibility that the lunar eclipses repeat over a Methonic series, as well as it occurs for the Saros cycles, for about thousand years. A lunar eclipse is the certitude that the Moon is full. It can occur that the days of such series changes of 1 or 2 days from a given eclipse, rightly for the aforementioned problem of secular years not multiple of 400. For example the year 2019 we had the lunar eclipse of 21 January, which follows the one of 21 January 2000, and the one of 21 January 1981. But there was also a Saros series dealing with the eclipse of 9 January 1982 and the one of 21 January 2000. So the eclipse of 21 January 2000 belong both to a Saros series and to a Methonic series. The Saros series of lunar eclipse are usually longer than thousand years, while the Methonic ones are slightly shorter. The calculated full Moon therefore is prevalent over the observed one in the ecclesiastic computus. The validation of this computus has been already done by the ancient astronomers.

## 5. Optics and energetics

The original circular pinhole was 20 mm wide and it projected the image of the Sun between 21 and 50 meters, and when the full Moon is the source, it is about 15 magnitudes fainter than the Sun. The windows of the church of S. Maria degli Angeli let enter nowadays a luminous background much higher than the sky background already much brighter than natural one. We can reconstruct some parameters by simplifying the situation as if the meridian line would be in an open space. The same considerations of this paragraph can be done by using a flat mirror and a pinhole, and projecting through the pinhole the lunar light over a screen at a given distance. For reproducing the original pinhole of st. Maria degli Angeli meridian line it is necessary to use a 2 cm wide circular pinhole and the screen from 21 to 50 m. To scale to shorter dimensions like 10 m, representative of a similar situation in S. Maria degli Angeli during spring, i.e. 30 meters of focal lenght for the spring Moon (due to its height above the horizon near the celestial equator... 27.5 m) we should use a smaller pinhole. Focal lenght in scale 10 m; focal length in truth 30 m. Energy per unit area is $E/30^2$ and has to remain constant scaling to 10 m, so the input energy has to diminish to $E'/10^2 = E/30^2$; $E' = E/9$, therefore the pinhole has to be 3 times smaller, i.e. 7.3 mm. To see the Moon projected by a 7 mm pinhole at 10 m of distance it is necessary to have the screen in full darkness. The magnitude of such pinhole lunar image on a 10% white reflecting paper screen or 20% reflecting white marble (the one of the meridian line) screen is 3 or 2.5 magnitudes dimmer than the ideal image at 10 m, which is 10 cm wide and it should contain all the energy fallen upon 7mm. The ratio between these areas is $(7.3/100)^2$ and the scaling in magnitude is 2.5 its logarithm (according to Pogson's law) i.e. 5.7. Finally the full Moon of magnitude $-13.6$ becomes $-13$ for the height above the horizon (atmospheric loss for transparency) and $-7.4$ for the projections and around $-4$ for the reflection efficiency. Now the problem of the sky background is that is integrated energy attains magnitude $-4$ and more! If we consider the brightness of the image of total magnitude $-4$ in term of magnitudes per arcsec$^2$ we obtain for the area of the Moon on the floor, of about 160 mm of radius, 8.26 magnitudes per mm$^2$ or 3.26 magnitudes per cm$^2$. Considering that this diffused luminosity for a single square centimeter is of the same order of the integrated magnitude of the Orion nebula, if the sky background does not allow to see the Orion nebula to the naked eye... it is difficult to see such projected Moon as well. A photo of the Moon on the floor of the Basilica required a long pose to be caught.

## 6. Sky background levels

In a rural site, the value of +22 magnitude/squared arcsecond is attained. The integrated energy of such sky over 2 pi of solid angle, or $2.7 * 10^{11}$ arcsec$^2$ is 11.4 magnitudes more than the single pixel of a single square arcsec of 22 mag, i.e. 10.5 magnitude. Evaluating the integrated energy equal to $-4$ means to have a single

pixel about 15 magnitudes more bright than the ideal rural site. This is not the case of the city of Rome, and probably of none of the urban sites worldwide, but in our case we have to remember that many of the lights around the basilica enters through the windows directly in the church letting the ambient rather luminous instead of dark.

## 7. Comparison with the Orion nebula observations

Rome was ending to be an *astronomical rural place* when in 1851 an English Company for gas illumination was charged to start the night illumination by the pope Pius XI. Father Angelo Secchi was the director of Collegio Romano Observatory at that time and published in 1868 a memoir on the observations and spectra of the Orion Nebula M42. The details he could see with a 24 cm refracting telescope with f=4.1m are astonishing for the astronomers of nowadays, they are indeed invisible for modern observers with equivalent and bigger telescopes without narrow bandpass filters. And even with such filters the rapid spread of bright LED illuminations are growing and polluting also the wavelengths which were left free of pollution by the gas lines. Using Newtonian telescopes f/4 of 25 cm of diameter (of the Urania firm, made in Rome and a brand new one made in China) only the greenish color of the nebula is visible (see Fig. 5), but not the details showed by Secchi. Rome passed from being a rural place (astronomically speaking) in 1851 to a present urban place. The angular dimensions of M42 observed through a 18 mm spotting scope in Rome and in Vigna di Valle (on Bracciano lake 60 km North from Rome) show the loss in terms of background magnitude. The observations of M42 have been made on April 5 at 20:42 UTC in Vigna di Valle $h = 9^o$ i.e. 4 airmasses and on April 7 at 19:10 UTC in Roma, Monteverde SW from the center of Rome $h = 23^o$

Fig. 1. Sequence of photos of the Moon on the meridian line of S. Maria degli Angeli. Pietro Oliva, 19 december 2007, from left to right. The luminous background determines the illumination of the rest of the meridian line.

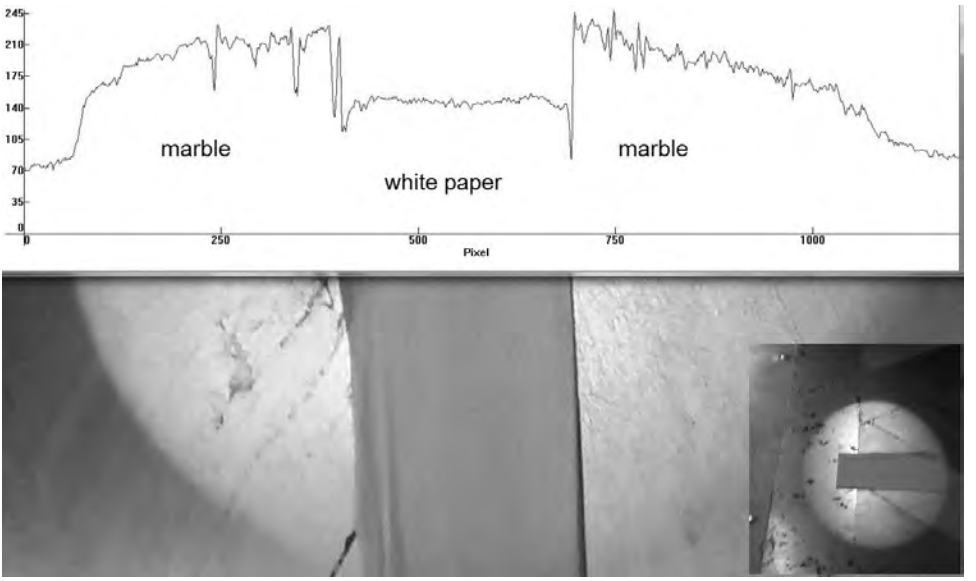

Fig. 2. The solar image at s. Maria degli Angeli shows the different reflective index of marbles and white paper. The histogram is obtained with IRIS software. While the white paper shows about 140 counts, the marbles get 245 counts on the same photo and in the most luminous regions, where the rays are reflected at the same incidence angle.

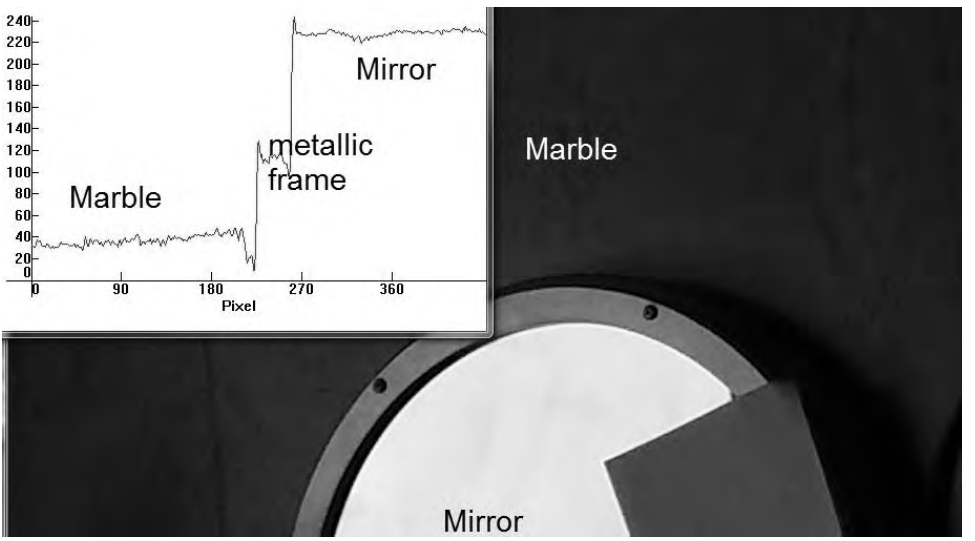

Fig. 3. The reflection of the marble compared with a mirror with 99.999% of reflectance, a glass solar filter of the Science Museum of Virginia. The marble reflects 40 units while the mirror 230. The reflectance of this marble is about 17%. We assumed 20% for the one of S. Maria degli Angeli.

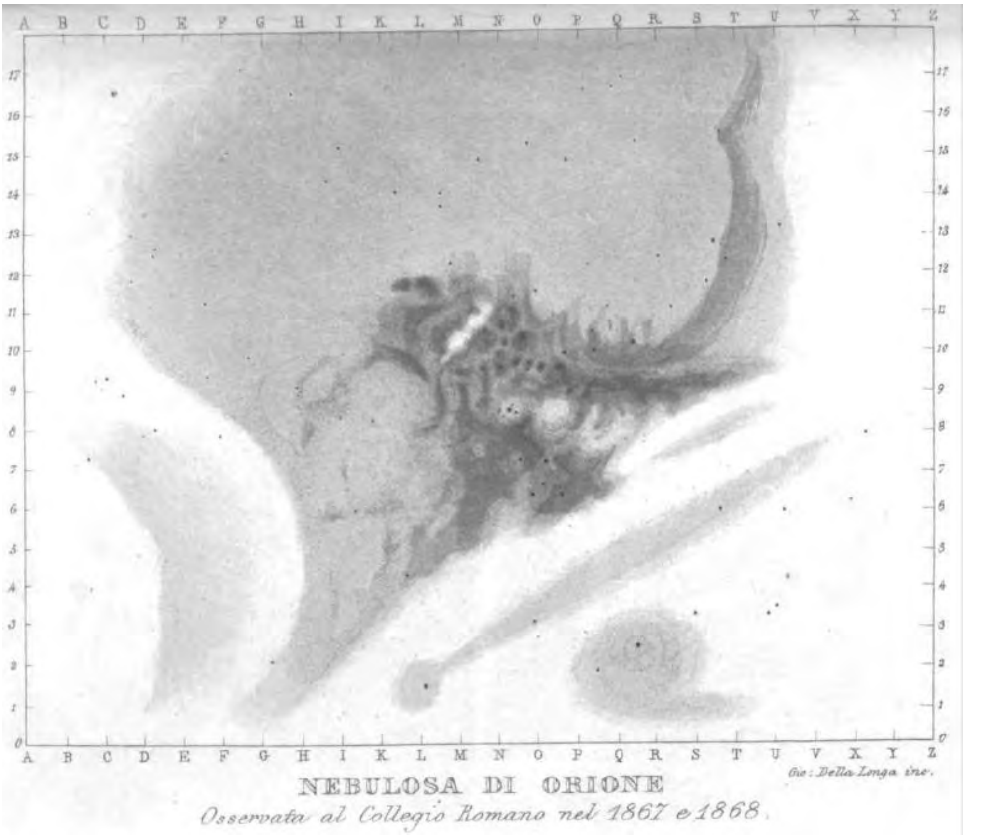

Fig. 4. The Orion nebula as seen by father Angelo Secchi in 1867–68.

i.e. 2.5 airmasses, and 20:27 UTC in Roma, Prati NW of the center of Rome, at $h = 10^o$. These observations showed the following results: in the rural place at same height of Rome the angular dimension of M42 is twice. The dimension of M42 is 1.5 smaller in Rome the rural place when compared the observations at $9^o$ and at $23^o$ of altitude. The passage from a rural place to Rome SW is the equivalent of 1.5 airmasses of absorption. Being 0.235 magnitudes for each airmass in Rome, the lower limit of the loss due to the ligth pollution is at least 0.35 magnitudes.

## 8. Conclusions

We studied two situations dealing with light pollution: the classical observation of a deep sky object like the Orion Nebula M42 in Rome now and in 1867–68 by father Angelo Secchi at Collegio Romano (center of Rome) and the observation of

Fig. 5. The Orion nebula photographed by Daniele Nocco and Emanuele D'Aleo in 2019 with Canon EOS 600d ISO 3200 exposition 10s, tube of 1.5 m, from Rome, Casaletto.

the Moon projected at 30 meters of distance on the meridian line of Santa Maria degli Angeli through a pinhole of 20 mm by Francesco Bianchini in 1702 and the similar experiment at 10 m through a 7mm pinhole. The difficulty to observe the projected Moon is due to the integrated magnitude of the sky of $-4$, 15 magnitude brighter than the rural site, this value included the direct lights entering through the windows in the church during the night. The Orion nebula observed from Rome and from a rural place, Vigna di Valle, showed a reduction of perceived angular dimensions from Rome of about 50% which would correspond to 0.75 magnitudes. A similar lower limit of 0.35 magnitudes is obtained by comparing an observation made in Rome at $h = 23^o$ with the one at $h = 9^o$ in Vigna di Valle. The site of Rome, when looking offcenter is not too bad with respect to a rural environment like Vigna di Valle located 60 Km from the city, even if many details have been lost when comparing with the observations made by Father Secchi on the Orion nebula.

# The Secchi-Rosa law on the solar diameter

Sigismondi, Costantino*

*ICRA/Sapienza and ITIS G. Ferraris, Roma, Italy
*E-mail: sigismondi@icra.it www.icra.it/gerbertus

As Secchi-Rosa law has been named the observed variation of the solar diameter with the solar cycle. It was considered a consequence of the solar activity on the outer layer of the stellar structure, and there was a discussion on the irradiation effect due to the Earth's atmosphere. A comparison with the penumbra effect measured on the meridian line of Santa Maria degli Angeli and its debate since Cassini and Manfredi is made, and the definition of the solar limb as inflexion point are discussed. A relationship between position on the meridian line and extension of the penumbra is proposed from the analyzed data.

*Keywords*: History of Science, Solar diameter, Angelo Secchi, Rosa.

## 1. Secchi-Rosa law as reported by Giorgio Abetti (1937)

The solar physicits giorgio Abetti in his book "il Sole" (1937, pp. 77–80) reported the Secchi-Rosa effect. The original text in Italian is here fully reported and after commented.

### La forma del Sole e la sua supposta variabilità

Già nel 1750 Bradley eseguiva misure sistematiche del diametro solare a varie latitudini e, a parte il problema di una sua eventuale diminuzione secolare, ben presto si incominciò a discutere sulla sfericità del globo solare e della variabilità del suo o dei suoi diametri, forse in relazione con le varie fasi di attività solare. Le misure del diametro sono state cominciate, e si fanno tuttora, con i cerchi meridiani, determinando a mezzo dei tempi dei passaggi in meridiano dei lembi ovest e est, il diametro orizzontale e, dalla differenza di declinazione fra i lembi Nord e sud, quello verticale. Il diametro viene inoltre determinato a mezzo degli eliometri o con la fotografia. Il P. Angelo Secchi e il P. Paolo Rosa, dell'Osservatorio del Collegio Romano, hanno discusso il problema delle variazioni del diametro solare dalle osservazioni allora esistenti, ed il secondo di questi, in un lavoro dettagliato, concludeva che in quelle epoche in cui il numero delle macchie e delle protuberanze è minore, il diametro equatoriale è maggiore. Similmente R. Wolf, dalla discussione delle osservazioni eseguite da Hilfiker col cerchio meridiano, trova, in corrispondenza del grande massimo del 1870, un risultato corrispondente a quella che egli chiama legge Secchi-Rosa. Anche all'Osservatorio del Campidoglio, dal 1877 si continuano ad eseguire sistematiche osservazioni con il passaggio al meridiano del diametro solare le quali dimostrano la sua variabilità. Ma è difficile stabilire in qual grado essa sia propria del Sole o dovuta ad altre cause. Intanto il problema è probabilmente complicato dal che i due diametri, polare ed equatoriale, presentano una lieve differenza, pur essa variabile, in relazione con il ciclo di attività. Secondo le ricerche di Lane Poor,

su osservazioni fatte da varie investigatori con diversi metodi, il rapporto fra i diametri polare ed equatoriale sarebbe periodicamente variabile. La lunghezza del periodo resta incerta, ma sembra essere approssimativemente quella del ciclo delle macchie. L'amplitudine di questa variazione è circa 0.2", la differenza fra i massimi valori positivi e negativi essendo di circa 0.5". A Greenwich, dove si osservano regolarmente col cerchio meridiano i diametri del Sole, dalla discussione del decennio 1915–1925 risulta, che il diametro verticale è maggiore di quello orizzontale di 0.3", differenza che, almeno in parte, può essere dovuta al differente metodo di osservazione, il quale, come già detto, per il diametro orizzontale consiste nel misurare i tempi del passaggio al meridiano, con un micrometro autoregistratore, per quello verticale nel misurare con i cerchi la differenza di distanza zenitale fra il lembo Nord e quello Sud. Un esame dei diametri osservati, in realzione col periodo delle macchie, ha condotto a risultati incerti; invece, ordinando per ogni mese durante il decennio, per ambedue i diametri, le differenze fra i diametri calcolati nel *Nautical Almanac* e quelli osservati, risultano delle variazioni massime di un secondo d'arco, essendo il diametro maggiore in estate e minore in inverno. Discutendo le varie cause, che possono produrre un simile effetto, si giunge alla conclusione che esso sia dovuta alla **irradiazione** e alla sua variazione nel corso dell'anno. Infatti, se si fa l'ipotesi che l'irradiazione sia variabile al variare dell'assorbimento atmosferico, secondo la diversa altezza del Sole sull'orizzonte, ed anche per variazioni di contrasto fra il disco luminoso del Sole, e lo sfondo del cielo, Cullen, il quale ha discusso le osservazioni di Grenwich, trova che le variazioni del diametro sono proporzionale alla secante della distanza zenitale del Sole, raggiungendo appunto un secondo d'arco. D'altra parte l'effetto totale della irradiazione sul diametro del Sole, che è in media di 1920", sembra sia di 3". Se ne deduce che le variazioni annue del diametro solare, dovute alla irradiazione, sono piuttosto notevoli, e quindi non deve far meraviglia che risulti assai difficile distinguere, da questa variazione apparente, una eventuale variazione effettiva del globo solare. La questione è lungi dall'essere risolta: sembra che sia necessario escogitare dei metodi di misura più precisi, ed eseguire le osservazioni in luoghi dove le variazioni dovute a cause terrestri siano le minori possibili. Che possa esistere una differenza fra il diametro polare e quello equatoriale del Sole, e che questa sia variabile, potrebbe venire confermato dal fatto che sembrano esistere delle variazioni nell'inviluppo esterno del Sole, chiamato "cromosfera", e dal fatto che hanno luogo periociamente notevolissime variazione nell'altro inviluppo più esterno, cioè la "corona solare" a noi visibile soltanto durante le eclissi totali. Era già stato notato da Respighi che la cromosfera ha altezza variabile alle diverse latitudini; dalle regolari osservazioni eseguite in Arcetri durante l'ultimo ciclo sembra resultare, che l'altezza della cromosfera è maggiori ai poli che all'equatore alle epoche di minima attività solare, ed ha invece approssimativamente la stessa altezza attorno a tutto il bordo durante le epoche di massima attività. La corona solare poi presenta, come vedremo, delle configurazioni ben definite con espansione della materia coronale ora all'equatore ed ora ai poli, in corrispondenza ai massimi e minimi dell'attività solare.

## 2. Comments on the text of Abetti and penumbra problem in pinhole gnomon

The text reports a full account of the debate on the Secchi-Rosa law, as named by R. Wolf, according to wich the solar diameter would vary along the solar cycle, with the maximum occurring at minimum solar activity, with typical amplitudes of 0.5". The reports made by Cullen on the measurements held at the Greenwich Observatory evidence also a monthly variation of the solar diameter, both vertical and horizontal, lead to the introduction of the "irradiation" effect, responsible of the different perceptions of the solar diameter because of the contrast of the solar disk with the sky. This irradiation effect would amount up to 3" for the whole mean apparent diameter of 1920". The contrast with the sky background is due to the amount of humidity in the air and to the Mie scattering of the atmosphere; this produces as well a variation on the measured penumbra in the pinhole meridian line as the Clementine Gnomon in Santa Maria degli Angeli in Rome, an effect already discussed by Cassini, Montanari and Bianchini in the XVII century. The phrases reported by Catamo and Lucarini (2012) who rediscovered the inscription on the penumbra algorithm on the "equinox meters" of the Clementine Gnomon (1702) explains the fact: Bianchini prendeva sempre in considerazione, per le sue rilevazioni, l'ellisse luminosa diminuita dell'*anello* di minore luminosità (la penombra). La larghezza di questo anello era stimata, con un criterio all'epoca condiviso da Gian Domenico Cassini e da Eustachio Manfredi, altro importante astronomo coevo, pari al semidiametro del foro gnomonico, quindi nel caso di Santa Maria degli Angeli, pari a 50 particelle, cioè un centimetro. Altri hanno ritenuto che l'anello è di misura variabile in relazione a diverse circostanze, tra cui quelle meteorologiche, e può raggiungere e anche superare, nel caso di un foro come quello di Santa Maria degli Angeli, la larghezza di due centimetri.

## 3. Penumbra measurements at the Clementine Gnomon

During the meridian transit of 21 August 2019 the phenomenon lasted 141.11± 0.58 s at a declination of +12d 07m 29.4s, corresponding to an angular extent of 2069" ± 9". The real diameter of the Sun was 1897"; the penumbral ring was 86.1" wide. The pinhole is presently 25.4 mm wide and at the distance of 57.201 centesimal parts on the meridian line corresponds to an angle of 223.4", therefore the penumbra was the 38.6% of the pinhole in these conditions of clear sky (with increased humidity with respect to 18 august) and illumination in the church. The timing was obtained by video inspection. Ephemerides from calsky.com. Air humidity from meteoblu.com archive: for 21 August at noon time it was 55%.

From a pure geometrical consideration the penumbra extension should be a ring of a thickness equal to the diameter of the pinhole, but the contrast inside the church is different if we consider the winter image, with respect to the summer image, which is more contrasted, falling in a darker place of the basilica. See Fig. 1 for the case of 18 August 2019 with penumbra ring as 41.1% of the pinhole diameter.

Fig. 1. *The Sun approaching the meridian line of the Clementine Gnomon on August 18, 2019. Penumbra 41% of pinhole diameter and air humidity 60%.*

The transit lasted 142.46± 0.65 s at a declination of +13d 06m 26.6s, corresponding to an angular extent of 2081" ± 10". The real diameter of the Sun was 1896"; the penumbral ring was 92.7" wide. The pinhole is presently 25.4 mm wide and at the distance of 54.948 centesimal parts on the meridian line corresponds to an angle of 225.6", therefore the penumbra was the 41% of the pinhole in these conditions of sky clear and illumination in the church. The timing was obtained by video inspection. Ephemerides from calsky.com. The humidity of the air was 60%. Moreover the sky conditions has its influence on the penumbra: a blue sky is less luminous than a white one, and the contrast of the solar image is larger; a wider penumbra is to expect, while in the case of the white sky the contrast is less and the sky is more luminous, so its light penetrates into the church through the large windows lowering the contrast of the observerd image with respect to the floor. In the first years of use of the meridian line the basilica's windows were closed eliminating the problem of the contrast inside the church, leaving only to the sky contrast the cause of the "irradiation" effect.

## 4. Inflexion point of the ligth curve

It has been evindenced that for the limb darkening function the horizontal and the vertical luminosity profiles of the Sun have their maximum at the center, and decrease with a typical slope toward the limbs, at which the luminosity if 16% of the center. This curve has an inflexion point slightly before the end. This inflexion point is considered stable, even if the conditions of background contrast vary. This concept is applied either in modern solar observations with appropriate detectors (digital) either in total eclipse images obtained with different density filters; the inflexion point has not to be cut out with too high density filter.

Fig. 2. *The Sun on the XX August MDCCII inscription, on 21 August 2019. Its penumbra is 38.6% of the pinhole width, instead of 100% geometrical. Air humidity 55%.*

## 5. Conclusions

The problem of the definition of the solar diameter in the XVIII and XIX centuries was heavily influenced by the luminosity of the sky background. Either in the pinhole meridian line of S. Maria degli Angeli in Rome or in S. Petronio in Bologna, for quoting the main instruments devoted to the measurements of the

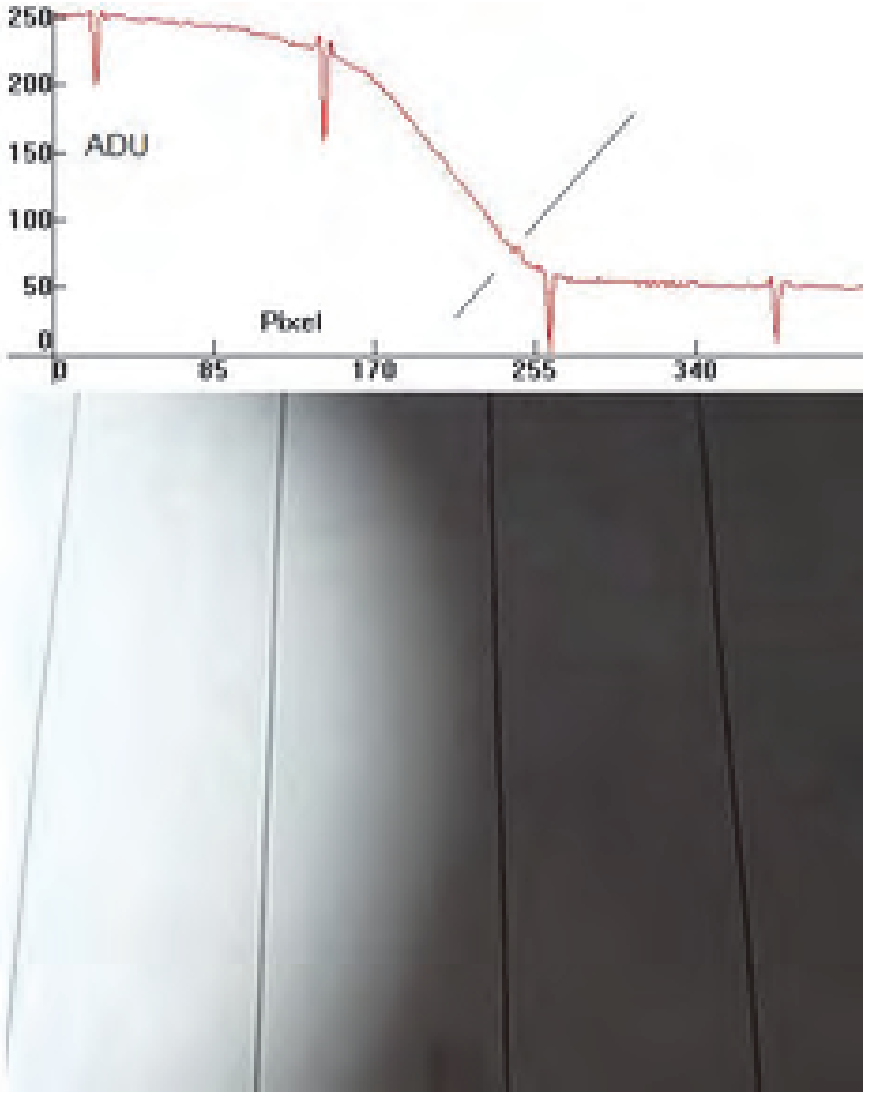

Fig. 3. *The inflexion point of the Limb Darkening Function of the Sun combined with the 25.4 mm Pinhole transfer function at the floor of Santa Maria degli Angeli, image of 13 July 2019.*

solar position and of the solar diameter, the dependance on the weather conditions is rather important. Two measurements devoted exactly to this purpose made on 18 and 21 August 2019 at the meridian line of the Basilica of Santa Maria degli Angeli proved a variation of the penumbra extent from 41% to 38.6% of the pinhole diameter, instead of being 100% as the geometry implies. The illuminination inside the Basilica was rather the same, being the Sun in a position only slightly different (less than 30 cm); but the conditions of humidity and color of the sky, which

was clear in both days, changed from 60% to 55%. This produced a reduction in the observed penumbra from 41%to 38.6%, suggesting a relationship between percentual humidity and percentual Penumbra. After these first measurements, other video have been inspected: 7 Dec 2018, 12 Jan 2019, 1 May 2019 and 13 Jul 2019. Other relationships between Penumbra and Temperature or air Pressure have been investigated; none of them are convincing, excepted the one with the position. The conclusion is that the Penumbra depends strongly on the contrast conditions inside the Basilica, more than from sky conditions. To observe the influences of the sky conditions it should be necessary obscure the church like Francesco Bianchini did in XVIII century. The assumption made by Francesco Bianchini that the Penumbra was half of the pinhole, say 50% of it, has been verified as optimal with respect to our videos with time resolution down to 0.26 s, and angular resolution down to 3 arcsec.

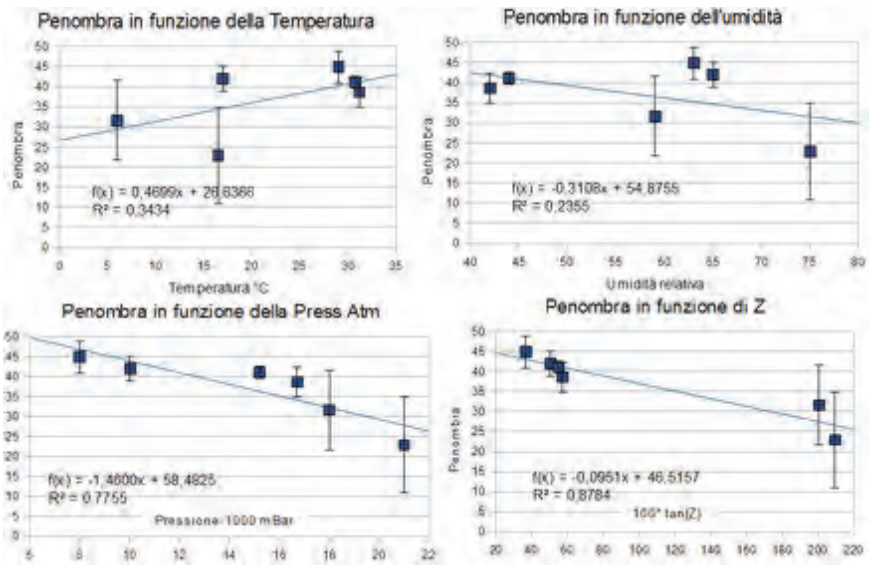

Fig. 4. *The relationships between Penumbra and air humidity (at 2 m), air temperature (at 2 m), air pressure (at sea level) and position on the meridian line; the best correlation is the last one, with z, zenital angle.*

The seasonal effect invoked by Secchi and Abetti to explane the seasonal variation of the observed solar diameter could be of the same type devised here, through the measurements made in Santa Maria degli Angeli and here presented and discussed. The inflexion points of the intensity profile along a solar diameter define in a more stable way the limbs of the Sun, but this was possible only in XX century with the advent of photography and digitalization. For visual inspection the inflexion point is missed, because the Penumbra varies from about 30% to 45% from Winter to Summer, but it would provide an evaluation very similar to the

50% chosen by Bianchini, who could work with solar images produced in the fully darkened basilica, by using tents outside the large windows.

# Agro-pastoral astronomical algorithms for seasonal feasts

Giannini, Francesco (1) and Sigismondi, Costantino*

*(1) FEMI srl, Chieti, Italy*

**ICRA/Sapienza University of Rome, E-mail: sigismondi@icra.it www.icra.it/solar*

The research started from the birthdate of Angelo Secchi: June, 28, that is the vigil of St. Peter and Paul in Roman Catholic Church. In this congress Matteo Galaverni assessed the baptismal names of Angelo Secchi, clarifying that the pointed letter "P." stands for Father, in Italian "Padre". So there is no connection between the names of Angelo Secchi, with the Prince of the Apostoles, but the question about the storicity of the feast of the two Apostoles dead both in Rome under the prosecution of Nero, remains. An archaic algorithm to fix relevant days of the year is still connected with some important dates of the present globalized World. These are ±40 days from solstices and equinoxes. The action of the Catholic Church to Christianize some of these feasts is outlined, but the conclusion is that the 29 of June is not connected with such algorithm and procedure, having reliably and historical root.

*Keywords*: Angelo Secchi, Astronomy, Gnomonics, Meridian line, Santa Maria degli Angeli, San Pietro, Equinoxes, Solstices, Zodiacal Signs, Play Cards.

## 1. The birthday of Secchi: A case study

Angelo Secchi was born in 1818 on June 28, the vigil of St. Peter and Paul. The "P." found in the internet before his name was interpreted not only by wikipedia, but also by D. Menzel in the book "Our Sun" and reliably by many other authors as his first name, but Matteo Galaverni demostrated that it was simply "Padre" i.e. Father (a Jesuit one in his case). The starting question for us was concerning this feast and its date: was it original or the result of an adaptation made by the Catholic Church to substitue some important dates coming from the ancient agro-pastoral culture.

## 2. Agro-pastoral Algorithms for feast and annual rithms

The transhumance, the periodical migration of the shepherds with their flocks, between the mountains of Abruzzo and the flat regions of the Apulia in Italy, required a knowledge of the annual solar rithms. To the equinoxes and the solstices were associated 40 days before and after some relevant yearly events for this society: occasions of gathering and celebrating together some feasts. The reckoning of such days was done by counting, and 40 was an apotropaic number obtained by the sum of the fingers of hand, feet of the man and of the woman. This is one reason why the Neapolitan play cards are 40.

The present feasts so individuated are 1st May (labor day) 31 October (All Saints Eve, Hallowe'en) 2 February (Candlemas) 15 August (August holiday, Assumption of Virgin Mary to the Heaven) 2 August (Santa Maria degli Angeli) 11 November (St. Martin, end of the ancient fiscal year). The 11 February is Our Lady of Lourdes, but it is only after 1858, when the Virgin Mary appeared in Lourdes at

the base of French Pyrenees. The 11–12 of May also are no relevant feast, even if we found the death date of two popes Sylvester II and Sergius IV respectively in May, 12 1003 and 1012, whose inscriptions are preserved in the Cathedral of Rome, St. John the Lateran; Sylvester II was an astronomer.

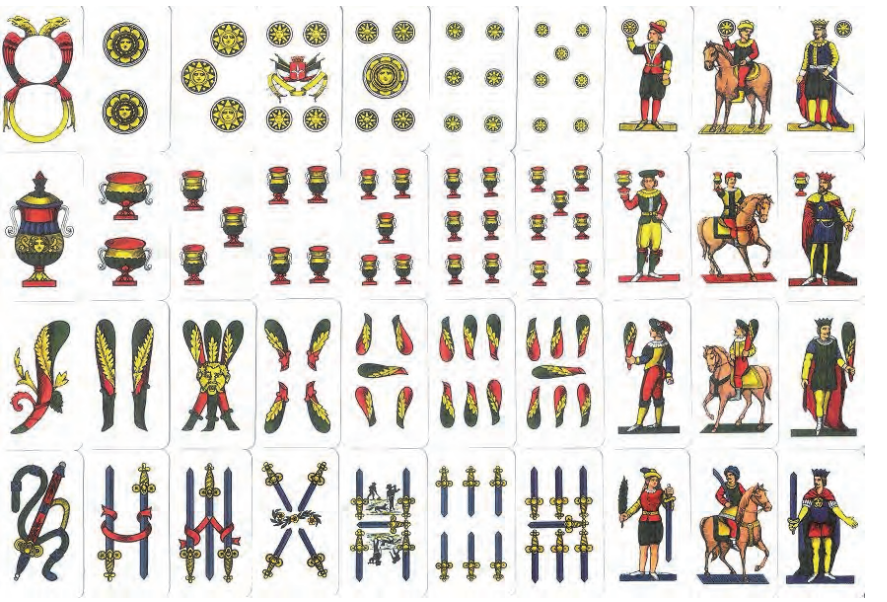

Fig. 1. The 40 Neapolitan Cards.

There are 4 card types (seeds) related to the seasons: cups for wine (autumn), money for summer, sword for spring (the time for was champaings), club for winter (needed for fire). The meaning of Kings, Knight and Soldier for each card type are related to the beginning days of the seasons: equinoxes and solstices. The numbers from 1 to 7 are the weekdays.

## 3. French cards and lunar months

Alternative interpretations are in the French cards with lunar months: 13 cards for each seed, as the 13 lunar months in the year. 52 cards and 1 jolly.

## 4. Zodiacal signs and annual rithms

Conventionally the Zodiacal Signs are referred to the geocentric annual orbit of the Sun around the Earth: since it is inclined of about 23° with respect to the celestial

equator we have the variation of the insulation and consequently the 4 seasons, corresponding to separation of 90° in this presumably circular orbit. The change in rising and setting points of the Sun is evident along the year for a give point of view: the extreme positions correspond to the solstices, and the mean position correspond to the equinoxes. The zodiacal signs represents a further division in 3 parts for each sector, slightly larger than a lunar month. But assuming precisely sectors of 30° implies the capability to compute the times of the year when these sectors are transpassed. And these dates and times are not constant from an year to the following because of the length of the tropical year approximately 365.2422 days, and because the obliquity of the Earth's orbit is changing from about 21° to 24° in 41000 years.

The Zodiacal signs have been used to describe the annual orbit of the Sun, and after Ptolemy's Almagest they were used for marking the great meridian lines built in the churches, namely St. Petronius in Bologna and Santa Maria degli Angeli in Rome.

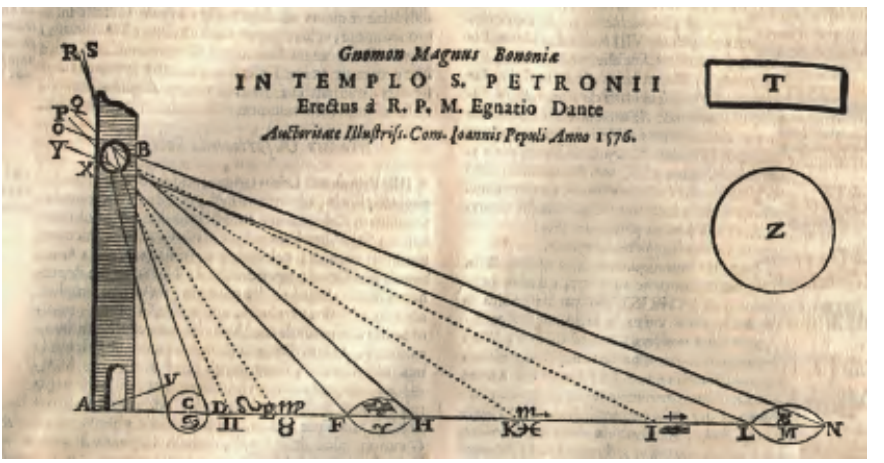

Fig. 2. The scheme of the Zodiacal Signs in St. Petronius's meridian line in Bologna, made by Egnazio Danti in 1577.

It happens that when the dates of the Zodiacal signs are rounded to an integer value, some incongruences appear. This is the case of the meridian line in St. Peter's square in Vatican, realized by Peter Maccaranius in 1817.

The dates are not compatible with the second law of Kepler and apsides on 4 July and 4 January. It is immediate by looking at them: the ingress in Acquarius should be on 20 January instead of 21.

Fig. 3. The dates of meridional Zodiacal Signs in St Peter's meridian line.

# Meridian Service in Rome at S. Maria degli Angeli with Francesco Bianchini and at Collegio Romano with Angelo Secchi

Baschetti, Beatrice (1) and Sigismondi, Costantino*

*(1) Sapienza University of Rome * ICRA/Sapienza University and ITIS G. Ferraris, Rome, Italy*

** E-mail: sigismondi@icra.it www.icra.it/solar*

The father of Italian geodesy is Francesco Bianchini (1662–1729), who built the meridian line in the Basilica of S. Maria degli Angeli in Rome with the purpose of measuring accurately the variation of the obliquity of Earth's orbit and the tropical year duration. He compared the observations of eclipses made in Rome and in Bologna, at the meridian line (1655) made by Giandomenico Cassini and found that the meridian of the Pontifical State was from Rome to Rimini. While Bianchini published many details of the meridian line in 1703, the presence of two decorations near the Summer solstice position has remained unexplained until 2018. Only one of them receives the image of the Sun nowadays and allows immediately to evaluate the secular shift of the solstice's position. The position of the red marble strip under this decoration is the materialization of the solstitial center of the solar image in 1702. For 150 years the noon signal was given by that meridian line; Angelo Secchi was able to automatize the procedure of the ball-drop, as in Greenwich observatory. A signal was spread to the city, through the fall of a sphere visible from far on top of the Flamsteed house, to give the instant of the local meridian transit. This was established in 1833 and automated in 1852 by George B. Airy. Secchi realized a similar device upon the roof of St. Ignatius, where his Observatory was located. This ball-drop gave the signal to a cannon located at Castel Sant'Angelo, the cannon was moved later on Gianicolo hill. Nowadays the tradition of the cannon continues, without the intervention of astronomers. Secchi measured carefully the meridian of Rome, and paved the way to the modern geodesy and the fundamental meridian of Italy at 12° 27' 08" from Greenwich on top of Monte Mario.

*Keywords*: Angelo Secchi, Astronomy, meridian line, Santa Maria degli Angeli.

## 1. The story of the meridian line in Santa Maria degli Angeli

The church of S. Maria degli Angeli is built inside a part of the old roman Baths of Diocletian in Rome, the present entrance is from Piazza della Repubblica. Michelangelo Buonarroti first adapted the old building to a church in 1561–64, further interventions were then made by Luigi Vanvitelli in 1749–50.

The meridian line of S. Maria degli Angeli was built by Francesco Bianchini between 1701 and 1702, upon the will of pope Clement XI who commissioned the work. This device was built for multiple purposes, one of which was measuring accurately the variation of the obliquity of Earth's orbit and the tropical year duration. However, it also had religious purposes as it was used to verify the date for Easter.

Bianchini took inspiration from other great meridian lines like the one built by Giandomenico Cassini in the church of San Petronio, Bologna, in 1655. Bianchini compared the lunar eclipse's observations in Rome and Bologna and found out

that the meridian of the Pontifical State was from Rome to Rimini. Bianchini's meridian line built in Santa Maria degli Angeli materialized this meridian, which crosses Rome at 12° 29' 51" from Greenwich.

Santa Maria degli Angeli's meridian line was inaugurated on 6th October 1702. It is made of bronze and is enclosed in white marble surrounded by a line of yellow marble. Originally the pavement in the church was made of earthenware tiles which made the meridian line stand out from all the rest. All around the line the twelve zodiac signs are represented.

The light of the Sun comes from a circular pinhole, the gnomon, situated in the middle of pope Clemens XI's emblem.

The image of the Sun traverses the meridian line at local noon everyday and during the year it crosses through the whole line. The image of the Sun projected on the pavement goes from being almost a circle during summer solstices to being very oblong at winter solstice. The presence of two decorations near the Summer solstice position has remained unexplained until 2018. During summer solstice the sun passes at the closest point from the base of the gnomon and is expected to meet the two decorations with the papal emblem. However, only one of them receives the image of the Sun nowadays, therefore this can be used to evaluate the secular shift of the solstice's position. The position of the red marble strip under this decoration is the materialization of the solstitial center of the solar image in 1702.

## 2. Luigi Vanvitelli and the alterations on the meridian line

Between 1749 and 1750 the church underwent some architectural changes, made by Luigi Vanvitelli and the meridian line was altered. From a manuscript of the Jesuit astronomer Ruggiero Boscovich found in Italian National Library Vittorio Emanuele II in Rome in 2009, we get a deeper insight about the work of Vanvitelli and how it affected the meridian line. The document, whose aim was to suggest a solution to fix the line after the work of Vanvitelli, clearly illustrates the changes that were made. Before Boscovich's inspection, the monks of the church had already noticed that the cornice built under the gnomon prevented the light of the Sun from reaching the meridian line. They therefore operated a cut in it that let the light coming from the gnomon pass. Boscovich focused on other unfixed alterations in the meridian line, like the precise determination of the point where the perpendicular line from the gnomon meets the meridian line. This fundamental part should had been indicated on a slab on the pavement but Vanvitelli had it eliminated. Moreover, the base of one of the column added by Vanvitelli during the works was built on a part of the meridian line and obstructed it. Boscovich recommended for that part to be levigated and a movable piece was built and substituted to the part that was on the meridian line. So nowadays what we see is, in many parts, not the original work of Bianchini due to the alterations made during Vanvitelli's works.

Fig. 1. Santa Maria degli Angeli's meridian line with the modern epigraph at its beginning.

## 3. Meridian services and the procedure of the ball drop in Greenwich

In the past, many people relied on sundials to tell the time, however time slightly changes basing on the location. The difference in time, in England, would be up to 30 minutes depending on the longitude of the place. This led to the introduction of the Standard Time which was based on the Prime Meridian at Greenwich. Having a device to signal the exact time of noon was therefore very important, an instrument to measure it was by using a meridian line. Everyone would then check their clocks and adjust them basing on a certain signal. In Greenwich, a bright red ball on the top of Flamsteed House is used as a signal: each day the ball rises up its mast and is dropped exactly at 13:00. In the past this served as a signal to ships and to the whole population and corresponded to the instant of the meridian transit at the location. This procedure was established in 1833 and automated in 1852 by Airy.

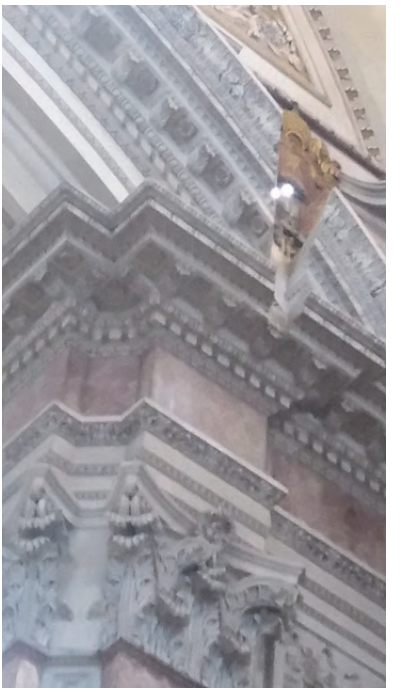

Fig. 2. The cut in Vanvitelli's cornice made in order to let the light from the gnomon reach the meridian line. The photo is on April 6, 2019 at 13:19:53. The two luminous points are the pinhole and, lower, the light reflected by the carved marble of the frieze.

## 4. Rome's meridian services

In Rome, for 150 years the signal was given by the meridian line at Santa Maria degli Angeli. In fact, as an epigraph inside the church reads, the meridian line served as a mean to indicate the time util 1846, when a cannon shot from Castel Sant'Angelo was established to mark midday, after receiving the visual signal from St. Ignatius roof. This part of the information is lacking in the modern epigraph visible in figure 1 on the pilaster at the beginning of the meridian line, leaving in the reader the wrong impression that a cannon could measure the local noon given by the solar transit on the local meridian.

A similar device to that of Greenwich was then used to give the signal to a cannon at the top of Castel Sant'Angelo. This device was created by Angelo Secchi and inspired by that of Greenwich, the aim of it was almost the same. However, the reason of such device was also to be found in the recent reform that concerned the day hours. The Pontificial State had been using a way of counting the hours in which the sunset coincided with the end of the day, that is the hour 24:00 was just after the sunset. Precisely, the sunset was set at 23:30. However, that meant a different time everyday for midday. This was the so called Italian way of counting

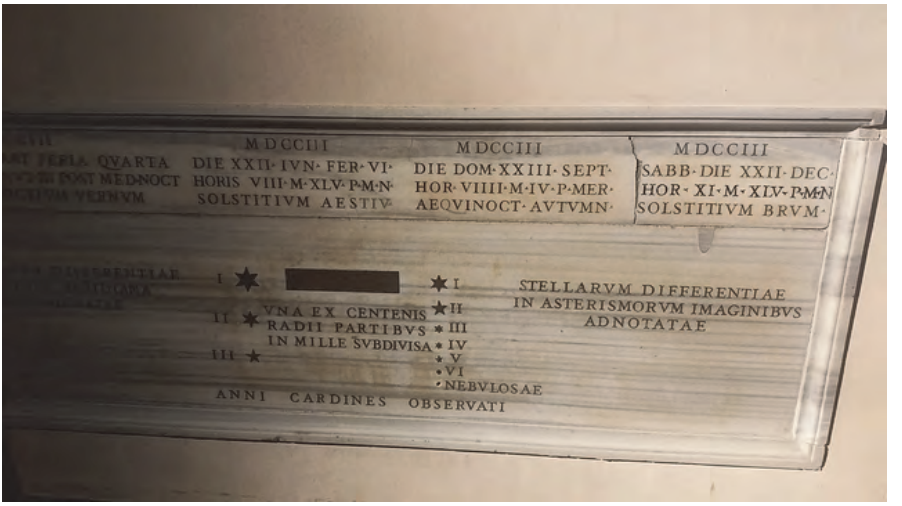

Fig. 3. The epigraph of the results of the observations made in the year 1703 with the meridian line. The photo is of 23 Jan 2019 at 13:26, when the sunlight hits the epigraph directly from the great window of SSW. The spring equinox was at HOR IX MIN III after local midnight on 21 March 1703.

hours. The sundials of Clavius at Collegio Romano, are still showing this use of measuring time. Using a meridian line, it is very easy to determinate the moment of midday, however with the method in use the hour 12:00 did not correspond to the moment the Sun was at its highest. Tables were required, basing on which people could get to know what time it was at the moment of the peak.

Pius IX changed this by adopting a method of measuring the time of the day which was used in France and in many other European countries. With this method the midday coincided with the hour 12:00.

Angelo Secchi's observatory in the Roman College was in charge of communicating the time of midday through a visible signal. As in Greenwich, a ball located on rooftop of St. Ignatius Church, gave the signal to the artillerymen that fired a cannon from Castel Sant'Angelo. Only at the beginning of the 20th century the cannon has been moved to the top of Gianicolo hill. There was now a reliable and unique signal to indicate the midday throughout the city.

Secchi also measured carefully the meridian of Rome, the fundamental meridian of Italy at 12° 27' 08" from Greenwich. The meridian passes through St. Peter's church in Rome and is physically indicated by a tower on Monte Mario hill. Santa Maria degli Angeli's meridian line is not along this meridian but about 8 seconds of time East of it. The measures of the meridian were part of a project with the aim of measuring the central European meridian, this was wanted mostly by Prussian government but many countries gave their contribute to it. Angelo Secchi was the person designated by the pontificial state to be in charge of the commission taking part in the measurements in the state's territory. With this work Secchi not only

demonstrated once again his great competence and capability but also paved the way to the modern geodesy.

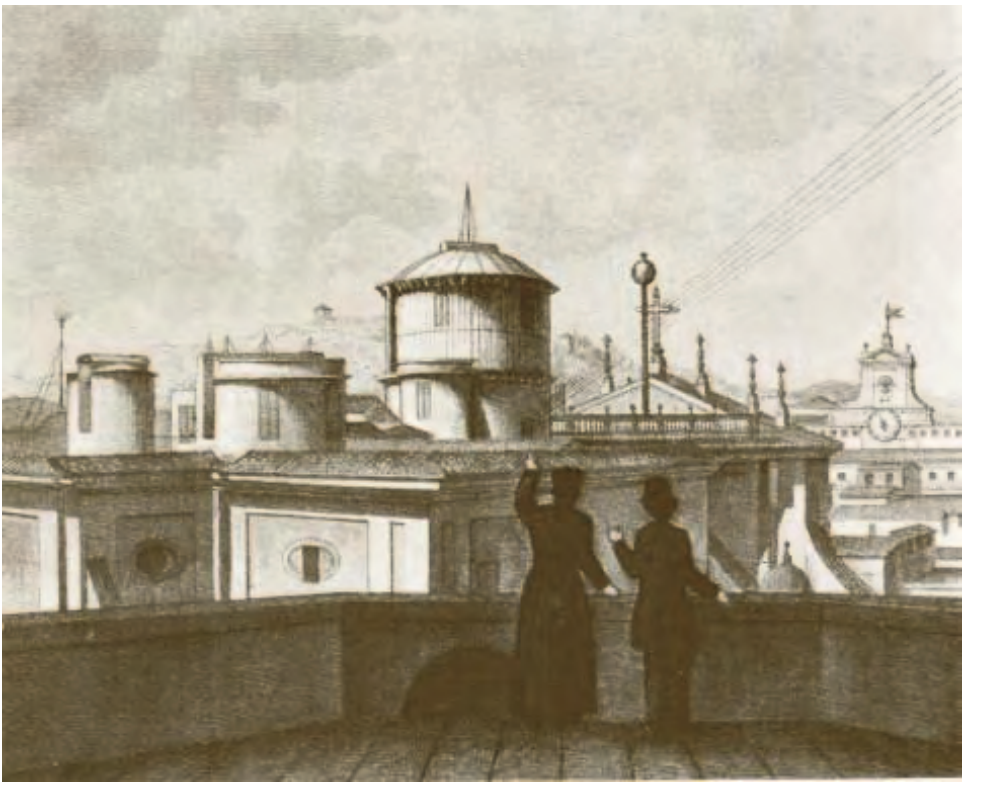

Fig. 4. The top of St. Ignatius church and the ball.

# Angelo Secchi, the tradition of Gnomonics at the Collegio Romano, and the Equation of Time during the centuries

Pietroni, Silvia (1) and Sigismondi, Costantino*

*(1) Sapienza University of Rome * ICRA/Sapienza University and ITIS G. Ferraris, Rome, Italy*

** E-mail: sigismondi@icra.it www.icra.it/solar*

Angelo Secchi, following the tradition started with father Christopher Clavius (1535–1612) who wrote a mathematical treatise (1581) on Gnomonics, realized sundials and quadrants. The equation of time determines the difference between the mean solar noon and the transit of the Sun at the meridian line. Its behavior depends on two facts: the obliquity of the ecliptic and its eccentricity. The first is determinant for the double sinus curve during a year and the second for the asymmetry of the approach to the solstices, which determines some cares when the parabolic fit is adopted. It confirms the difficulty of measuring the solstices with respect to the equinoxes already evidenced in Ptolemy's Almagest.

*Keywords*: Angelo Secchi, Astronomy, Gnomonics, Christopher Clavius, meridian line, Santa Maria degli Angeli.

## 1. The book on Gnomonics of Clavius and the Sundials at Collegio Romano

Fig. 1. The Clavius sundial at the Collegio Romano between the Calandrelli tower (right) and the top of the façade (left): the Italic hours, with Sunset at 23:30 and Ave Maria half hour later at 24 h.

## 2. Sundials at the time of Father Secchi

Secchi built some sundials in Grottaferrata and in Sicily, but Gnomonics at his time was a subject of study of some extent. The priest Angelo Giuseppe Sarto, born in

1835, built two sundials in his parish at Tombolo and Fontaniva in Veneto. He later become pope Pius X (1903–1914). When he was pope had to answer about the equation of time to his former parishioners, because in the passage between the local time to the European one, TMEC, every sundial and also his own showed immediately the equation of time to everyone.

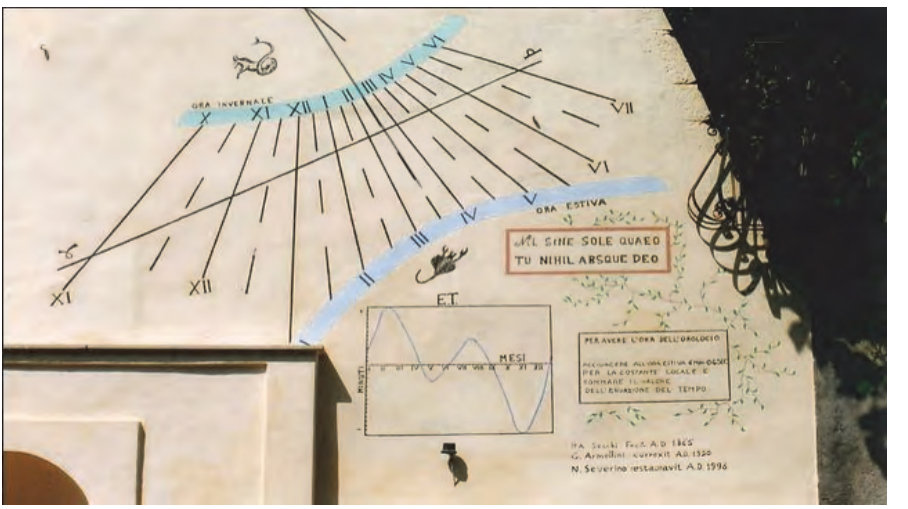

Fig. 2. The equation of time obtained with approximation.

## 3. Cause of the equation of time and first representations

Se puoi Jean des Murs e gli altri se no solo Tolomeo in Almagesto.

## 4. The bisection of the eccentricity from Ptolemy to Kepler

Kepler introduced the elliptical orbits, but it happened, already with Cassini data, that the ptolemaic eccentricity was exactly the double of the keplerian one, by definition of eccentricity of an ellipse. Therefore the introduction of an eccentricity, well before Ptolemy, after Eudoxus with Apollonius that in 3rd century BC who explained the equivalence with epicycles, already was an early evidence that the orbit of the Sun or of the Earth was showing different velocities in time and the existence of two opposite apsides. The perigee and the apogee become perihelion and aphelion, but the date remained the same. Arab astronomers understood their westward rotation, and between 15 and 17 centuries the astronomers tried to measure these modifications to the perfect two-body problem with increasing accuracy.

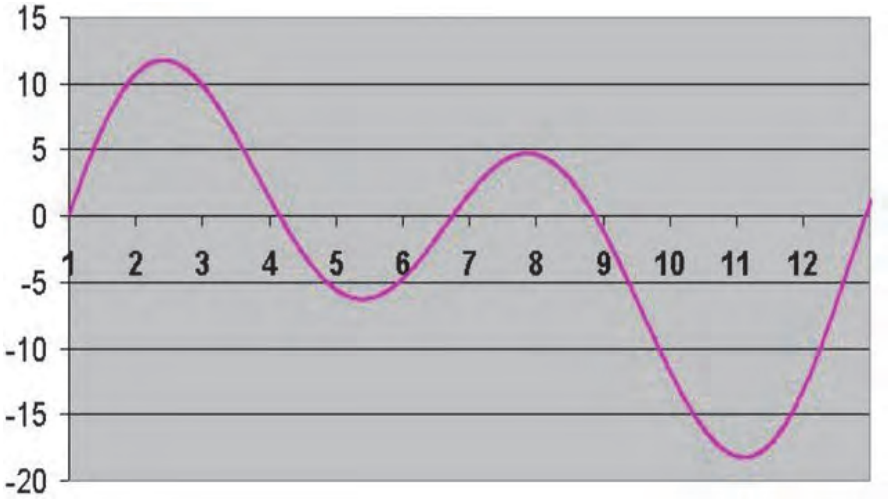

Fig. 3. The equation of time obtained with approximation.

The presence of the axis of apsides now occurring on 3–4 January and 3–4 July determines an asymmetry in the solar approach to the solstices: slower before the perigee on January with a faster farthening, conversely the summer solstice of June 21 is approached with a faster speed than later. This fact produces an estimate of the solstice instant which is sistematically earlier than the true instant as we increase the timespan between symmetric dates with the meridian Sun at the same heigth. Example the cardinal Nicholas Cusano estimated the winter solstice averaging the two dates in which his pinhole allowed the sunlight entering in his room at Andraz Castle. Now it happens between 2 February and 18 November at the 19 of December is the result of this estimate, because the Sun reach the same height of 18 November slightly faster after the perigee which now is Jan 4. At the time of Cusano the perigee was in January 1st 1450 and dividing by 2 the timespan the solstice estimate yielded probably 13 of december (the tradition of St. Lucy in Italian sounds "santa Lucia il giorno più corto che ci sia" says that st Lucy feast on Dec. 13 is the shortest day. Cusano already was able to measure that the solstice occurred well earlier than 21 december. The difference between the legth of the days near the winter or the summer solstice was not measurable accurately without chronometers. Cusano and other scholars already knew that the solstice was a minimum in the meridian height of the Sun, then its estimate by symmetry was one rapid solution to obtain that day, and the proverb tells us that the people was aware of the true solstice at the beginning of the Renaissance.

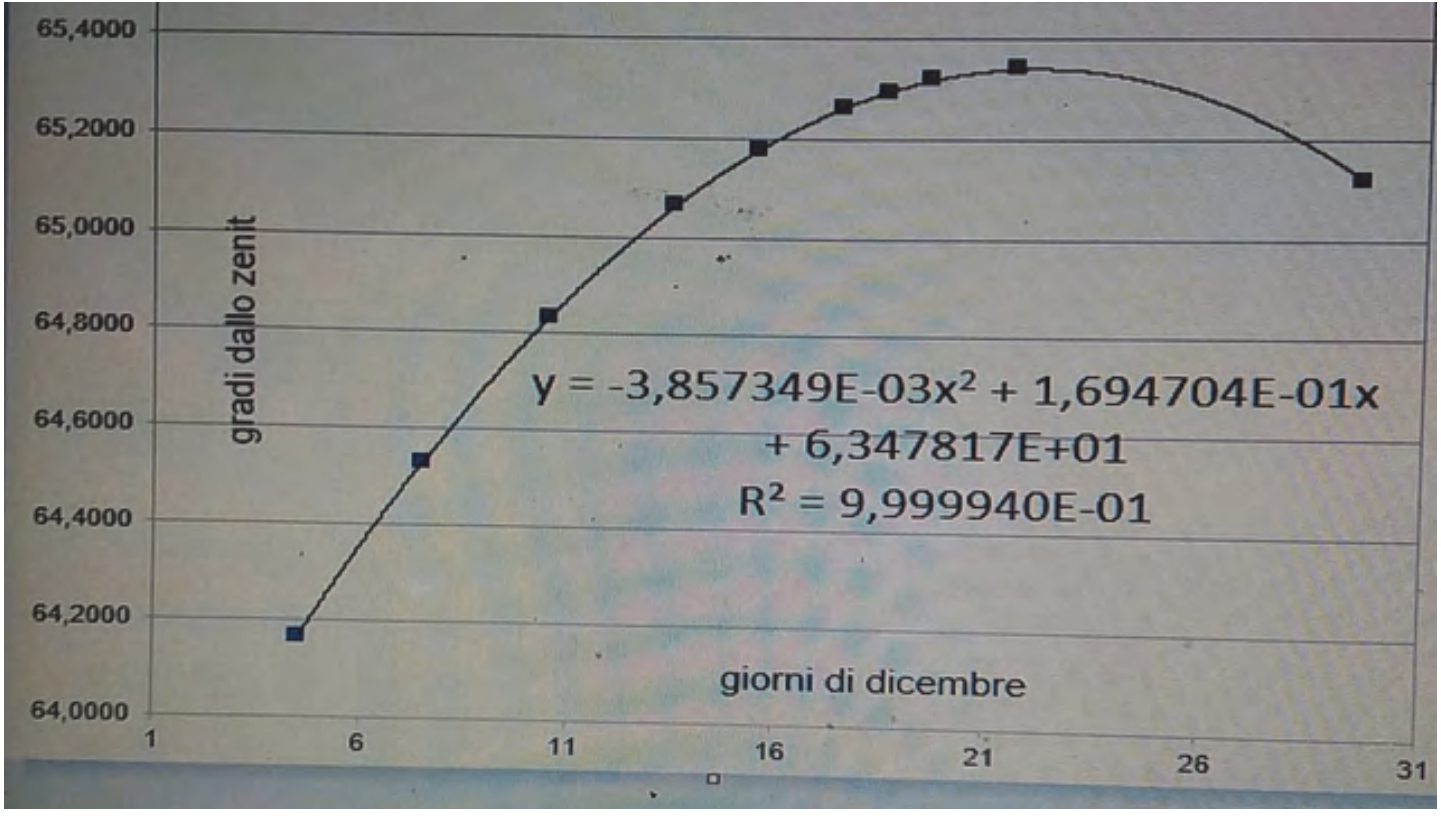

Fig. 4. The winter solstice measured in S. Maria degli Angeli in 2018–19 until December 29, with the asymmetry not yet evident.

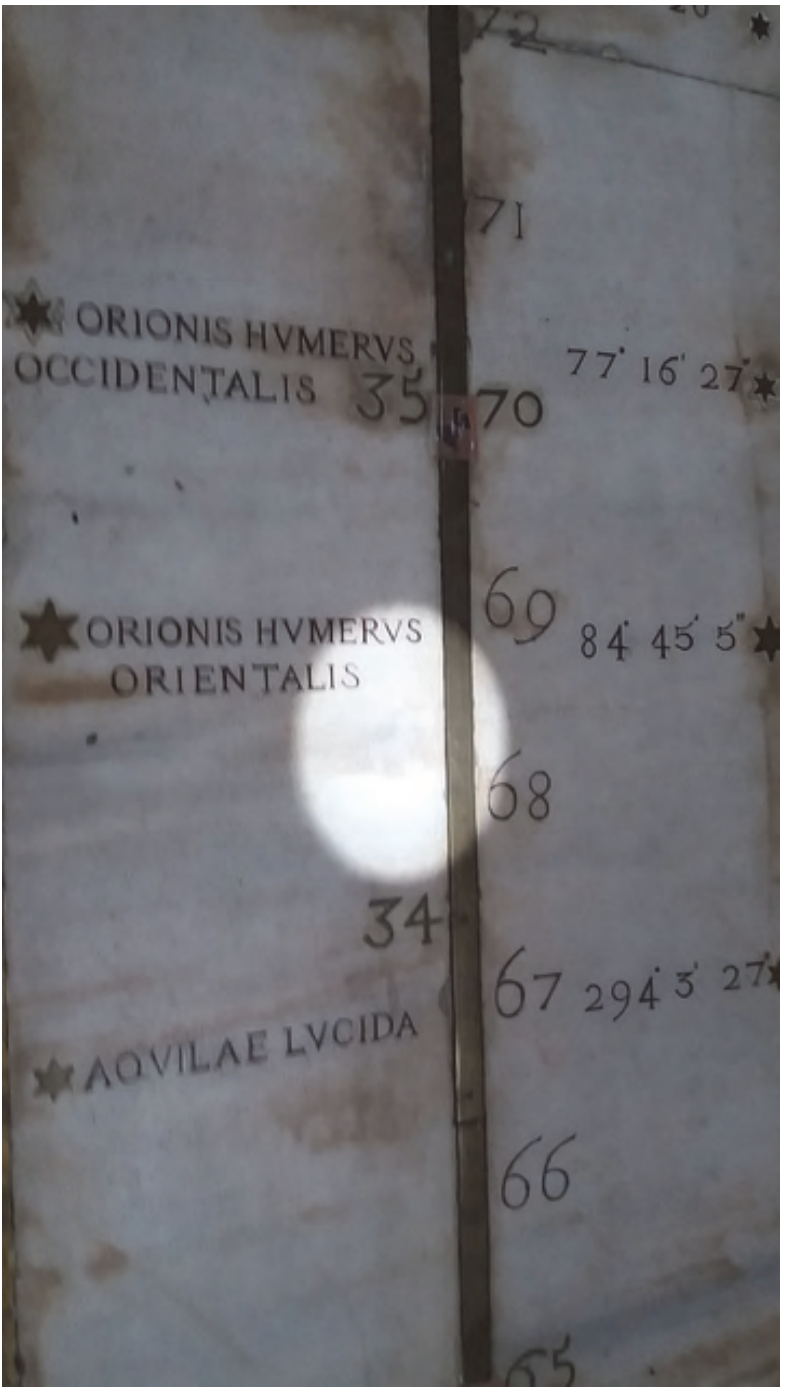

Fig. 5. The position of Betelgeuse, Humerus Orientilis Orionis, in 1701 atlas of Philippe de la Hire. The Southern solar limb was on it near April 10; nowadays the Sun is much southern with respect to Betelgeuse, for the precession. Betelgeuse is in the opposite direction of local motion of the Celestial North Pole from 1701 to present.

# Angelo Secchi: Un inquadramento storico-scientifico

Namara, Alexandre

This paper is rewritten from an original paper of 1976. It is in Italian and gives a complete framing of the scientific activity of Angelo Secchi in comparison with his contemporaries. Alexandre Namara published this contribution in a famous book "les secrets de l'Astronomie" published in Geneva in 1976 and translated into 4 languages.

*Keywords*: Angelo Secchi, Astronomy, Astrophysics.

## 1. I primi incontri con la neonata astrofisica

Padre Angelo Secchi (1818–1878) esiliato dall'Italia con i Gesuiti, fu inviato all'osservatorio astronomico di Georgetown. Tornato in patria, venne nominato direttore dell'osservatorio del Collegio Romano, che dotò di nuovi e più adatti strumenti, come egli stesso racconta: "In questi ultimi anni è sorto un ramo di studio non guari prima considerato. Cioè lo studio fisico degli astri. Se ne togliamo i lavori degli Herschel, i quali non mai ebbero un osservatorio regolare propriamente detto, questi studi non furono coltivati che sporadicamente e da pochissimi amatori. Anzi gli Herschel stessi sparirono dalla scena dopo l'immortale spedizione di Sir John al Capo di Buona Speranza. Talché l'astronomia fisica era quasi un terreno abbandonato all'epoca in cui fummo chiamati a dirigere l'Osservatorio del Collegio Romano, onde ci risolvemmo di dedicare ad essa le nostre fatiche... Questo concetto fu quello che regolò tutti i nostri studi posteriori e la scelta stessa degli strumenti per il nuovo osservatorio. Questo studio fu allora creduto una superfetazione e ci fu perfino chi disse che al Collegio Romano non si coltivava la scienza astronomica, ma la fisica, e vi è stato chi ha rifiutato il titolo di astronomo, quasi che Galileo e gli Herschel, la cui vita fu spesa in tali studi, non fossero astronomi. Ma il tempo ha fatto giustizia, e senza vanità possiamo dire che ora, sulle nostre pedate, sorgono altrove osservatori esclusivamente fisici per lo studio dei corpi celesti, come a Oxford, a Berlino, a Parigi stessa, a Calcutta e in altri siti. Questa fisica degli astri, allora bambina, si è svolta nell'intervallo di 25 anni dacché lavora l'osservatorio e questo ha tenuto un qualche posto nel suo avanzamento".

## 2. Gli strumenti e gli studi di Secchi a Roma

Gli studi di padre Secchi erano cominciati già quando poteva disporre solo di strumenti inadeguati. Si era interessato allora del Sole e, con una pila termoelettrica, ne aveva misurato l'intensità di radiazione in occasione dell'eclisse del 1851 e in seguito sull'immagine solare fornita dal telescopio. Era sua intenzione di valutare il rapporto fra la radiazione al centro del Sole e quella sul bordo. Sull'immagine proiettata dal rifrattore egli riuscì a calcolare le deviazioni galvanometriche provocate dalla pila, ottenendo la conferma che l'intensità di radiazione al centro del disco solare è quasi doppia che ai bordi. Padre Secchi si dedicò anche alle comete: ne scoprì una nel 1853 che aveva un nucleo multiplo e l'anno prima aveva rintracciato i due

resti della cometa di Biela, che si era frantumata durante il suo ritorno periodico del 1846. Avendo intravisto attraverso il nucleo di uno dei due pezzi una debole stella, aveva concluso che le comete sono costituite di materiale molto rarefatto. Ancora non si conosceva l'origine delle stelle cadenti, ma, dagli studi condotti, egli propendeva per una loro natura cosmica e per accertarsene eseguì delle regolari osservazioni annuali dei punti radianti.

Quando fu finalmente in possesso di strumenti più moderni e più precisi, si occupò di Saturno e analizzò it suo anello determinandone l'intensità luminosa delle varie parti, notò che l'anello interno è nebuloso e che la superficie non è piana e ne calcolò it diametro, lo schiacciamento e l'eccentricità. Osservò anche Giove, di cui ha lasciato molti disegni riguardanti le particolarità presenti sulla sua superficie, e rilevò la presenza nell'atmosfera di grandi perturbazioni. Fu in grado perfino di seguire le orbite dei pianeti Medicei e ne misurò i diametri, il periodo di rotazione assiale e la loro diversa capacità di riflettere la luce solare. Fu poi la volta di Marte, sul quale scoprì la presenza di due formazioni di colore rosso cupo e di carattere stabile, che egli chiama ⟪canali⟫. Si accorse inoltre che le calotte erano eccentriche rispetto ai poli e le considerò erroneamente nubi.

### 3. La Spettroscopia

Cominciò ben presto ad introdurre l'uso dello spettroscopio nell'analisi dei pianeti e in tal modo osservò che nello spettro di Giove e Saturno vi erano righe relative alla presenza di vapor acqueo, ma soprattutto che erano presenti righe caratteristiche nel rosso, che lo portarono a concludere che la loro atmosfera ⟪non era ancora purgata⟫ ed era costituita diversamente dalla nostra. Gli spettri di Nettuno e Urano apparivano discontinui, mentre da quello di Marte ricavava che la sua atmosfera era molto trasparente. Riguardo alla Luna egli eseguì dei disegni e delle fotografie. Nei disegni insiste su alcune caratteristiche dei crateri, in particolare su "Copernico". Le fotografie risalgono addirittura al 1859 e furono eseguite come esperimento di fotografia celeste. Padre Secchi si avvide in tal modo che rifrattori non erano adatti per la occhio umano, perché i loro obiettivi erano corretti per l'occhio umano, ma non adeguati alla sensibilità della lastra fotografica. Bisognava allora utilizzare a tale scopo i riflettori.

Venuto a conoscenza che G. B. Donati era riuscito ad ottenere lo spettro di 15 stelle, P. Secchi volle cimentarsi nell'impresa. Potendo utilizzare spettroscopi già perfezionati per questo uso, gli fu possibile distinguere vari tipi di spettri stellari. Ora, la sua intenzione era di studiare il maggior numero possibile di stelle per vedere se "come sono innumerevoli le stelle, fosse pure proporzionatamente varia la loro composizione". Dopo aver messo a punto uno strumento appositamente adattato allo scopo, il prisma-obiettivo di Merz, iniziò le sue osservazioni che lo portavano a concludere che "le stelle sono numerosissime, eppure i loro spettri si riducono a poche forme ben definite e distinte, che per brevità noi chiamiamo tipi. L'esame delle stelle ci ha occupati per parecchi anni; furono esaminate quasi tutte le principali e

moltissime altre, almeno 4000 in tutto, perché oltre la stella principale si esaminava tutto il suo contorno".

Le stelle furono suddivise a seconda delle fondamentali caratteristiche spettrali in tre tipi principali: stelle bianco-azzurre, gialle e rosse; inoltre ne esiste un quarto definito "assai bizzarro e vario. Potrebbe credersi a prima vista che esso risulti dal terzo sopprimendo alcune delle righe oscure"; il quinto tipo è formato dalle stelle che hanno spettri con righe brillanti di emissione. Questa classificazione ebbe molto successo e venne subito adottata, anche perché apparve chiaro che essa doveva corrispondere ai diversi stadi dell'evoluzione stellare.

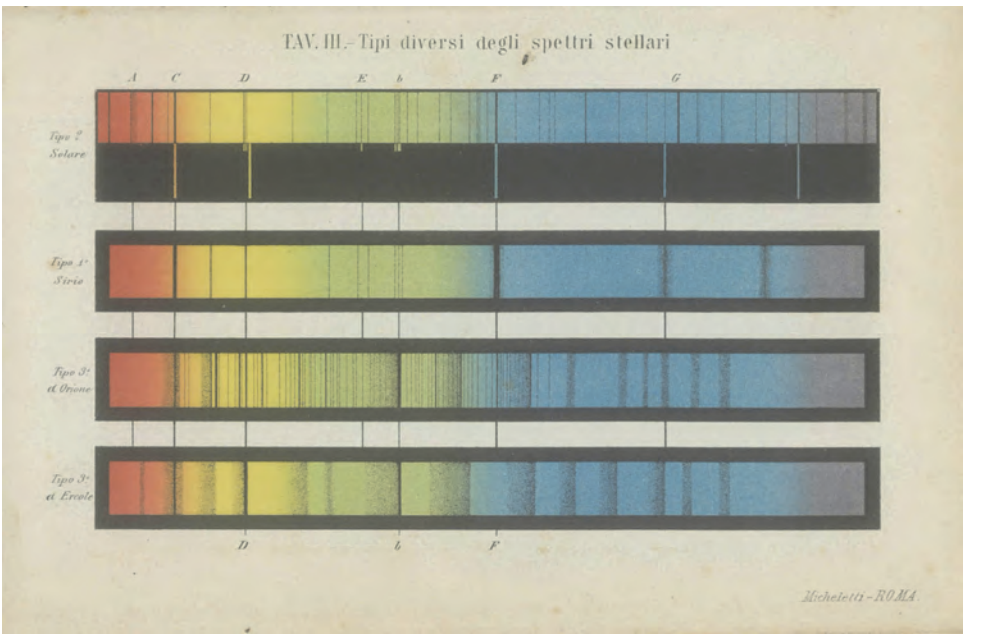

Fig. 1. Spettri di alcune stelle studiate da Secchi.

## 4. La fotografia di spettri

Intanto Sir William Huggins (1824–1910) analizzando vari spettri terrestri e celesti e ponendoli a confronto, osservò alcune analogie: entrambi tipi di spettri presentavano dei caratteristici due raggruppamenti di righe corrispondenti a determinati elementi come soprattutto l'idrogeno, il sodio e il magnesio. Le nebulose fino ad allora erano considerate degli ammassi di stelle troppo lontani per essere investigati anche coi più potenti telescopi mediante l'analisi spettroscopica poteva scoprire che alcune nebulose dovevano considerarsi piuttosto degli ammassi di gas. Infatti gli spettri di varie nebulose presentavano delle righe brillanti di emissione, caratteristiche dei

gas incandescenti. I suoi potenti spettroscopi gli avevano fra l'altro consentito di scoprire la presenza in certi spettri di un debole effetto Doppler. Dopo qualche anno Huggins potè determinare la velocità di allontanamento o di avvicinamento al Sole di varie stelle. Nel 1880, utilizzando lastre fotografiche "asciutte", Huggins fotografò sulla stessa lastra uno spettro terrestre e uno stellare, riuscendo così a determinare immediatamente la velocità della stella lungo la visuale. In seguito al perfezionamento di questo metodo, Vogel nel 1881 confrontò lo spettro dei due lembi, del Sole durante la rotazione e potè confermare l'esistenza dell'effetto Doppler. P. Secchi ebbe il merito di considerare il Sole un utile mezzo di conoscenza delle proprietà stellari, difatti esso è l'unica stella vicina a noi ed è la sola di cui possiamo osservare ampiamente la superficie. Le caratteristiche rilevabili dall'analisi spettroscopica si sarebbero potute generalizzare per la altre stelle. Egli stesso si occupò della natura delle macchie solari e si convinse che esse sono zone a temperatura inferiore rispetto alla fotosfera come sarebbe poi risultato dall'analisi dello spettro. Anche R. C. Carrington si occupò di questo problema e giunse a conclusioni sulla legge di rotazione del Sole a varie latitudini, l'esistenza e la direzione di correnti sistematiche, la distribuzione delle macchie sulla superficie solare.

Spetta invece a J. F. Janssen di aver fotografato per la prima volta la fotosfera, che si presenta ricoperta da piccoli granuli luminosi, per la maggior parte di forma ovale. Fotografò, inoltre, un'eclisse parziale di Sole, con la quale si poteva dimostrare l'inesistenza di un'atmosfera lunare: infatti i granuli che si trovavano presso il lembo lunare non subivano la minima distorsione. Tali granulazioni erano considerate da Padre Secchi come la punta delle colonne di gas surriscaldato, che uscivano dalla fotosfera. La presenza di macchie, penombre, granulazioni e facole faceva pensare che sul Sole esistesse una zona di grandi perturbazioni.

## 5. La natura delle macchie del Sole

A causa di tale zona sorse una polemica tra Padre Secchi e un membro dell'Accademia delle scienze di Francia, Hervé Faye. Quest'ultimo sosteneva che il Sole poteva essere paragonato a una macchina termica, che emanava calore dalla sua superficie. La sorgente di calore era la massa stessa del Sole, la sorgente del freddo lo spazio celeste, il condensatore era la fotosfera. Il meccanismo di funzionamento consisteva in correnti ascendenti e discendenti, le une portanti i vapori, le altre le sostanze raffreddate e solidificate. Le macchie solari non sarebbero che dei cicloni. Contro questa ipotesi P. Secchi obiettava, in primo luogo, che le macchie solo di rado presentano un movimento vorticoso, necessario per ammettere loro natura ciclonica. Infatti di trecento macchie da lui osservate nel corso di un anno solo otto rilevavano un movimento vorticoso arguibile dalla struttura a spirale. Fra l'altro, questa, quando è presente, permane solo uno o due giorni, mentre le macchie mostrano un carattere più duraturo. Egli quindi riteneva che la massa solare fosse costituita prevalentemente di gas, come facevano supporre le caratteristiche delle macchie, la cui struttura era paragonabile a quella delle nuvole o delle fiamme.

Un'ulteriore conferma della sua ipotesi venne dallo studio di quelle eruzioni gassose che spesso si osservano nei nuclei delle macchie. La fotosfera sarebbe allora un fluido elastico analogo ai nostri gas e i movimenti a spirale possono effettivamente essere ricondotti a fenomeni simili a cicloni terrestri. I vortici sono più frequenti nel periodo di formazione delle macchie, ma in seguito scompaiono e al loro posto subentrano correnti regolari convergenti verso il nucleo delle macchie.

## 6. Le foto del Sole

Nel 1857 fu costruito il primo "fotoeliografo" con lo scopo di fotografare regolarmente il Sole ogni giorno. Si ottenne così una preziosa documentazione dell'attività variabile del Sole durante l'anno. Le fotografie stereoscopiche delle macchie e delle facole evidenziarono che queste si trovano nella parte alta della fotosfera, mentre le macchie sembrano dei buchi o vortici sprofondanti nella parte più bassa di essa. Padre Secchi ne potè determinare allora, la "parallasse di profondità" cioè gli spostamenti apparenti determinati dalla depressione della superficie solare durante la rotazione. Egli potè proseguire le ricerche di Angstrom e Kirchoff sullo spettro solare e inoltre notò che l'aspetto delle righe di Fraunhofer (più o meno diffuse) dipendeva dallo stato fisico di pressione e di temperatura delle zone d 'atmosfera in cui avviene l'assorbimento.

## 7. Le eclissi del Sole

Nel 1860 vi fu un'eclisse totale di Sole e Padre Secchi ne approfittò per studiare che natura avessero quelle protuberanze rosse, cioè quelle grandi eruzioni di idrogeno che erano già state notate dagli antichi nel corso delle eclissi. Dalle fotografie che egli eseguì sull'immagine diretta del disco solare occultato dalla Luna, e da quelle che realizzò Warren de la Rue con l'eliografo di Kew risultò che le protuberanze effettivamente esistono e non sono giochi di luce; che appartengono alla superficie solare; che anche la corona è reale e che le sue dimensioni sono meno estese ai poli che all'equatore, e raggiungono un massimo a 450 di latitudine. Janssen, invece, osservò l'eclisse di Sole del 1868 in India, per osservare le protuberanze allo spettroscopio. Queste presentavano uno spettro di emissione molto brillante ed egli pensò che quindi potevano essere osservate anche normalmente, senza eclisse. Adottò, a tale scopo, un metodo che sarebbe risultato utilissimo. Egli puntò la fessura dello spettroscopio radialmente, in, parte sul disco solare, in parte al di fuori, e osservò una parte del lembo. Notò così che la riga C di Fraunhofer presentava un prolungamento, una sottile riga rossa e brillante che perdurava nonostante gli spostamenti della fessura su altre regioni, ma che variava notevolmente in altezza e splendore a seconda delle regioni perlustrate. C. A. Young, osservando una nuova eclisse totale, riuscì a dimostrare la costituzione della corona, la cui natura appariva gassosa. Dall'analisi del suo spettro si osservava la presenza di una riga verde di emissione che egli identificò con la riga cromosferica vicina, che ha analoga lunghezza d'onda.

La cromosfera, un attimo prima dell'oscuramento è molto brillante, ma scompare rapidamente subito dopo il principio della totalità quando diventa visibile la riga coronale molto più debole. à probabile che per la piccola dispersione allora usata, le due righe possano essere state confuse.

Contemporaneo di Young fu Sir J. Norman Lockyer, il quale mise a punto, quasi negli stessi anni di Janssen, la tecnica per studiare le protuberanze solari in piena luce. Con le sue ricerche scoprì che esse si originavano da un involucro gassoso che circonda il Sole e a cui diede nome di ⟪cromosfera⟫. Dallo studio degli spettri solari e soprattutto da quello della cromosfera, egli potè formulare una sua ipotesi sulla dissociazione degli elementi alle alte temperature presenti nelle atmosfere stellari. Secondo la sua teoria le righe spettrali H e K della regione del violetto, sono dovute alla dissociazione del calcio, ed esse aumentano di intensità man mano che aumenta la carica elettrica.

## 8. L'Elio e le perturbazioni magnetiche

Nello spettro delle protuberanze era presente una riga gialla brillante D3, che non era determinata da nessun elemento presente sulla Terra. essa fu quindi attribuita a un nuovo gas che prese il nome di ⟪elio⟫. In Italia, allievi e successori di Padre Secchi furono Pietro Tacchini e Annibale Riccò che si interessarono soprattutto alle relazioni fra fenomeni solari e fenomeni terrestri. Il primo si occupò di valutare l'influenza delle eruzioni solari sulle aurore polari nelle parti alte dell'atmosfera terrestre. Il Riccò eseguì molte osservazioni sulle macchie solari e sulle protuberanze e studiò le eventuali relazioni fra esse e le perturbazioni del magnetismo terrestre. Riuscì così a rilevare un ritardo nella perturbazione magnetica sulla Terra di circa 45 ore dopo il passaggio delle macchie solari per il meridiano centrale del Sole. In Russia nel 1894 A. Belopolsky scopriva variazioni periodiche nella velocità radiale di Delta Cephei, dimostrando che questa è una proprietà generale delle variabili a corto periodo.

## 9. I primi cataloghi stellari e i principali temi dell'Astronomia dell'ottocento

Intorno alla metà dell'ottocento incominciano ad apparire cataloghi stellari redatti con sempre maggiore accuratezza e precisione, e Bessel riesce a calcolare, con ottima approssimazione, la prima distanza stellare; sempre in questo Draper ottiene la prima fotografia Luna e Daguerre fotografa un'eclisse solare. Galle, nel 1846, scopre il pianeta Nettuno e, poco più tardi, Doppler riesce dare una spiegazione al fatto che le righe spettrali di una sorgente luminosa si spostano verso il violetto o verso il rosso a seconda che l'astro si avvicini od allontani dall'osservatore (fenomeno poi conosciuto col nome di effetto Doppler). Con lo studio dell'analisi spettrale, che consente di calcolare la temperatura e la composizione chimica di qualsiasi sorgente luminosa, ha inizio una nuova corrente astronomica, l'astrofisica che, come abbiamo visto, ebbe per primi ferventi sostenitori A. Secchi e W. Huggins. Verso la

fine del XIX secolo viene determinata, prima in modo approssimato, poi sempre più accuratamente, la parallasse solare, la cui importanza abbiamo già rilevato nei capitoli precedenti. Nel 1891 H. Deslandres e G. E. Hale eseguono particolari fotografie solari servendosi di un nuovo strumento: lo spettroeliografo. Intanto gli apparati strumentali vengono ancora maggiormente perfezionali seguendo il parallelo sviluppo della tecnica; allora incominciano ad essere determinabili quei piccoli spostamenti degli astri che prima non potevano essere notati. Così Chandler potè riscontrare alcuni piccoli mutamenti net valori delle latitudini di alcuni osservatori e, di conseguenza, scoprire il fenomeno della variazione di latitudine. Vengono frattanto pubblicati alcuni cataloghi stellari tra cui il Draper Catalogue, che comprende classificazione di oltre diciannovemila stelle, e quello di F. A. Argelander di 324 mila stelle dell'emisfero boreale.

Le scoperte di piccoli pianeti si susseguono freneticamente, potendosi ora gli astronomi servire del valido aiuto della fotografia. Schiaparelli, l'astronomo italiano più rappresentativo di questo periodo, compie all'osservatorio di Brera di Milano i suoi studi sui canali di Marte, che tanto hanno fatto discutere fino ai nostri tempi; egli scopre inoltre che il periodo di rotazione di Mercurio intorno al proprio asse è uguale a quello di rivoluzione intorno al Sole. J. C. Maxwell espone la sua teoria secondo cui gli anelli di Saturno sono composti di piccoli corpi o frammenti di corpi celesti, che ruotano intorno al pianeta. Intanto si scopre che la Luna è priva di atmosfera e si osserva la ⟪macchia rossa⟫ di Giove. Pickering, servendosi delle teorie espresse da Doppler, scopre un nuovo tipo di stelle doppie che, trovandosi ad una distanza apparente molto vicina, non potevano essere osservate visualmente: a queste venne dato il nome di ⟪binarie spettroscopiche⟫. Come era stato previsto da Bessel in linea teorica, si riesce ora ad osservare le compagne di Sirio e Procione.

# Father Angelo Secchi: A giant solar physicist of the 19th century

Koutchmy, Serge*

*emeritus scientist at the Paris Institut d'Astrophysique de Paris (CNRS) and the Sorbonne University
E-mail: koutchmy@iap.fr

Why Angelo Secchi has been a giant in solar physics? the following considerations will demonstrate this thesis. Both observationally, experimentally and theoretically Secchi was always at the cutting edge of his times in the realm of solar physics and astrophysics. His book Le Soleil has recently been reprinted by Forgotten Books (August 6, 2018) and Il Sole, Italian version, is being published by Gerbertus Academic Journal (2019). The experience of Secchi drove me during the PhD Thesis at Sorbonne University, through his book Le Soleil.

*Keywords*: Angelo Secchi, Solar Physics.

## 1. Introduction

It is difficult to pay a full or even a partial tribute to father A. Secchi S. J. so extended are his contributions to different fields of the Astrophysics of the 19th century and so highly appreciated has been his life almost entirely devoted to Science and Education. Let me just restrict myself to a memory that I vividly keep since the late 1960ies, when I discovered the double big volume of his wonderfully written in French books "Le Soleil" edited by the House "Gauthier- Villars" in Paris. I mean the 2d Edition issued in 1877 made of 8 so-called "books" of a total of more than 900 pages plus an atlas containing the 1st solar spectra (1st never published I guess). The reading of each volume that I performed several times at the Paris Observatory Library, impressed me so much that I seriously decided to continue and deepen my research on the Sun in general, instead of restricting on the analysis of total eclipse observations and their applications to the study of the expanding solar corona and structures which was the topic of my PhD at Sorbonne University.

## 2. Secchi's book and solar eclipses

The 1st volume indeed contains a very detailed account of the observations performed by several famous scientists and by father Angelo Secchi himself, at eclipses, starting with the 1842 eclipse. Secchi described with great details the chromosphere and prominences discovered at time of the totality and just before and after: it seems legitimate to claim that he discovered indeed the solar chromosphere and prominences, including its finest details that today are called spicules. It was amazing to read in 1970–71 how the Jesuit-Astronomer interpreted the observation of the white- light aureola seen around the Sun during the totality that now is called the solar corona, with the chromospheric red fringe at the feet. I cannot resist in showing in Figure 1, a copy of one of his drawing reproduced in the book IV, p. 350 of vol. I showing the eclipse observation of 1868 which reflects for the 1st time the

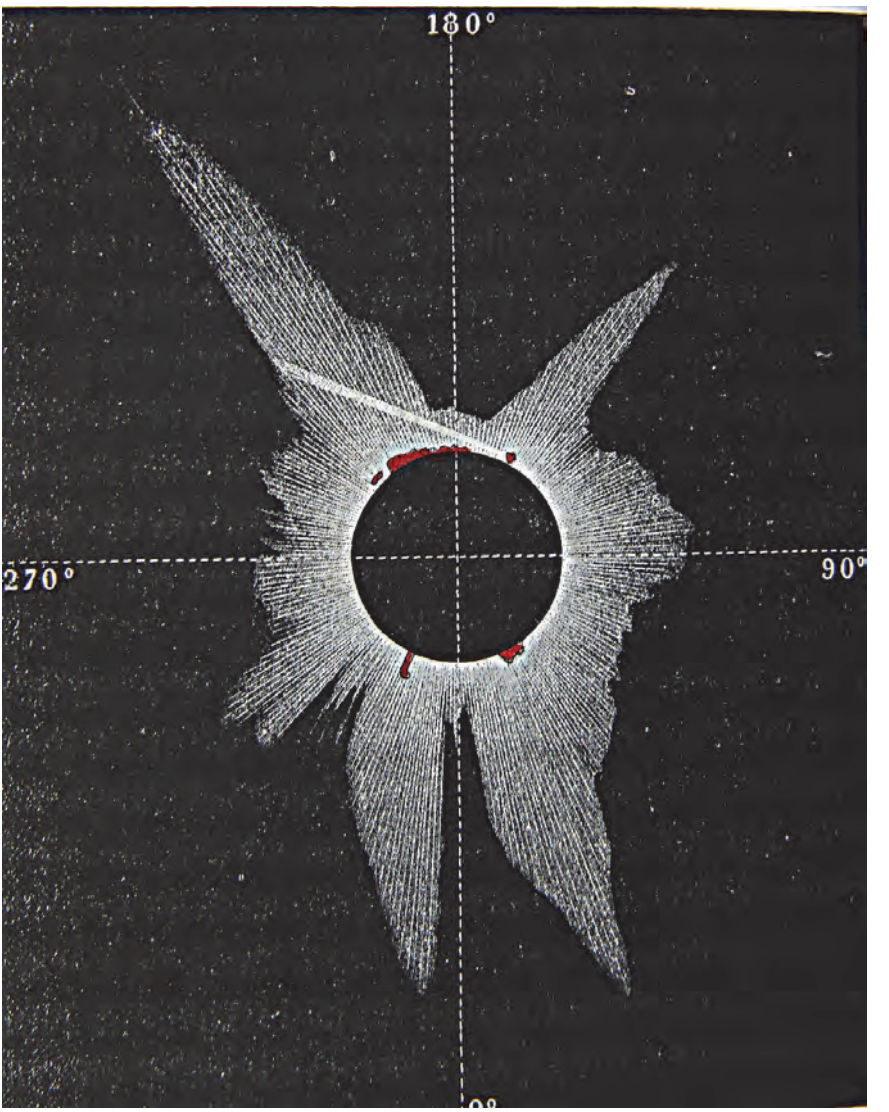

Fig. 1. Drawing of the 1868 solar total eclipse corona from the Angelo Secchi's book "Le Soleil" 1877, p. 350, vol. I. Note the prominences, in red, and large streamers shown for the 1st time. Because observations were done near a solar minimum of activity, the polar axis is horizontal (270 to 90° direction) and streamers extend about the equatorial plane.

behavior of the outer corona with what he called "aigrettes" and that today are called streamers. This was at a time when the Sun itself was still poorly understood (remember that the great Newton thought it is a giant planet and his follower W. Herschel considered until the beginning of the 19th century, the Sun was inhabited); the plasma high temperature properties of the corona, its magnetism and

its expansion towards the interplanetary medium was completely ignored or totally not understood. His very accurate and critical account of observations made by eclipse observers who started to use the photographic method to help in making a more objective drawing of their fugitive and transient observations. This was of great help for a young student, not only for analyzing the solar corona, but also from the epistemological point of view. Just by comparing the far reaching Secchi's suggestions with what was established in the late 1960s, following the numerous and enlightening works produced on the same subject by Grotrian, Lyot, Edlen, Alfven, Shklovsky, Van de Hulst, Parker et al., the delicate processes leading to the discovery of new properties in Physics and in Nature can be evaluated.

## 3. The mission Stereo and the solar corona

Angelo Secchi is today broadly recognized as the founder of the stellar classification based on spectroscopic data; in his honor the most famous experimental package of the international Space Mission "Stereo" hold his name. He was clearly influenced and even impressed by spectra in general and he seriously described solar spectra and spectroscopic methods in his books. Regarding eclipses, he was the 1st to extensively comment the coronal spectrum obtained by Rayet at the 1868 eclipse in Malacca, p. 395 of Vol. 1. Interestingly he reported the observation of a new strong line he called E, situated between the line F (identified with H beta line of HI that Secchi knew from the prominence spectra) and line D (much later identified as the D3 line of HeI). The line E of the Rayet spectrum is now known as being the brightest emission line of the corona due to Fe XIV, the so-called green line that the today literature is used to attribute to Young who described it a little bit later and paid attention to the absence of any identification using the known at that time prominence spectra, concluding on the coronal nature of the line. The Rayet spectrum was reproduced in the Secchi's book (his Fig. 142) and it is easy to notice that the green line E is very well apparent without any additional comment! Regarding prominences, Secchi also published a large number of observations in his treatise. This work was illustrated with magnificent color plates of the chromosphere and of the various types of prominences. Limb eruptive phenomena were extensively observed in the Halpha line of hydrohen with his 25 cm aperture refractor equipped with a broad slit with a large dispersion spectroscope thanks to 3 consecutive prims put inside. Several plates were later used to illustrate and comment new works of the genial observer, including the study of the famous very fine spicules that the chromosphere is made of. I notice that following the D. Menzel studies of the 1930s, small parts of the books were translated after the WWII at Sacramento Peak Observatory and both J. Beckers and especially R.B. Dunn developed the topic. An instrument called the chromopsheric telescope was built by R.B. Dunn to specially analyzed the Secchi's spicules and the chromospheric limb. Figure 2 shows one of the plate of the book illustrating how deep and extended was the analyzed limb features! Several of his plates could even today illustrate a book dealing with

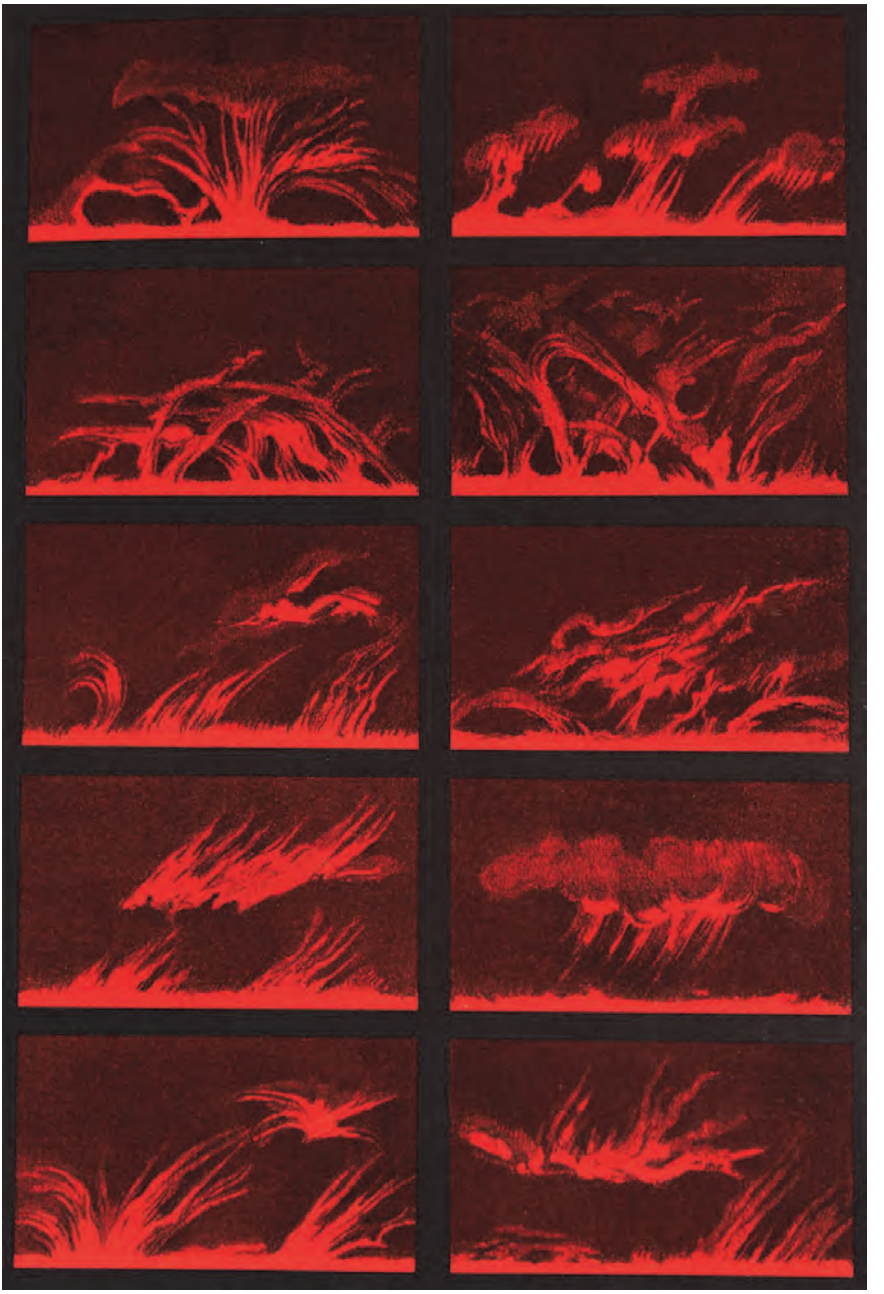

Fig. 2. Contrasted reproduction of one of the plate from the Secchi's book "Le Soleil" 1877 to give a sample of his gallery of drawings of prominences. Note the chromosphere at the bottom of each drawing, with spicules protruding.

the solar chromosphere which is not yet understood even with the extended today space-born experiments and numerical simulations.

Prominent scientists like the father Angelo Secchi are missing in order to progress not only in solar and helio-physics, but as well, to deepen our understanding of Mother Nature.

Magnetic fields affect the structure of compact objects. The anisotropy produced by the magnetic field in the pressures suggests the necessity of using structure equations considering the axial symmetry of the magnetized system. In this work, we propose a model that generalizes the Tolman-Oppenheimer-Volkoff equations for the magnetized case and discuss some preliminary results for WDs equations of state. Our calculations are based on the $\gamma$-metrics where the parameter $\gamma$ relates the deformation with the anisotropy in the pressures.

*Keywords*: White dwarfs; magnetic fields; general relativity; anisotropic structure equations.

## 1. Introduction

The influence of a magnetic field is relevant in compact objects. Measurements of periods and spin down of soft-gamma repeaters (SGR) and X-ray luminosities of anomalous X-ray pulsars (AXP), support the idea of the existence of magnetars[1] which exhibit surface magnetic fields as large as $10^{14} - 10^{16}$ G[2]. However, the interior magnetic fields can not be observed directly, so one can only estimate their bounds with theoretical models based on macroscopic and microscopic analysis. The maximum magnetic fields estimated for magnetized white dwarfs are around $10^{13}$ G[4] and about $5 \times 10^{18}$ G for quark stars[3].

The action of a magnetic field in a fermion system is breaking the spherical symmetry, which gives rise to an anisotropy in the quantum-statistical average of the energy-momentum tensor. This produces a pressure splitting in two components, one along the magnetic field (the parallel pressure $P_{\parallel}$) and another in the transverse direction (the perpendicular pressure $P_{\perp}$), $T^{\mu}_{\nu} = \mathrm{diag}(\rho, -P_{\perp}, -P_{\perp}, -P_{\parallel})$, $\rho$ is the energy density[5]. Consequently, the system composed by fermions under the action of a uniform magnetic field has an anisotropic equation of state (EoS)[5]. This form of the energy-momentum tensor suggests that when modeling the structure of magnetized compact objects, one should consider axial symmetry.

Our first attempt addressing this issue was to consider a cylindrical coordinates $(t, r, \phi, z)$ metric to obtain Einstein field equations following the procedures of Trendafilova and Fulling[6]. In order to do so and for simplicity, we assumed that all the magnitudes in the model depend only on the radial coordinate $r$. This

approximation allowed us to obtain upper limits for the values of the magnetic field that compact stars can sustain, but compromised the computation of a total mass [3,4].

Then, in order to be able to determine the total masses, we went back to spherical coordinates. First, we would like to remark that anisotropies in the energy-momentum tensor are not new to spherical symmetry, which admits tensors of the form $T^{\mu}_{\nu} = \mathrm{diag}(\rho, -p_r, -p_t, -p_t)$, where $p_r$ is a radial pressure and $p_t$ is a tangential one [7,8]. However, this is not compatible with the anisotropies due to magnetic fields. Therefore, in this work, we take into account a generalized version of spherical metric, with a $\gamma$ parameter associated with the deformation of the stars. We propose an ansatz that relates it with the perpendicular and the parallel pressures [9]. This allows us to obtain structure equations that generalizes the Tolman-Oppenheimer-Volkoff (TOV) equations to the magnetized case, where the mass is computed as for spheroidal objects. In Section 2, we present the model and in Section 3 illustrate its solutions with EoS for magnetized white dwarfs.

## 2. $\gamma$-Metric and structure equations for magnetized compact objects

In Refs. 10–12 it is shown that a deformed compact object with axial symmetry can be described by the metric

$$ds^2 = -\left[1 - 2M(r)/r\right]^{\gamma} dt^2 + \left[1 - 2M(r)/r\right]^{-\gamma} dr^2 + r^2 \sin\theta d\phi^2 + r^2 d\theta^2, \qquad (1)$$

where $\gamma = z/r$ parametrizes the polar radius in terms of the equatorial one and $M(r)$ is the mass of the star. Note that the Schwarzschild metric is recovered for $\gamma = 1$.

As we are interested in the effects on the structure equations coming from the magnetic field and the related anisotropy and using smaller central pressures in TOV equations leads to smaller radii, we propose to interpret $\gamma$ as the ratio between the central pressures, parallel and transverse to the magnetic field respectively [9],

$$\gamma = \frac{P_{\parallel_0}}{P_{\perp_0}}. \qquad (2)$$

Then, since the parallel pressure has its maximum central value at $z = 0$ and goes to zero at the surface, we assume it depends just on the $z = \gamma r$ coordinate. The perpendicular pressure, on the contrary, is zero at $r = 0$, therefore depending on the radial coordinate.

Taking into account these considerations and using the mass of a spheroid to compute the star's mass, we obtain the following structure equations

$$\frac{dM}{dr} = r^2 \frac{(E_\parallel + E_\perp)}{2}\gamma, \tag{3a}$$

$$\frac{dP_\parallel}{dz} = \frac{1}{\gamma}\frac{dP_\parallel}{dr} = -\frac{(E_\parallel + P_\parallel)[\frac{r}{2} + r^3 P_\parallel - \frac{r}{2}(1-\frac{2M}{r})^\gamma]}{\gamma r^2 (1-\frac{2M}{r})^\gamma}, \tag{3b}$$

$$\frac{dP_\perp}{dr} = -\frac{(E_\perp + P_\perp)[\frac{r}{2} + r^3 P_\perp - \frac{r}{2}(1-\frac{2M}{r})^\gamma]}{r^2 (1-\frac{2M}{r})^\gamma}, \tag{3c}$$

which describe the mass variation and pressures with the spatial coordinates $r, z$ for an anisotropic magnetized compact object. The solutions of this system are computed similarly to how it is done usually for the TOV equations. Starting from a central point with $E_0 = E(r=0)$, $P_{\parallel_0} = P_\parallel(z=0)$ and $P_{\perp_0} = P_\perp(r=0)$ taken from the EoS, the structure equations are integrated until reaching the surface, where $P_\parallel(Z) = 0$ and $P_\perp(R) = 0$. In practice, this condition is established by the lower central pressure, which determines the value of the corresponding radius ($R$ if $P_{\perp_0}$ and $Z$ if $P_{\parallel_0}$), from where the other radius can be computed by means of $\gamma$ and the mass of the star is set to $M = M(R)$.

The difference of the integration process with respect to TOV solution lies in the manner of computing the energy density from the EoS at $r + dr$, since Eqs. (3) are updated taking into account $E = E_\parallel(P_\parallel(r))$ and $E = E_\perp(P_\perp(r))$ respectively, while the expression for the mass must include information from both, $E_\parallel$ and $E_\perp$, in order to consider the mass density anisotropy, so it is updated with its average value $E = (E_\parallel + E_\perp)/2$.

## 3. Results and important remarks

To validate the model we show some results using the equations of state given in Ref. 15 for magnetized white dwarfs for magnetized WDs with a carbon/oxygen composition at fixed values of the magnetic field, $10^{12}$ G, $10^{13}$ G and $10^{14}$ G, compared to the non-magnetized solution (Fig. 1).

Contrary to the case of Neutron Stars and Quark Stars[13], where the energy density and pressures are of the same order, WDs energy densities are three orders higher than the pressures. Therefore, the value delimiting when the Maxwell term becomes relevant is determined by the pressure, with $P_\perp^B$ comparable to the statistical pressures for magnetic fields higher than $1.78 \times 10^{11}$ G.[a] Anyhow, we tackle two situations with respect to the Maxwell contribution to the pressures and the energy density, $P_\perp^B = E^B = -P_\parallel^B = B^2/8\pi$. In the first case we neglect this term (upper panels of Fig. 1) while the second one is done considering it (lower panels).

[a]The magnetic energy density becomes relevant at $10^{14}$ G[14].

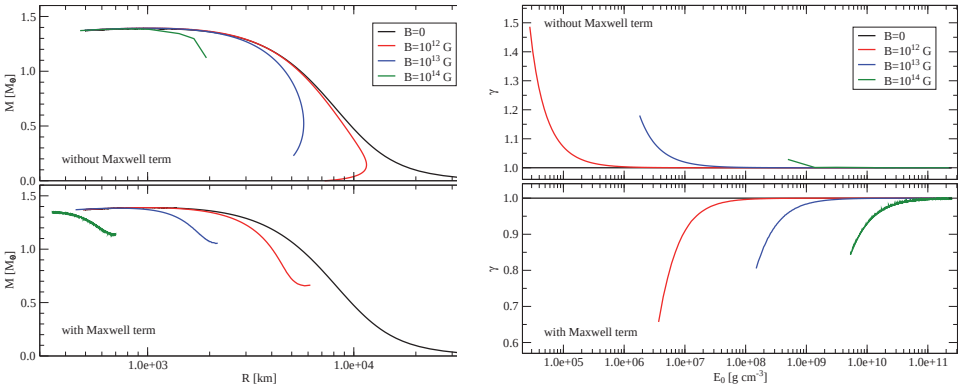

Fig. 1. Left: Mass versus the equatorial radius $R$ and the polar radius $Z$. Right: $\gamma$ parameter as a function of the central density of the magnetized white dwarfs.

The left graph on Fig. 1 displays the mass versus the equatorial radius. At the highest central densities and smaller radii, the masses reach values close to the Chandrasekhar limit [16,17], and both radius are equal and quite similar to the radius of the $B = 0$ case.

Analyzing the magnetized solution at lowest densities and biggest radii, we note on the right graph of Fig. 1 that for a certain value of mass and energy density, the case without (with) Maxwell term features $\gamma > 1$ ($\gamma < 1$), i.e. the polar radius is higher (lower) than the equatorial one. So, the corresponding star is a prolate (oblate) object, which gives us information about the anisotropy in the compact stars with those densities.

Also, it is important to remark that when $B = 0$, the model automatically yields $P_\perp = P_\parallel$ and $\gamma = 1$. This means that we recover the spherical TOV equations from Eqs. (3) and thus, the standard non-magnetized solution for the structure of compact objects.

Our results point out that the magnetic fields effects become relevant in the low density regime and can be practically neglected for high densities. Even more, such effects are more relevant to the deformation of the magnetized compact objects than to their masses, at least when we study magnetized white dwarfs. Also, note that once again, we do not obtain masses above the Chandrasekhar limit.

As $\gamma$-structure equations are general, they can be useful to study other types of magnetized compact objects.

## Acknowledgments

We examine crustal torsional oscillations, newly taking into account the effect of the pasta structure. We find from eigenmode analyses for various models of the equation of state of uniform nuclear matter that the fundamental frequencies of such oscillations are almost independent of the incompressibility of symmetric nuclear matter $K_0$, but strongly depend on the slope parameter of the nuclear symmetry energy $L$. On the other hand, we also find that the frequencies of the 1st overtones depend strongly on not only $L$ but also $K_0$. By comparing the resultant frequencies to the quasi-periodic oscillations observed in the giant flares, we can constrain the values of $L$ and $K_0$. Furthermore, considering the constraints on $K_0$ obtained from the terrestrial nuclear experiments, we can successfully make a more severe constant on $L$.

*Keywords*: Equation of state, neutron star crust, shear oscillations.

## 1. Introduction

Neutron stars would be produced via supernova explosions at the last moment of massive stars. The density inside the star significantly exceed the normal nuclear density, the magnetic field inside/around the star can become very strong, and the gravitational field is also so strong. The neutron stars, thus, are good candidate to probe physics under such extreme conditions. In order to extract the interior information of stars, the asteroseismology is very powerful technique. In practice, it would be possible to probe the stellar mass, radius, equation of state (EOS) of dense matter, and theory of gravity in the strong-field regime via future observations of gravitational waves[1–3].

The possible oscillations of neutron stars are observed as quasi-periodic oscillations (QPOs) in the giant flares from the soft-gamma repeaters[4]. In order to theoretically explain these observed QPOs, several studies have been done in terms of crustal torsional oscillations[5–9] or magnetic oscillations[10,11]. The magnetic oscillations strongly depend on uncertain magnetic field structure, field strength inside the star, and uncertain EOS in core region if magnetic fields penetrate the core. On the other hand, the crustal torsional oscillations are confined into the crust region because the shear modulus inside the core should be zero. With such reasons, we focus on the crustal torsional oscillations in the present study by especially taking into account the effect of presence of cylindrical nuclei as well as the phase of spherical nuclei. Then, comparing the observed QPO frequencies to the frequencies of crustal torsional oscillations, we can constrain the nuclear saturation parameters, which are important parameters for describing the neutron star crust. More details of this study can be seen in Ref. 9.

## 2. Crust in equilibrium

To avoid the uncertainties in the EOS of core region, we construct the crust in equilibrium by integrating Tolman-Oppenheimer-Volkoff equations from the stellar surface inward to the bottom of the curst, assuming the stellar mass $M$ and radius $R$. The bulk energy per baryon of uniform nuclear matter at zero temperature for any EOS can be expanded as a function of baryon number density and neutron excess with five expansion parameters, i.e., the saturation density $n_0$, the saturation energy, incompressibility $K_0$ of symmetric nuclear matter, symmetry energy at $n_0$, and the slope parameter $L$. Among five parameters, $K_0$ and $L$ are more difficult to be constrained by terrestrial nuclear experiments, because such parameters are higher order coefficients with respect to the change in density from $n_0$. In the present study, we adopt the phenomenological EOS, where $K_0$ and $L$ are considered as free parameters and the other parameters are determined in such a way as to reproduce the empirical nuclear data[12,13]. The shear modulus is another important property describing the shear oscillations. Here, we adopt the standard shear modulus in the phase of spherical nuclei[14] together with that in the phase of cylindrical nuclei[15], where we also adopt the results by Ref. 16 as the effect of neutron superfluidity inside the phase of spherical nuclei, while the effect of it inside the phase of cylindrical nuclei is considered by introducing a parameter of $N_s/N_d$ with the superfluid neutron density $N_s$ and the dripped neutron density $N_d$. At last, to construct the crust in equilibrium, one has to choose $M$, $R$, $K_0$, $L$, and $N_s/N_d$ in the phase of cylindrical nuclei.

## 3. Torsional oscillations and comparison to the observations

In the left panel of Fig. 1, the calculated frequencies of fundamental torsional oscillations with various values of $\ell$ are shown as a function of $L$ together with the QPO frequencies observed in SGR 1806–20 for the neutron star model with

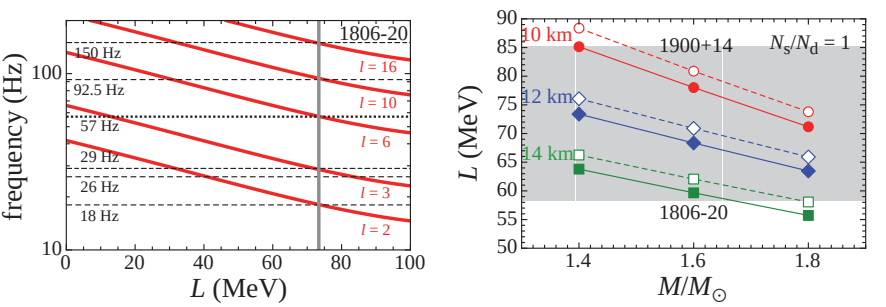

Fig. 1. Comparison of the low-laying QPOs observed in SGR 1806–20 with the fundamental frequencies of crustal torsional oscillations with various values of $\ell$ in the left panel[9]. For various stellar models, the optimal value of $L$ obtained by the comparison of QPOs in SGR 1806–20 and in 1900+14 with the fundamental torsional oscillations in the right panel[9].

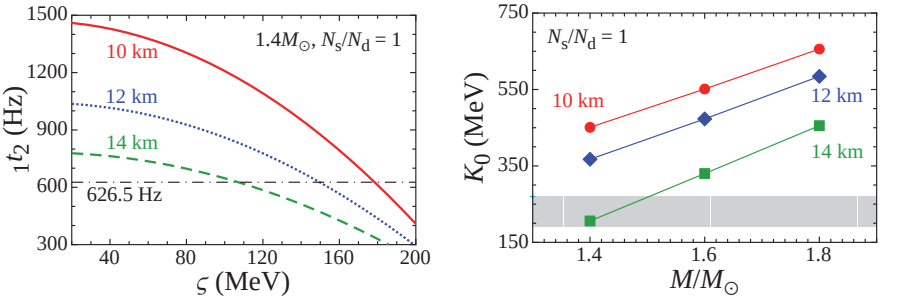

Fig. 2. The frequencies of 1st overtones for the $1.4M_\odot$ neutron star models with different stellar radii in the case of $N_s/N_d = 1$ in the phase of cylindrical nuclei are compared with the 626.5 Hz QPO in SGR 1806 (left panel), while the value of $K_0$ constrained by the combination of constraints on $L$ from the fundamental torsional oscillations and those on ς from the 1st overtones for the various stellar models (right panel)[9].

$M = 1.4M_\odot$ and $R = 12$ km. From this figure, one can see that the QPO frequencies except for the 26 Hz can be identified by the crustal torsional oscillations with $L \simeq 73.4$ MeV. We remark that the 26 Hz QPO may be identified by the torsional oscillations confined in the phase of bubble structure[8]. In a similar way, the optima value of $L$ for identifying the observed QPOs with the fundamental crustal torsional oscillations is shown in the right panel of Fig. 1 for various stellar models, where the filled and open marks denote the results for identifying the QPOs observed in SGR 1806–20 and 1900+14, respectively, and the painted region is allowed region of $L$.

On the other hand, the frequencies of overtones depend on the crust thickness, which depends on $L$ and $K_0$[17]. As a result the frequencies of overtones depend on $L$ and $K_0$. We successfully find that the frequencies of the 1st overtones can be expressed well with a combination of $L$ and $K_0$[9] as

$$\varsigma \equiv \left(K_0^4 L^5\right)^{1/9}. \tag{1}$$

In the left panel of Fig. 2, we show the 1st overtone frequencies for the $1.4M_\odot$ stellar model with different radius as a function of ς. By identifying the QPO frequencies observed in SGR 1806–20 with the 1st overtones, one can determine the optimal value of ς, with which one can determined the value of $K_0$ by combining the results obtained from the identification of the QPO frequencies with the fundamental oscillations as shown in Fig. 1. Such a value of $K_0$ is shown in the right panel of Fig. 2, where the value of $K_0$ constrained from terrestrial nuclear experiments also denote by the painted region[18]. By considering the both constraints from the observations of QPOs and terrestrial nuclear experiments, the preferable stellar model as SGR 1806–20 is relatively low mass and larger radius neutron star, such as $M = 1.2 - 1.4M_\odot$ with $R = 13$ km or $M = 1.4 - 1.5M_\odot$ with $R = 14$ km. With this constraint on the stellar model for SGR 1806–20, we further constrain the value of $L$ from the right panel of Fig. 1, i.e., $L \simeq 58 - 73$ MeV, which is consistent with the terrestrial nuclear experiments[19].

## 4. Conclusion

In this study, we successfully constrain the value of $L$ and $K_0$ by identifying the low-laying QPOs and higher QPO observed in giant flares with the fundamental oscillations and 1st overtones of crustal torsional oscillations. The constraint on $K_0$ obtained from terrestrial nuclear experiments makes a constraint on the stellar model and further constraint on $L$.

# Contributions to neutron star's tidal deformability from the low density equation of state

A. M. Kalaitzis, T. F. Motta and A. W. Thomas

*CSSM and ARC Centre of Excellence for Particle Physics at the Terascale, Department of Physics, University of Adelaide SA 5005 Australia*

The low density contribution to the tidal deformability and moment of inertia of a neutron star are calculated via various well known equations of state. The contributions to the moment of inertia are directly calculated, whilst the tidal deformability's are constructed through comparing an equation of state with a fit with the low density region removed. With the recent measurement of GW170817[1,2] providing constraints on the tidal deformability, it is very important to understand what features of the equation of state have the biggest effect on it.

*Keywords*: Neutron Stars, Tidal Deformability, Low Density, Equation of State, Nuclear Matter, GW170817.

## 1. Introduction

Neutron stars (NS) being the densest known repositories of nuclear matter contain fascinatingly complex phase changes between their regions of finite and infinite nuclear matter, more commonly known as their layers, denoted crust and core[3–5]. The crust poses challenges with regards to modelling because of the variety of finite nuclei that may appear and complex phase structures that can occur[6].

On the other hand, after the recent GW170817 measurement[1,2], there has been a tremendous push to calculate the tidal deformability (TD) and the moment of inertia (MOI)[7–13] across a variety of equations of state (EOS). This is due to the bounds produced on the TD in Ref 1, 2 of $\Lambda_{1.4} = 190^{+390}_{-120}$, which has recently been analysed via the I-Love-Q relations in Ref. 14 to produce a constraint on the MOI of $\overline{I} = 11.10^{+3.64}_{-2.28}$.

In this paper we explore the proportional contribution that the low density region (LDR) of the EOS makes to the MOI and TD.

## 2. Theoretical Framework

We will be using the well known EOS shown in Fig. 1 acquired from the online data base in Ref. 15 which details the models in question. In order to calculate the NS profile, ordinarily one would match the model EOS description of the core to some low density EOS in order to account for the NS crust or model it directly[4,6]. We have fit to each EOS using a polytropic of the form given in equation 1 where $A, B, C$ and $D \in \mathbb{R}$. This will act as the EOS without the LDR modelling, with the original EOS data from Ref. 15 containing LDR modelling. As seen in the enlargement in Fig. 1

$$P(\epsilon) = A\epsilon^B + C\epsilon^D. \tag{1}$$

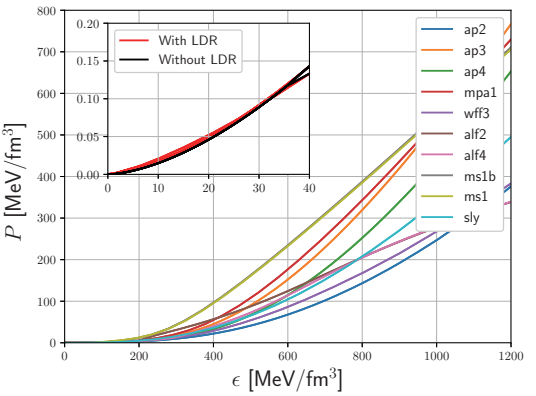

Fig. 1. EOS (pressure $P$ vs energy density $\epsilon$) for all the models[15], nucleon only. Two EOS for each EOS, one with the LDR and one produced from the polytropic fit. The enlargement shows the LDR with all EOS and their fits displayed (There is much overlap between the EOS for the LDR).

We will use these fits to analyse the percentile contributions to the TD via direct comparison of their values. This is done as the TD is defined mathematically as a boundary point and not something cumulative (e.g. integral)[16,17], so that the direct calculation of its LDR contribution is impossible. This is equivalent to modelling a core only NS, consisting of only infinite nuclear matter. The LDR contribution to the MOI may be calculated directly as it is defined as a cumulative integral[18,19].

The NS masses are obtained by numerically integrating the Tolman-Oppenheimer-Volkoff (TOV) equations[20]

$$\frac{\mathrm{d}P}{\mathrm{d}r} = -\frac{(P(r)+\epsilon(r))(m(r)+4\pi r^3 P(r))}{r(r-2m(r))}, \tag{2}$$

$$\frac{\mathrm{d}m}{\mathrm{d}r} = 4\pi r^2 \epsilon(r), \tag{3}$$

until $P(r = R) = 0$ ($R$ the radius of the NS). This produces the mass radius relations given in Fig. 2. We will define the variation of a parameter $\alpha$ as $\Delta\alpha/\alpha$, which is reported as the percentage difference of that parameter when compared to its LDR removed counterpart. This is calculated via (MOI variation $\Delta I/I$ is defined differently as seen in Refs. 12, 21)

$$\frac{\Delta\alpha}{\alpha} = \frac{(\alpha_{\text{with LDR}} - \alpha_{\text{Without LDR}})}{\alpha_{\text{with LDR}}}. \tag{4}$$

Note that this requires one parameter to be fixed. For example the compactness parameter $\beta = M/R$, we would fix the mass and look at the variations in the radius or visa versa. The MOI $I$ is calculated through the formula in Refs. 18, 19, with $\Delta I/I$ defined in Refs. 12, 21.

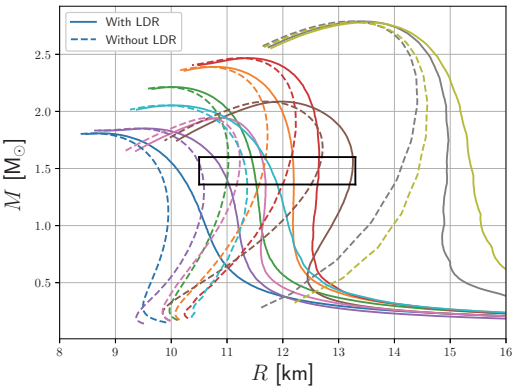

Fig. 2. Mass radius relation for EOS given in Fig. 1. The box represents the 90% confidence constrained mass region given from the GW170817 measurement[1,2]. Mass radius curves retain name and colour convention as in Fig. 1 with dashed versions being the fits.

The tidal Love number, $k_2^{\text{tidal}}$, TD, $\Lambda$, and binary tidal deformability, $\widetilde{\Lambda}$, equations are verbatim those seen in Refs. 16, 17, 11. For future reference, the TD and binary tidal deformability are calculated via

$$\Lambda = \frac{2}{3} k_2^{\text{tidal}} \beta^{-5}, \tag{5}$$

$$\tilde{\Lambda}^{\text{Tid}} = \frac{16}{13} \frac{(12q+1)\Lambda_1 + (12+q)q^4\Lambda_2}{(1+q)^5}, \tag{6}$$

where $q = m_2, m_1$ and $m_2 \leq m_1$. With these equations we can now calculate our desired quantities and the percentage contributions from the LDR.

## 3. Results and Discussion

Numerically solving the MOI equations[11,18,19,21] produces Fig. 3 which shows the proportion of crustal MOI $\Delta I$ over the total MOI $I$. It should be noted that for any realistic star[21] of solar mass

$$0.8 M_\odot \leq M \leq 1.92 M_\odot, \tag{7}$$

we find $|\Delta I/I| < 17.5\%$, with this percentage decreasing rapidly as the mass increases. In particular, a star of solar mass $1.4 M_\odot$ has $|\Delta I/I| < 7.5\%$.

In order to calculate the LDR contribution to the tidal deformability, we simply solve the equations in Refs. 16, 17 for each set of mass radius curves in Fig. 2 and then make use of equation 4 which produces Fig. 4. We find that $|\Delta\Lambda/\Lambda| < 15\%$ for all NS within equation 7's mass range. However, it is important to note that if we disregard the three EOS that lie outside the 90% confidence interval from Refs. 1, 2

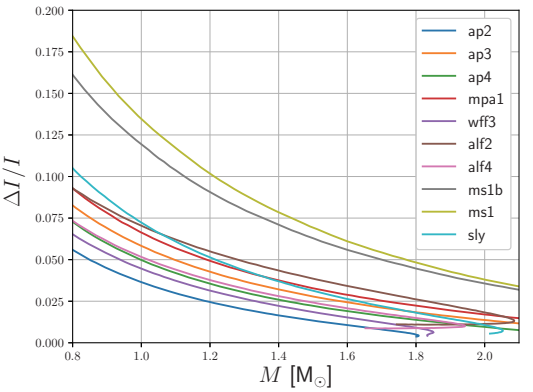

Fig. 3. Percentage of the MOI due to the LDR, scaled via the neutron star's total MOI. Only shown for the EOS with the LDR.

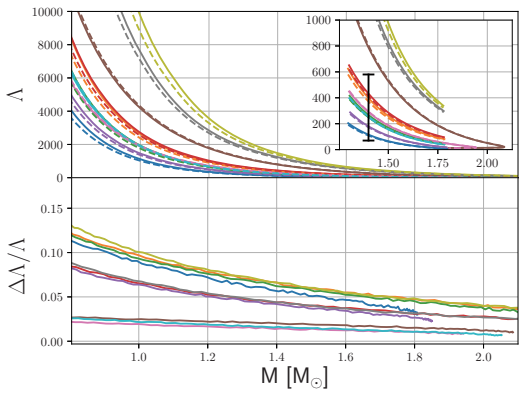

Fig. 4. Percentage of the TD due to the LDR, scaled via the neutron star's total TD. The enlargement shows a shorter range with the black bar representing the bound $\Lambda_{1.4} = 190^{+390}_{-120}$.

in Fig. 4, then our new bounds become

$$|\Delta I/I| < 9.0\%, \qquad |\Delta\Lambda/\Lambda| < 12.0\%, \tag{8}$$

$$|\Delta I/I|_{M=1.4M_\odot} < 3.5\%, \qquad |\Delta\Lambda/\Lambda|_{M=1.4M_\odot} < 7.0\%, \tag{9}$$

within mass range given in Eq. (7). For clarity the tidal Love numbers are displayed in Fig. 5

This happens in spite of the visibly large difference in the mass radius relations (by extension the compactness parameter $\beta = M/R$) and tidal Love numbers shown in Fig. 2 and Fig. 5. The variance in the TD remains relatively low due the large negative power from the $\beta$ term in Eq. (5).

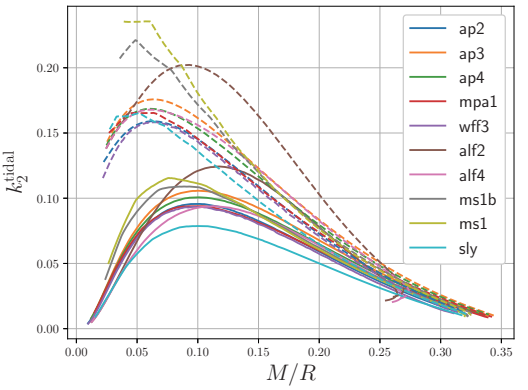

Fig. 5. Tidal Love numbers $k_2^{\text{tidal}}$ keeping same conventions as in Fig. 2 and Fig. 1

Due to the low variance in the TD, by extension the variance in the BTD is of a similar order of magnitude as it depends linearly on $\Lambda_1$ and $\Lambda_2$, with $m_1, m_2$ being its free parameters, i.e, these two parameters offer no more increase in the variance.

These results have been summarised as the following:

- The impact on macroscopic quantities (e.g. mass, radius etc.) from LDR decreases in significance as the mass increases.
- The TD and MOI are affected to just a small percentage via the inclusion of the low density EOS for all stars with mass $M \geq 0.8M_\odot$, and to a greater extent for stars with mass $M \geq 1.4M_\odot$. Percentages are shown in Eqs. (8) and (9).

This is not to say that the LDR's effects are uniformly negligible, as seen in Fig. 2 where the LDR contributes significantly to the radius. With the imminent measurements of the neutron star radii by NICER, this low density EOS modelling will prove incredibly significant in ascertaining correct predictions for the radius.

## 4. Conclusion

In summary we see that despite the LDR's proportionally significant contribution to the radius and percentage of the NS content, its contributions to the TD and MOI are small, especially when considered for a star of $1.4M_\odot$ or greater.

Different extensions of the Nambu-Jona-Lasinio model, known to satisfy expected QCD chiral symmetry aspects, are used to investigate a possible hadron-quark phase transition at zero temperature and to build the corresponding binodal sections.

*Keywords*: NJL; QCD; Effective models; Binodals.

## 1. Introduction

Effective models remain a good source of information about regions of the QCD phase diagram inaccessible by terrestrial experiments or by LQCD methods[1], providing qualitative results and theoretical insights. The present work intends to help in advancing our knowledge towards some of the regions of the QCD phase diagram through this strategy. When this approach is applied to the study of the transition of hadronic matter to the deconfined quark matter, it is sugested that the QCD phase diagram shows a first order phase transition[2] at high chemical potentials and low temperatures, while from the LQCD perspective, the hadron-quark transition is believed to be a crossover at low chemical potentials and high temperatures. This seemingly contradictory picture can be reconciled by the existence of a critical end point in the phase transition curve, linking the LQCD crossover with the effective model first order transition. This idea is reinforced by experimental results[3] signaling to a first order phase transition and pointing out to the possible existence and location of the critical end point.

Considerations on the phase transition at zero temperature have already been done in many works[4–9], but we do believe the formalism we employ in the present work is more adequate, as the effective models employed here exhibit chiral symmetry in both hadronic and quark phases, which is demanded to take seriously the appearance of the quarkyonic phase[10]. The models used here are all included in the Nambu–Jona-Lasinio (NJL) model framework[11], in order to naturally describe the chiral characteristics of QCD matter.

In Refs. 6 and 9, the hadron-quark phase transition was investigated with the help of two different models, namely, the non-linear Walecka model (NLWM) for the hadronic phase and the MIT bag model for the quark phase. A formalism we understand as a more adequate one was used in Refs. 7, 12, 13 at zero temperature and in Ref. 8 for finite temperatures, all considering NJL-type models for the two

phases. To describe the hadron phase, the standard NJL model with vector interaction is extended to include a scalar-vector channel in order to render the model capable of saturation at low densities. We revisit the approach of Refs. 7 and 8, but applying an extended NJL model for the hadron phase that includes additional channels to achieve a better description of important nuclear bulk properties[14]. A similar extension of the NJL model for hadronic matter has been developed[15,16] with a different choice of interaction channels. Recently, this version was also applied to investigate the hadron-quark phase transition[17], but the quark phase was still described by the MIT bag model. Hence, we describe the hadronic matter with the extended NJL model from Ref. 14 and the quark matter with the NJL model in its SU(2) version in order to check for which parameters a phase transition is possible, considering both symmetric and asymmetric systems. Whenever possible, the binodal sections are obtained.

## 2. Binodals

The QCD phase-diagram is characterised by potentially multiple phases, whose phase separation boundaries are referred as *binodals*[18]. Over those boundaries, the phases from the regions of either side of the boundary can coexist. The binodals may be determined using the Gibbs conditions[6]:

$$\mu_B^Q = \mu_B^H, \qquad T^Q = T^H, \qquad P^Q = P^H, \tag{1}$$

where the indexes $H$ and $Q$ refer to the hadronic and quark phases. The chemical potentials $\mu_B^i$ are obtained from the chemical potentials of the particles of each phase[6].

At a certain fixed temperature ($T = 0$ in the present context), the phase coexistence condition may be obtained by plotting $P^i \times \mu_B^i$, $i = Q, H$, and looking for the

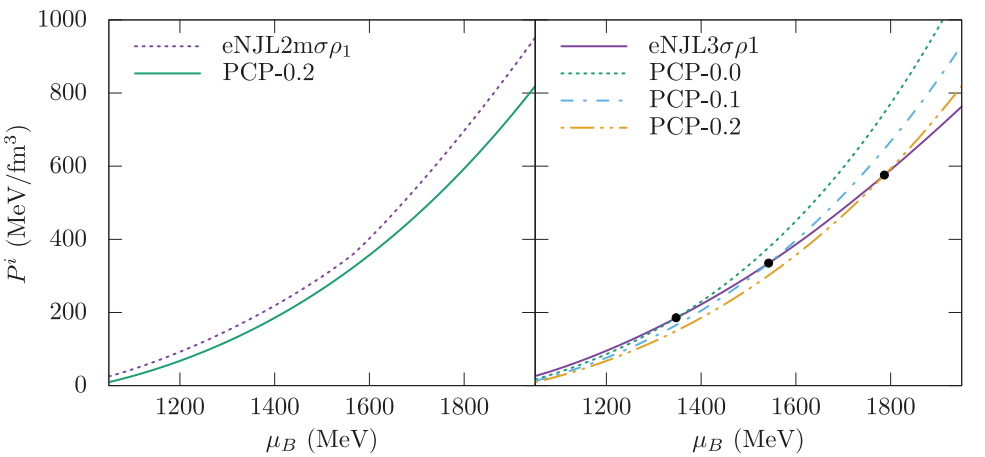

Fig. 1. Combinations of parameter sets for which hadron-quark phase transition is not allowed to happen (left), and combinations for which the transition is allowed to happen (right).

intersection of both curves. In Fig. 1 (left) we display a combination of parameterizations for which there are no intersections, implying that there are no transitions (i.e., the hadron phase is always more stable). In Fig. 1 (right), we compare the results for a hadron parameter set with three quark matter parameter sets, with varying strenght of the vector coupling, obtaining the transitions indicated by the dots.

The conditions of phase coexistence are also important in asymmetric matter and to obtain the binodal sections as a function of the system asymmetry, we use the prescription given in Ref. 4. The isospin chemical potentials are defined as

$$\mu_3^H = \mu_p - \mu_n, \qquad \mu_3^Q = \mu_u - \mu_d, \tag{2}$$

and enforced to be identical according to the Gibbs conditions. The asymmetry parameters of the hadron and quark phases are respectively

$$\alpha^H = (\rho_n - \rho_p)/(\rho_n + \rho_p), \qquad \alpha^Q = 3(\rho_d - \rho_u)(\rho_d + \rho_u), \tag{3}$$

in such a way that $0 \leq \alpha^H \leq 1$ (just nucleons) and $0 \leq \alpha^Q \leq 3$ (just quarks).

The *binodals* are obtained through the determination of hadron and quarks phase pressures for each value of $\mu_B$ and $\mu_3$ (the $\mu_3$ parameter directly controls the proton fraction of both phases): whenever the pressure difference is below 0.1 MeV, we assume that both phases coexist. This procedure leads to the results shown in Fig. 2. The pressures shown for $\alpha = 0$ in the right panel correspond to the intersections marked in Figure 1. Also from this figure, we can clearly see that the increase in strength of the vector coupling causes a substantial modification on the transition point, which reflects in the values of the pressure in the binodal sections.

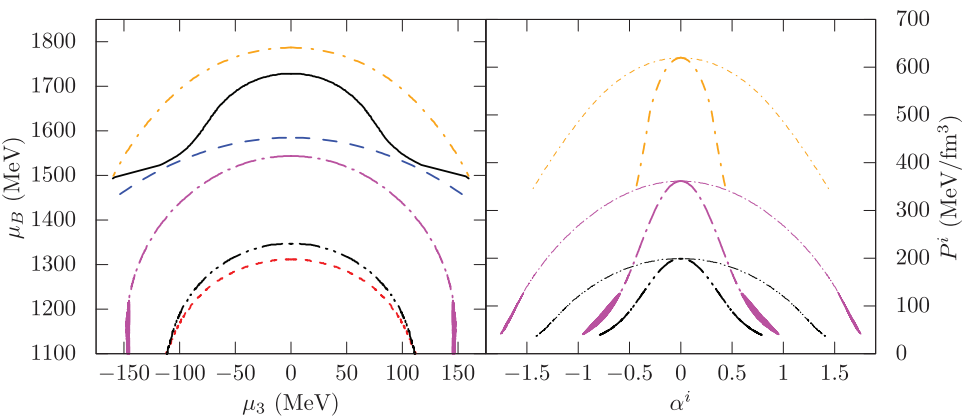

Fig. 2. Baryonic chemical potentials as a function of $\mu_3$ (left) and pressure as a function of asymmetry (right) at the coexistence point for: BuballaR-2 and eNJL2m$\sigma\rho$1 (black line), BuballaR-2 and eNJL3$\sigma\rho$1 (blue long-dashed line), PCP-0.0 and eNJL2m$\sigma\rho$1 (red short-dashed line), PCP-0.0 and eNJL3$\sigma\rho$1 (black double-dot dashed line), PCP-0.1 and eNJL3$\sigma\rho$1 (magenta long-dash dotted line), and PCP-0.2 and eNJL3$\sigma\rho$1 (orange short-dash dotted line).

## 3. Conclusions

We have revisited the study of hadron-quark phase transition at zero temperature with different extensions of the NJL model, which are more appropriate to describe systems where chiral symmetry is an important ingredient. We analysed possible phase transitions from a hadron phase described by an extended NJL model to a quark phase described by the SU(2) NJL with the inclusion of a vector interaction of arbitrary strenght. We have first considered symmetric matter and checked that not all parameterization combinations produce a system in which a phase-transition is favored. Another manifestation of the dependence of the results on the choice of parameters is the range of barionic chemical potentials for which the transition takes place, spanning from around 1300 MeV to around 1800 MeV, indicating a strong parameter dependence. We have next analysed assymetric systems and whenever possible, binodal sections were obtained. Both pressures and chemical potential increase drastically with the increase of the vector interaction strenght in the quark sector. As a next step on this analysis, we plan to expand our results to include finite temperature in the system and obtain the complete binodal sections.

# Dark mechanism for nucleation inside old neutron stars

M. Ángeles Pérez-García*

*Department of Fundamental Physics, University of Salamanca, Plaza de la Merced, s/n, E-37008, Spain*
** E-mail: mperezga@usal.es*

Neutron stars are objects where matter and fields can be tested to the extreme. In their interior, ordinary matter with a majority of nucleons ($N$) may coexist with a component of exotic matter that constitutes the so-called dark matter. It is believed that this latter type of matter constitutes nearly 80% of all mater in the currently accepted cosmological paradigm for our Universe. Popular candidates for such a kind of matter belong to extensions of the Standard Model of particle physics. In this contribution we discuss the impact of a component of self-annihilating fraction of dark matter ($\chi$) that may be present in the star. We focus on the microscopics of the energy deposit arising from the annihilation process $\chi\chi \to N\gamma$ in the dense core of a NS. We show that even if a tiny portion of matter inside the NS is dark matter it may trigger critical changes in the equation of state (EoS) of regular hadronic stars, provided its mass, $m_\chi$, and cross-section scattering off nucleons, $\sigma_{\chi N}$, resides in a suitable allowed region of the dark parameter phase space.

*Keywords*: Neutron star; dark matter; nuclear matter; phase transition.

## 1. Introduction

Neutron stars (NSs) are compact objects born in the aftermath of a supernova explosive event[1]. They are believed to be among the densest known objects in our Universe and where extreme conditions determine the region of the matter phase space that can be tested. i.e. cold and dense matter. Namely, in most of the volume of the quasi-spherical object with mass $M_*$ and radius $R_*$ densities are several times that of nuclear saturation density $n_0 \sim 0.16$ fm$^{-3}$. Solutions to the structure equations provided by the theory of General Relativity in the static approximation provide values of the compactness parameter $M_*/R_* \sim 0.1$ which is much larger than for the Sun or any other stellar body. NS typical values for $M_* \sim 1.5 - 2M_\odot$ and $R_* \sim 11 - 12$ km. Thus NSs can be considered to be efficient attractors of a massive $\chi$ dark matter (DM) component from a halo where they may be inmerse. That is the specific case under study in this contribution. So far this kind of elusive matter has been searched for using different techniques including direct searches with terrestrial targets where scattering events off nuclei would allow to measure the corresponding recoiling energies[2]. Another existing effort is that of the so-called indirect searches[3] where emission of secondaries (photons or additional Standard Model particles) may signal the presence of DM. This means for some popular models of DM a dark component that could self-annihilate into gamma rays or any other particle pairs as many reviews on the subject explain[4]. As there is so far no consensus about the fermionic or bosonic nature of the DM candidate $\chi$, we will assume an effective treatment where they are considered as a semiclassic, non relativistic matter component. The validity of our treatment is assured as

we consider a finite fraction of an accreted dark component that is able to exist thermalized in the interior of these dense stars. The combined effect of gravitational capture and multiple scattering suffered by an incoming DM particle traversing the NS volume can be summarized in an expression for the global capture rate[5]

$$C_\chi \simeq 6\times 10^{25}\left(\frac{M_*}{1.5M_\odot}\right)\left(\frac{R_*}{12\,\mathrm{km}}\right)\left(\frac{1\,\mathrm{GeV}}{m_\chi}\right)\left(\frac{\rho_\chi^{ambient}}{0.3\frac{\mathrm{GeV}}{\mathrm{cm}^3}}\right)\left(\frac{\sigma_{\chi N}}{\sigma_0}\right)\ \mathrm{s}^{-1}, \qquad (1)$$

where $\sigma_0 \sim 10^{-44}$ cm$^2$. The typical mean free path of a DM particle inside the core is approximated by $\lambda_\chi^{-1} \sim \sigma_{\chi N} n_N$ with $\sigma_{\chi N}$ the $\chi N$ scattering cross-section and $n_N$ the number density of nucleons inside the NS core. At least one scattering event is needed to capture the DM particle then $\lambda_\chi/R \lesssim 1$ in the NS core at a typical density $\sim 3n_0$ yields $\sigma_{\chi N} \gtrsim 10^{-45}$ cm$^2$. At current level of sentitivity this is allowed for heavy DM candidates with masses beyond the $m_\chi \sim 1$ TeV scale.

## 2. Role of Dark Matter and changes in the NS EoS.

From an accreted component of DM and once it is thermalized with the rest of matter we can assume that a spatial distribution arises under a gaussian form $n_\chi(r) = n_{0,\chi}\exp(\frac{\mathrm{r}}{\mathrm{r_{th}}})^2$ where $r_{\mathrm{th}} = \sqrt{\frac{3k_BT}{2\pi G\rho_N m_\chi}}$ stands for the thermal radius and $\rho_N \simeq m_N n_N$. $G$ and $k_B$ are the gravitational and Boltzmann constants, respectively. We consider that the inner core in the old NS has attained an internal temperature $T \sim 10^5$ K, low with respect to Fermi energies in the baryon sector.

It is in this context that DM is gathered forming a density enhancement in a central stellar region with volume $V_{\mathrm{th}} \sim r_{\mathrm{th}}^3$ and can undergo self-annihilation following a chain of possible reactions into photonic final states $\chi\chi \to N\gamma$. PYTHIA package[6] can simulate this using Monte Carlo techniques and it is obtained that the energy injection due to this kind of events yields $E_\gamma \sim 0.6 m_\chi$. We are interested in the study of the possible consequences of such a microscopic energy transfer at the nuclear and sub-nuclear (quark) level. As we know, a description of nuclear matter from an effective field theory picture based on nucleons (neutrons and protons) is adequate for a limited set of (low energy) thermodynamical conditions. A novel effect, such as the local nucleation of quark droplets could be in principle studied, provided stability conditions for their existence are fulfilled. This intriguing possibility is indeed not new in the literature as pioneering works[7] referred to it early in the 1970's and 1980's and are coined today as the Bodmer-Witten conjecture. However the actual procedure leading to the deconfined state is far from being understood. A stochastic procedure where NS central density (pressure) is increased due to spin-down or mass accretion has been invoked, as well as fluctuations in high temperature young protoneutron stars[8,9].

On a more technical ground, relativistic nucleation theory developed by Lifshitz-Kagan[10] can model phenomenological bubble nucleation by using a relativistic lagrangian that describes the formation of a fluctuation i.e. a spherical bubble of

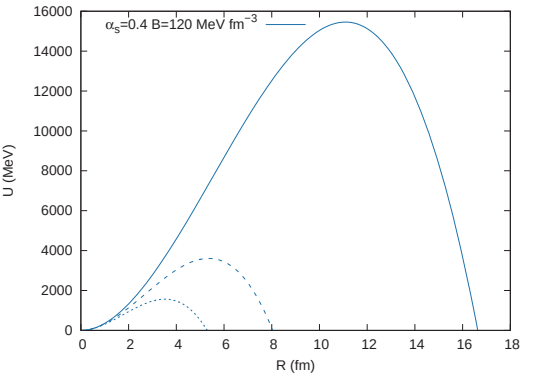

Fig. 1. Potential barrier energy as a function of radius. Solid, dashed and dotted lines depict pressures $P = P_0 + 10$ MeV, $P = P_0 + 20$ MeV, $P = P_0 + 30$ MeV, respectively for each case. We fix $\alpha_s = 0.4$, $B = 120$ MeV fm$^{-3}$, $\sigma = 30$ MeV fm$^{-2}$. $P_0 = 525$ MeV fm$^{-3}$.

mass $M$ and radius $R$,

$$\mathcal{L}(R, \dot{R}) = -M(R)\sqrt{1 - \dot{R}^2} + M(R) - U(R), \tag{2}$$

where $\dot{R} = dR/dt$ is the radial growth rate and $U(R)$ is an effective potential that confines the quark content. The latter depends on the thermodynamical conditions of the medium and it can be written in terms of the leading contributions approximately by

$$U(R) = \frac{4}{3}\pi R^3 n_{\rm Quark}(\mu_{\rm Quark} - \mu_{\rm Had}) + 4\pi\sigma R^2. \tag{3}$$

We label $\mu_{\rm Had}$ ( $\mu_{\rm Quark}$) as the chemical potentials of the metastable hadronic (stable quark) phases of matter at fixed pressure value, $P$. $n_{\rm Quark}$ is the number density of the stable phase and $\sigma$ is the surface tension. Contributions from volume as well as surface terms are the most energetically relevant in the nucleation process although some other corrections can be accounted for as well. This expression may result familiar to the reader as in terrestrial experiments for DM search based on bubble chambers such as PICO[11] another target is used but the spirit is still the same.

Back to our description of both high density phases, this is done in this contribution by a relativistic mean field (RMF) approach including neutrons, protons, electrons and mesonic fields $\sigma, \omega, \rho$ as in Ref. 12 while for the quark deconfined phase we choose the MIT bag model[15] with massive uds quarks for simplicity. The system fulfills electrical charge neutrality and baryon number conservation.

## 3. Results

Examples of U potential barriers can be seen in Fig. 1 for the case of beta-equilibrated matter at T=0 and three values of pressure. Solid, dashed and dotted lines depict $P = P_0 + 10$ MeV, $P = P_0 + 20$ MeV, $P = P_0 + 30$ MeV, respectively. To

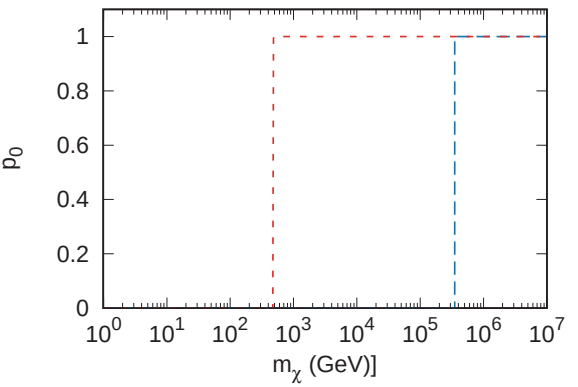

Fig. 2. Tunneling probability as a function of mass of the DM particle. We fix $\alpha_s = 0.4$, $B = 120$ MeV fm$^{-3}$ and $P = 535$ MeV fm$^{-3}$. Short dashed and long dashed lines depict cases with $\sigma = 30$ MeV fm$^{-2}$ and $\sigma = 10$ MeV fm$^{-2}$ respectively.

describe quark matter in the droplet we fix $\alpha_s = 0.4$, $B = 120$ MeV fm$^{-3}$, $\sigma = 30$ MeV fm$^{-2}$. The transition pressure of both equations of state $P(\varepsilon)$ for the hadronic and quark degrees of freedom is $P_0 = 525$ MeV fm$^{-3}$. The potential height and critical radius fulfilling $U(R_c) = 0$ decreases as pressure grows, for example for the $P = 535$ MeV fm$^{-3}$ case we obtain $R_c = 16.6$ fm. Note that the hadronic and electromagnetic cascades expected from the self-annihilating DM are of that size $X_\chi \lesssim R_c$ and can be considered to be contained in the droplet region.

The probability of nucleation is determined by the tunneling process for each thermodynamical case considered. In the WKB approximation[13] this is given by $p_0 = \exp\left(-\frac{\mathrm{A(E)}}{\hbar}\right)$ where the action $A(E)$ can be written as

$$A(E) = 2\int_{R_-}^{R_+} \sqrt{[2M(R) + E - U(R)]\,[U(R) - E]}\, dR, \tag{4}$$

being $E$ the energy of the particle (quark) confined in the region between the returning point $R_-$ and $R_+$. It is worth to remind that the treatment sketched here is valid for pressures above that of transition $P_0$. Nucleon confinement prevents from having any quark freedom in hadronic objects.

The determination of the transition point from a nuclear to quark EoS in an extended system is established by the Gibbs criteria relating the equality of baryonic chemical potentials at a given pressure $P_0$ where equilibrium holds. Namely,

$$\mu_b(P_0)\Big|_{\mathrm{Had}} = \mu_b(P_0)\Big|_{\mathrm{Quark}}, \tag{5}$$

where $\mu_b$ is the baryonic chemical potential at $T = 0$ , $\mu_b = \frac{\varepsilon + P}{n_b}$. It is assumed that it corresponds to a first order phase transition[14]. The probability of the formation of the quark droplet is related to the tunneling probability for the selected

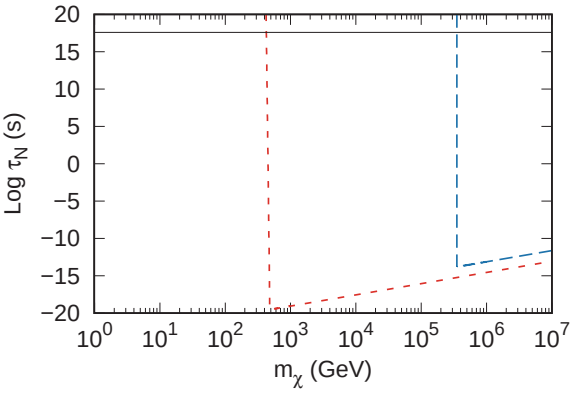

Fig. 3. Logarithm of the nucleation time as a function of mass of the DM particle. We fix $\alpha_s = 0.4$, $B = 120$ MeV fm$^{-3}$ and $P = 535$ MeV fm$^{-3}$. Short dashed and long dashed lines depict cases with $\sigma = 10$ MeV fm$^{-2}$ and $\sigma = 30$ MeV fm$^{-2}$ respectively. The black thin line shows the Universe lifetime value.

thermodynamical conditions. In Fig. 2 we show $p_0$ as a function of the DM particle mass. We fix $\alpha_s = 0.4$, $B = 120$ MeV fm$^{-3}$ and take $P = 535$ MeV fm$^{-3}$ (10 MeV above the transition density $P_0$). Short dashed (red) and long dashed (blue) lines depict cases with $\sigma = 10$ MeV fm$^{-2}$ and $\sigma = 30$ MeV fm$^{-2}$, respectively. We can see that the larger the $\sigma$ the more massive DM needs to be in order to trigger the quark droplet formation. The nucleation time can be obtained from the expression $\tau_N = \frac{\tau}{N_C} = \frac{1}{\nu_0 p_0 N_C}$ where $N_C$ is the number of nucleation centers available in the star and determined from the sites (bubbles with volume $\sim R_c^3$) where energy injection can happen $N_C = \frac{V_{\rm th}}{V_B} \sim (r_{\rm th}/R_c)^3$. $\nu_0 = 10^{-23}$ $s^{-1}$ is a frequency that is obtained from the fundamental energy configuration [12] and in this U height range can be approximately taken as constant. In Fig. 3 we show the logarithm (base 10) of the nucleation time as a function of the mass of the DM particle for the same sets of parameters as in Fig. 2. The critical radii for the $\sigma = 30$ MeV fm$^{-2}$ and $\sigma = 10$ MeV fm$^{-2}$ cases are $R_c = 16.6$ fm and $R_c = 5.5$ fm, respectively. The thin solid line signals the upper limit of the Universe lifetime $\tau_U \sim 4 \times 10^{17}$ s. The oldest NSs have a characteristic age of nearly $\sim 4.9$ Gyrs such as for PSR J04374715 [17]. We can see that the surface tension (still poorly known) highly influences the nucleation process. Light DM mass prevent from having nucleation ($\tau_N > \tau_U$) while it is surely predicted for higher DM masses where $\tau_N$ is tiny.

## 4. Discussion and conclusions

From the current constraints of the DM phase space and for $m_\chi \gtrsim 500$ GeV these results can be complementary to the ones arising from scans of the parameter space of typical SUSY models such as CMSSM, NUHM1, NUHM2, pMSSM10, see Fig. 26.1 in Ref. 16, which integrates constraints set by ATLAS Run 1 and from

SuperKamiokande. As observable consequence of the explained dark mechanism the nucleated stellar object changes its EoS. It is a matter of further study to determine the adjustment of the stellar equilibrium[18] but is is anticipated that could end in the emission of an energetic and very short gamma ray burst[19]. This could be measured with modern capabilities of satellite missions in the $\sim 0.1$ MeV energetic range such as Astrogam[20].

We present two recent parametrizations of the equation of state (FSU2R and FSU2H models) that reproduce the properties of nuclear matter and finite nuclei, fulfill constraints on high-density matter stemming from heavy-ion collisions, produce $2M_\odot$ neutron stars, and generate neutron star radii below 13 km. Making use of these equations of state, cooling simulations for isolated neutron stars are performed. We find that two of the models studied, FSU2R (with nucleons) and, in particular, FSU2H (with nucleons and hyperons), show very good agreement with cooling observations, even without including nucleon pairing. This indicates that cooling observations are compatible with an equation of state that produces a soft nuclear symmetry energy and, thus, generates small neutron star radii. Nevertheless, both schemes produce cold isolated neutron stars with masses above $1.8M_\odot$.

*Keywords*: Neutron stars, cooling, mass-radius constraints, equation of state, hyperons.

## 1. Introduction

The thermal evolution (or cooling history) of neutron stars strongly depends on the equation of state (EoS) and the associated composition of these compact objects[1,2]. Several works have addressed the cooling history of neutron stars and they agree that it is imperative to establish whether fast cooling processes take place, since if the star cools down too fast, it will yield to a disagreement with most observed data. If the stellar proton fraction is high enough, the most important fast processes (the so-called direct URCA, DU) will take place, thus leading to a direct connection between the thermal behavior and the symmetry energy of nuclear matter.

In this paper we investigate the thermal evolution of neutrons stars using EoSs for the nucleonic and hyperonic inner core[3,4] that reconcile the $2M_\odot$ mass observations[5,6] with determinations of stellar radii below 13 km (see Ref. 7 for an overview), the latter being confirmed from analysis of the gravitational-wave emission of GW170817 (see Table II in Ref. 8 and references therein) detected by the LIGO and Virgo collaborations[9]. Moreover, the aforementioned microscopic models satisfy the properties of nuclear matter and finite nuclei[10,11] and constraints from heavy-ion collisions (HICs)[12–14].

In particular, the two models FSU2R and FSU2H, based on the nucleonic FSU2 model[11], differ on the onset of appearance of each hyperon, whereas the neutron star maximum masses calculated with these models show only a moderate dispersion of about $0.1M_\odot$[4]. In the present study, we focus on how the hyperons, as well as the symmetry energy of the microscopic model influence the cooling history of isolated neutron stars, considering also different nucleon pairing scenarios[15].

## 2. FSU2R and FSU2H models

Our models are based on two new parametrizations of the FSU2 RMF model[11]. We start by considering only nucleons. The FSU2R(nuc) model produces a soft symmetry energy and a soft pressure of neutron matter for densities $n \lesssim 2n_0$, as seen in Fig. 1 (left). This is done by increasing the $\Lambda_\omega$ coefficient of the mixed quartic isovector-vector interaction that modifies the density dependence of the nuclear symmetry energy, thus turning the EoS softer[3,4]. As a result, radii within the range of 11.5–13 km are obtained from FSU2R for neutron stars with masses between the maximum mass and $M = 1.4M_\odot$, as seen in Fig. 1 (right). FSU2R predicts $E_{\rm sym}(n_0) = 30.7$ MeV and $L = 46.9$ MeV[4], that differs from the FSU2 model with $E_{\rm sym}(n_0) = 37.6$ MeV and $L = 112.8$ MeV and is in agreement with the limits of recent determinations (see Fig. 1 of Ref. 4 for a summary and references therein). In the high-density sector of the EoS, the FSU2R and FSU2 EoSs are similar, and, hence, FSU2R also reproduces heavy neutron stars (see Fig. 1 (right)).

When hyperons are incorporated, a softening of the high-density EoS with hyperonic degrees of freedom takes place (compare the FSU2R(hyp) and FSU2R(nuc) EoSs in Fig. 1 (left)), so we obtain a reduction of the maximal neutron star mass below $2M_\odot$ in FSU2R(hyp). We may readjust the parameters of the nuclear model by stiffening the EoS of isospin-symmetric matter for densities above twice the saturation density, where hyperons set in. We do that by changing the quartic isoscalar-vector self-interaction (with reducing coupling $\zeta$), which stiffens the EoS at high densities[3,4]. The FSU2H allowing for hyperons, FSU2H(hyp), successfully fulfills the $2M_\odot$ mass limit with moderate radii for the star (see Fig. 1 (right)), while the base nuclear model still reproduces the properties of nuclear matter and nuclei, with $E_{\rm sym}(n_0) = 30.5$ MeV and $L = 44.5$ MeV[4]. The parameter set of FSU2R(nuc) and FSU2H(hyp) and some nuclear matter properties can be found in Refs. 4, 15.

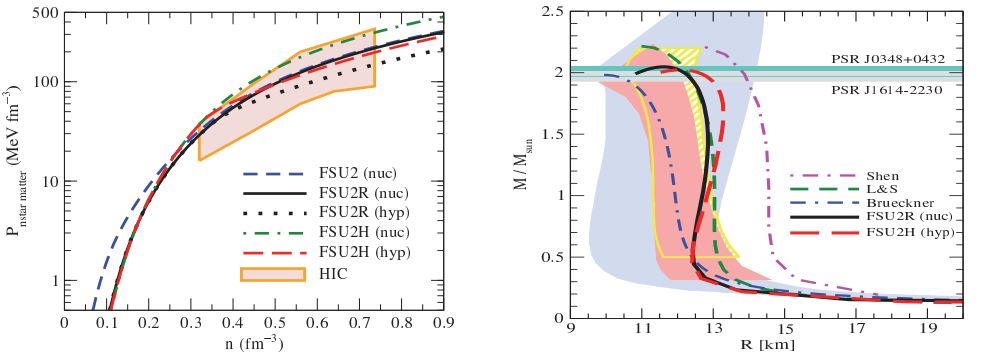

Fig. 1. Left: Pressure of $\beta$-stable neutron star matter as a function of baryon number density for different models[15], with the colored area being compatible with HiCs[12]. Right: Mass versus radius for neutron stars from the models FSU2R and FSU2H[4] together with Shen[16], L&S[17], Brueckner[18]. The thin horizontal bands indicate the $2M_{\odot}$ observations[5,6], the vertical blue band is the region constrained from chiral nuclear interaction[19], the vertical red band is the area derived from five quiescent low-mass X-ray binaries and five photospheric radius expansion X-ray bursters[20], and the vertical striped yellow band is the mass-radius constraint from cooling tails of type-I X-ray bursts in three low-mass X-ray binaries[21].

## 3. Cooling of neutron stars

We first consider the thermal evolution of neutron stars without taking into account any sort of pairing (neither in the core nor in the crust). This is done in Figs. 2 and 3 for the FSU2R and FSU2H models, with and without hyperons. The figures also display the observed surface temperature versus the age of a set of prominent neutron stars, including that of the remnant in Cas A. The nucleonic DU and hyperonic DU thresholds from each microscopic model are given in Table 1 for low-mass to high-mass neutron stars. When DU reactions are allowed in the model, that is, the DU threshold takes place for densities below the central density of the star, they lead to an enhanced cooling of the star, thus to a fast cooling.

Several conclusions can be drawn from the comparison between the different plots in Figs. 2 and 3 together with the analysis of Table 1:

- Low-mass stars of $1.4M_{\odot}$ when only nucleons are considered: the cooling pattern of a $1.4M_{\odot}$ star is slow for FSU2R(nuc) and FSU2H(nuc). This is mainly due to the density dependence of the symmetry energy around saturation and, hence, to the symmetry energy slope parameter ($L$). The smaller the value of $L$ is, the less protons are produced and, thus, the DU process appears at higher densities, making the cooling less efficient.
- High-mass stars of $1.8-2M_{\odot}$ when only nucleons are considered: the different behaviours exhibited by the cooling curves of FSU2R(nuc) (fast cooling) and FSU2H(nuc) (slow cooling) are correlated with the different values of the central densities in these stars, as seen in Table 1. The stiffer the EoS is, the lower central densities are and the slower the cooling is.

Table 1. The nucleonic DU thresholds for FSU2(nuc), FSU2R(nuc), FSU2R(hyp), FSU2H(nuc) and FSU2H(hyp) models, together with the hyperonic DU threshold for each of them. Also shown is the central density $n_c$ for three selected neutron star masses.[15]

| Models | $DU_{th}$ (fm$^{-3}$) | hyp $DU_{th}$ (fm$^{-3}$) | $1.4M_\odot$ $n_c$ (fm$^{-3}$) | $1.76M_\odot$ $n_c$ (fm$^{-3}$) | $2.0M_\odot$ $n_c$ (fm$^{-3}$) |
|---|---|---|---|---|---|
| FSU2 (nuc) | 0.21 | — | 0.35 | 0.47 | 0.64 |
| FSU2R (nuc) | 0.61 | — | 0.39 | 0.51 | 0.72 |
| FSU2H (nuc) | 0.61 | — | 0.34 | 0.39 | 0.45 |
| FSU2R (hyp) | 0.57 | 0.37 | 0.40 | 0.87 | — |
| FSU2H (hyp) | 0.52 | 0.34 | 0.34 | 0.44 | 0.71 |

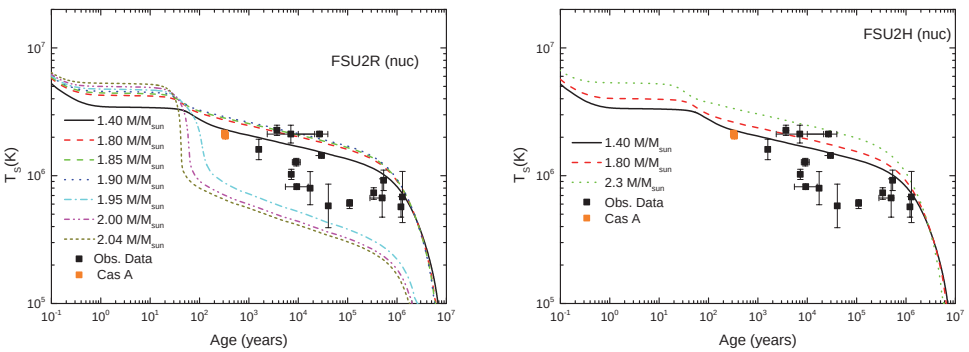

Fig. 2. Surface temperature as a function of the stellar age for different neutron star masses for FSU2R(nuc) (left) and FSU2H(nuc) (right). Also shown are different observed thermal data.[15]

- The inclusion of hyperons in medium- to heavy-mass stars speeds up the cooling (compare in Figs. 2 and 3 FSU2R(nuc) and FSU2R(hyp) or FSU2H(nuc) and FSU2H(hyp)). On the one hand, this is because the presence of hyperons (mostly $\Lambda$ particles) reduces the neutron fraction at a given baryon number density and, consequently, the DU restriction $\vec{k}_{Fn} = \vec{k}_{Fp} + \vec{k}_{Fe}$, can be fulfilled at a lower density. Here $k_{Fn}$, $k_{Fp}$ and $k_{Fe}$ are the Fermi momenta of the neutron, proton and electron, respectively. On the other hand, the appearance of hyperons softens the EoS, thus FSU2R(hyp) and FSU2H(hyp) produce stars with higher central densities than the nucleonic counterparts, so that they may overcome the DU threshold (see Table 1).

We now investigate the effect of neutron superfluidity and proton superconductivity on the cooling of neutron stars. We study the two most relevant cases, the FSU2R(nuc) and the FSU2H(hyp) models, which are the ones that best reproduce the observed data on cooling in Figs. 2 and 3. On the one hand, the introduction of a superfluidity (conductivity) gap in the energy spectrum of baryons reduces the neutrino reaction rates, leading to a sharp drop of neutrino emissivity after the matter temperature drops below the pairing critical temperature. On the

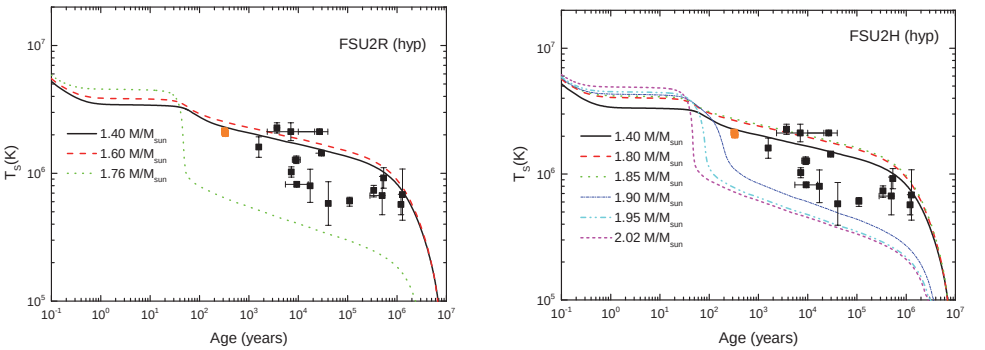

Fig. 3. Surface temperature as a function of the stellar age for different neutron star masses for FSU2R(hyp) (left) and FSU2H(hyp) (right). Also shown are different observed thermal data.[15]

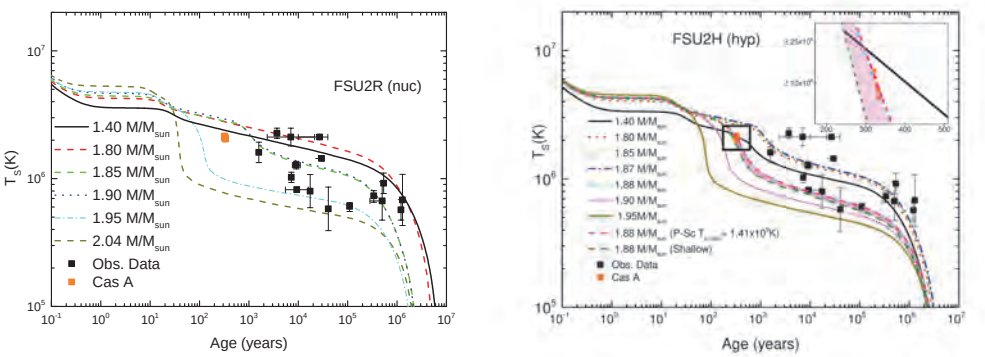

Fig. 4. Surface temperature as a function of the stellar age for different neutron star masses for FSU2R(nuc) (left) and FSU2H(hyp) (right) with medium proton pairing and neutron pairing.[15]

other hand, a new transient neutrino emission process appears, commonly known as pair breaking-formation (PBF) process, where two quasi-baryons with similar anti-parallel momenta annihilate into a neutrino pair.

The analysis of the plots in Fig. 4 indicates that the inclusion of medium proton pairing, in addition to the neutron pairing, improves the agreement of the cooling curves of the FSU2R(nuc) and FSU2H(hyp) models with data, specially for Cas A in the case of the FSU2H(hyp) model, as can be seen in the inset of Fig. 4 (right). Note that in a very recent publication[22], Posselt and Pavlov have revised the Cas A cooling data, concluding that the cooling of this object could be slower. In other words, we find that a shallow/medium proton superconductivity does not lead to an over-suppression of the DU processes, a fact that, combined with miscroscopic models with a soft nuclear symmetry energy, leads to an optimum agreement with observations. However, the calculations favour rather large stellar masses to explain the observed colder stars with surface temperatures $T \lesssim 10^6$ K.

BlackHoleCam is a project funded by a European Research Council *Synergy Grant* to build a complete astrophysical description of nearby supermassive black holes by using a combination of radio imaging, pulsar observations, stellar astrometry and general relativistic magneto-hydrodynamic models. BlackHoleCam* scientists are active partners of the Event Horizon Telescope Consortium†. In this talk I will discuss the use of pulsars orbiting Sagittarius A* for tests of General Relativity, the current difficulties in detecting such sources, recent results from the Galactic Centre magnetar PSR J1745−2900 and how BlackHoleCam aims to search for undiscovered pulsars in the Galactic Centre.

*Keywords*: Pulsars; Black Holes; Gravity Tests.

## 1. The science case for observing pulsars orbiting Sagittarius A*

For over 40 years observations double neutron star systems − the collapsed and degenerate remnants of massive stars − where one, or both, stars are active radio pulsars have demonstrated that they form exceptional natural "laboratories" for precision tests of theories of gravitation[1,2]. In this vein, a pulsar in a close orbit around the supermassive black hole at the centre of our Galaxy (Sagittarius A* − Sgr A* for short) would be at the apex of gravity experiments made possible using pulsars[3,4].

*www.blackholecam.org
†www.eventhorizontelescope.org

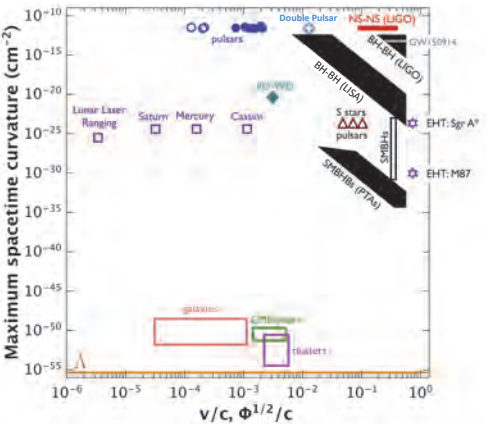

Fig. 1. Parameter space of observations and tests of gravity. On the x-axis, $v$ denotes the typical velocity of the system's components while $\Phi$ denotes the gravitational potential being probed by photons propagating in the corresponding spacetime. On the y-axis the maximum spacetime curvature (taken at the horizon for black holes) in the system is indicated as a measure of how much the system deviates from flat spacetime. Filled areas indicate gravitational wave tests, while hollow areas stand for quasi-stationary tests, including accretion onto compact objects. The rightmost hollow blue circle stands for the Shapiro delay test in the double pulsar. Figure and caption reproduced from Ref. 6 with the kind permission of Wex and Kramer.

Such a system will allow the fundamental predictions of black-hole properties in General Relativity (GR) to be tested; properties that Advanced LIGO, which measures the strongly dynamical regime of a merger, potentially cannot[5]. These include the *no-hair theorem* and the *cosmic censorship conjecture*[3,4]. For example, the latter is tested through measurements of frame dragging caused by the spinning black hole, which manifests itself as a contribution to the precession of the pulsar orbit. A Kerr black hole should exhibit a dimensionless spin parameter $\chi$ which is no larger than unity; a spin parameter greater would be in conflict with GR posing a direct contest to the theory. Fig. 1 shows how pulsar tests fit into the relativistic regime of other gravity tests past and present. In Fig. 2 (*l*eft panel) from Ref. 4 the expected signature of the black hole quadrupole moment in pulsar timing residuals for a putative pulsar closely orbiting Sgr A* is displayed. Ref. 7 have shown that by combining measurements of the black hole spin from stellar astrometry, pulsar timing and interferometric imaging of the black hole shadow, an unbiased and quantitative test of the no-hair theorem is possible (Fig. 2 *right* panel).

## 2. Galactic Centre pulsar searches

Over the last couple of decades a number of searches of the inner tens of parsecs have taken place[8–12]. In 2013, the Galactic Centre (GC) pulsar population[a] was

[a]Here we define the GC pulsar population as those with pulses detected in radio at a projected offset of less than 0.5° (∼73 pc) from Sgr A*.

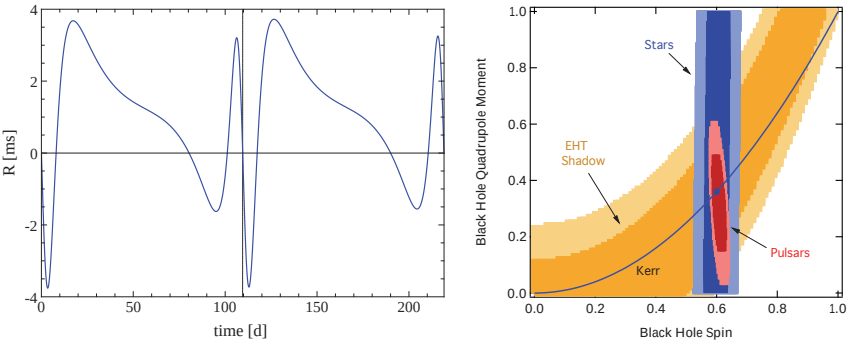

Fig. 2. (*left*) A simulation showing the effect of the quadrupole moment of Sgr A* "imprinted" upon pulsar timing residuals over two orbital cycles. Here an orbital period of 0.3 yr, an eccentricity of 0.5 and a dimensionless black hole spin parameter of unity were assumed. Figure reproduced from Ref. 4. (*right*) Comparison of the posterior likelihood of measuring the spin and quadrupole moment of Sgr A* using the orbits of two stars (blue), timing of three periapsis passages of a normal pulsar (red) and the shape of the black hole shadow from radio interferometric imaging (gold). The solid curve shows the expected relation between the two quantities for a Kerr metric. The filled circle marks the assumed spin and quadrupole moment. Figure reproduced from Ref. 7.

brought to a total of six with the detection of PSR J1745−2900, first through its gamma ray emission[13,14] and then finally in radio[15,16].

As radio telescope hardware and analysis techniques are improved, GC pulsar searches are carving out additional areas of parameter space neglected by previous searches. An example is the progression to higher than "normal" pulsar observing frequencies ($f_{\rm obs} \gtrsim 10\,{\rm GHz}$) where the deleterious effects of interstellar dispersion and scattering (effects that are at their highest in GC) are reduced. Unfortunately, improvements in sensitivity by choosing higher frequencies are limited by the steep spectrum of pulsar emission, where detection signal-to-noise ratio S/N is typically $\propto f_{\rm obs}^{\sim -1.7}$. This is one case where competing selection effects affect the performance of GC pulsar searches (Table 1). In general, higher observing frequencies and longer integration lengths $T_{\rm obs}$ (given the large distance of the GC) are more favourable, however this predisposes searches to flatter spectrum isolated pulsars. Binary pulsar searches can become computationally prohibitive above certain $T_{\rm obs}$ where even single parameter acceleration search computations $C_a$ scale with $T_{\rm obs}^3$.

## 3. BlackHoleCam pulsar work

BlackHoleCam[18], and members of the Event Horizon Telescope (EHT) Consortium, aim to tackle these observational constraints by using the largest and most sensitive telescopes operating at millimetre wavelengths which form elements of the EHT telescope. Because both EHT VLBI imaging and pulsar observations can utilise the same raw data product from each array element, EHT VLBI and pulsar observations can be commensal.

Table 1. Competing observational selection effects for GC radio pulsar searches. Pulse broadening effects, such as dispersion smearing $\tau_{\rm ch}$, scatter broadening $\tau_{\rm s}$ and acceleration broadening $\tau_a$, add in quadrature to the intrinsic pulse width $W$ making $W_{\rm eff}$, which scales with the detection signal-to-noise ratio as S/N $\propto \sqrt{(P - W_{\rm eff})/W_{\rm eff}}$ where $P$ is the spin period. ✓ indicates favourable observational configurations while ✗ are unfavourable.

| Observing frequency related | Higher $f_{\rm obs}$ | Lower $f_{\rm obs}$ |
|---|---|---|
| Intra-channel pulse dispersion smearing ($\tau_{\rm ch} \propto f_{\rm obs}^{-3}$) | ✓ | ✗ |
| Pulse scattering broadening ($\tau_{\rm s} \propto f_{\rm obs}^{-3.8}$) | ✓ | ✗ |
| Intense GC background continuum emission[17] (S/N $\propto f_{\rm obs}^{-0.8}$) | ✓ | ✗ |
| Pulsar spectra (S/N $\propto f_{\rm obs}^{\sim -1.7}$) | ✗ | ✓ |
| **Integration length related** | **Longer $T_{\rm obs}$** | **Shorter $T_{\rm obs}$** |
| GC distance (S/N $\propto \sqrt{T_{\rm obs}}$) | ✓ | ✗ |
| Pulse broadening from acceleration ($\tau_a \propto T_{\rm obs}^2$) | ✗ | ✓ |
| Pulse broadening from jerk ($\tau_j \propto T_{\rm obs}^3$) | ✗ | ✓ |
| Computational operations for acceleration search ($C_a \propto T_{\rm obs}^3$) | ✗ | ✓ |

Thus far, pulsar search efforts have concentrated on analysing data from the single most sensitive element of the EHT: "fully phased" ALMA. In the future we can envisage using a phased array of the largest components of the EHT to further increase sensitivity or to mitigate site specific interference contamination.

We study the gravitational lensing by a Kerr-Sen black hole spacetime which arises a solution to the low-energy effective field theory for four-dimensional heterotic string theory. A closed form expression of the deflection angle of light rays lensed by the Kerr-Sen black hole is derived as a function of impact parameter, spin and charge in the equatorial plane of the black hole. It is observed that charge parameter behaves differently from the spin parameter for the photons in direct and retrograde orbits around the black hole. The deflection angle becomes larger in strong field limit with an increment in the value of charge parameter and it is observed that this effect is more perceptible in case of the direct orbits as compared to the retro orbits. The results obtained are also compared with the corresponding cases of well known Kerr black hole in general relativity (GR).

*Keywords*: Gravitational lensing; Kerr-Sen black hole; Heterotic string theory; Deflection angle.

## 1. Introduction

One of the consequences of Einstein's general relativity (GR) is that the light rays passing a massive body are deflected by the virtue of gravity and the resulting phenomenon is known as Gravitational lensing[2] (GL), as first observed by Eddington during the solar eclipse of 1919. The GL, theory and observations, is one of the most important areas in modern astronomy[3] and it also provides a clean and unique probe of the dark matter at all the distance scales since it is independent of the nature and physical state of the lensing mass[4].

The main objective of the present work is to study the GL by a Kerr-Sen BH in equatorial plane to have exact closed-form solutions for the deflection angle of light such that both the strong and weak field limits are satisfied[5–11].

In the next section, structure of KSBH spacetime is discussed alongwith the first integrals of geodesic equations for null geodesics. The critical parameters for obtaining the exact deflection angles are then calculated in section 3. The closed-form expression for the deflection angle as a function of impact parameter and BH spin is derived in section 4. Finally, the results are summarised in last section.

## 2. Kerr-Sen BH Spacetime

The Einstein metric for KSBH,

$$ds^2 = -\left(\frac{\Delta - a^2\sin^2\theta}{\Sigma}\right)dt^2 + \frac{\Sigma}{\Delta}dr^2 - \frac{4\mu a r\cosh^2\alpha\sin^2\theta}{\Sigma}dtd\phi + \Sigma d\theta^2 + \frac{\Xi\sin^2\theta}{\Sigma}d\phi^2, \tag{1}$$

where the metric functions are described as, $\Delta = r^2 - 2\mu r + a^2$, $\Sigma = r^2 + a^2\cos^2\theta + 2\mu r\sinh^2\alpha$, and $\Xi = \left(r^2 + 2\mu r\sinh^2\alpha + a^2\right)^2 - a^2\Delta\sin^2\theta$. The parameters $\mu$, $\alpha$ and $a$ are related to the physical mass $M$, charge $Q$ and angular momentum $J$ as follows,

$$M = \frac{\mu}{2}(1+\cosh 2\alpha), \qquad Q = \frac{\mu}{\sqrt{2}}\sinh^2 2\alpha, \qquad J = \frac{a\mu}{2}(1+\cosh 2\alpha)\,. \tag{2}$$

For a nonextremal BH, there exist two horizons, determined by $\Delta(r) = 0$ as,

$$r_\pm = M - \frac{Q^2}{2M} \pm \sqrt{\left(M - \frac{Q^2}{2M}\right)^2 - a^2}\,, \tag{3}$$

where $r_+$ and $r_-$ represent the outer and the inner horizons of the BH respectively.

### 2.1. *First Integrals of Geodesic Equations*

The first integral of radial and latitudinal coordinates (i.e. $r$ and $\phi$) for null geodesics[13] can be obtained as,

$$\dot{r}^2 \;=\; L^2\left(\frac{1}{b^2} + \frac{a^2}{b^2 r(r+x)} + \frac{2Ma^2}{b^2 r(r+x)^2} - \frac{4Ma}{b_s r(r+x)^2} - \frac{1}{r(r+x)} + \frac{2M}{r(r+x)^2}\right) \tag{4}$$

and

$$\dot{\phi} \;=\; \frac{L}{\Delta}\left(1 - \frac{2M}{r+x} + \frac{2Ma}{r+x}\frac{E}{L}\right), \tag{5}$$

where $x = Q^2/2M$ and $M = GM_\star/c^2$ (gravitational radius) with $M_\star$ defined as the physical mass of the BH. The time derivatives in 4 and 5 are taken with respect to the coordinate time variable $t$ defined as, $t = c\tau$ where $\tau$ represents the physical time with,

$$b_s \;=\; s\left|\frac{L}{E}\right| \equiv sb. \tag{6}$$

## 3. Critical Parameters

Using the change of variable as $u = 1/r$, the orbit equation can be obtained from Eq. (5) and Eq. (4) as,

$$\left(\frac{du}{d\phi}\right)^2 = \frac{\left(a^2u^2 + (1-xu)(1-2Mu)\right)^2}{\left(1-2Mu+2Mau/b_s\right)^2(1-xu)}\mathcal{B}(u), \tag{7}$$

where,

$$\mathcal{B}(u) = \frac{(1-xu)}{b^2} + \left(\frac{a^2}{b^2}-1\right)u^2 + \left(1-\frac{a}{b_s}\right)^2 2Mu^3. \tag{8}$$

We will further consider the case of one real negative root $u_1$ and two real distinct positive roots $u_2$ and $u_3$ given in terms of two intermediate constants $P$ and $Q$ that allow one to line up the order such as, $u_1 < u_2 < u_3$, $u_1 = \frac{P-2M-Q}{4Mr_0}$, $u_2 = \frac{1}{r_0}$, $u_3 = \frac{P-2M+Q}{4Mr_0}$.

By comparing the coefficients in $\mathcal{B}$(u) to those in the original polynomial in Eq. (8), one can first obtain the following relationship between $P$ and $\{a, b, s, r_0\}$,

$$P = r_0\frac{\left(1-\frac{a}{b_s}\right)}{\left(1+\frac{a}{b_s}\right)}. \tag{9}$$

It leads to the following relation between the critical parameters,

$$r_{sc} = 3M\frac{\left(1-\frac{a}{b_s}\right)}{\left(1+\frac{a}{b_s}\right)}. \tag{10}$$

$$r_0 = \frac{2\Theta}{\sqrt{3}}\sqrt{\left(b^2\left(1-\frac{a^2}{b^2}\right)+\frac{x^2}{3}\right)}. \tag{11}$$

where,

$$\Theta = \cos\left[\frac{1}{3}\arccos\left\{-\frac{\sqrt{3}}{18}\left(\frac{54Mb^2\left(1-\frac{a}{b_s}\right)^2 - 9b^2x\left(1-\frac{a^2}{b^2}\right) - 2x^3}{\left(b^2\left(1-\frac{a^2}{b^2}\right)+\frac{x^2}{3}\right)^{3/2}}\right)\right\}\right]. \tag{12}$$

The above relation among the distance of closest approach ($r_0$) and the invariant impact parameter is extremely important in Strong Deflection Limit (SDL) as well as Weak Deflection Limit (WDL) series expansions in terms of the invariant normalised quantity $b'$. The expression also reduces to the corresponding Schwarzschild limits when charge and spin parameters are zero.

In the strong deflection limit, $P = 3M$and the following expressions involving the critical quantities:

$$r_{sc} = 3M\frac{\left(1-\frac{a}{b_{sc}}\right)}{\left(1+\frac{a}{b_{sc}}\right)} \tag{13}$$

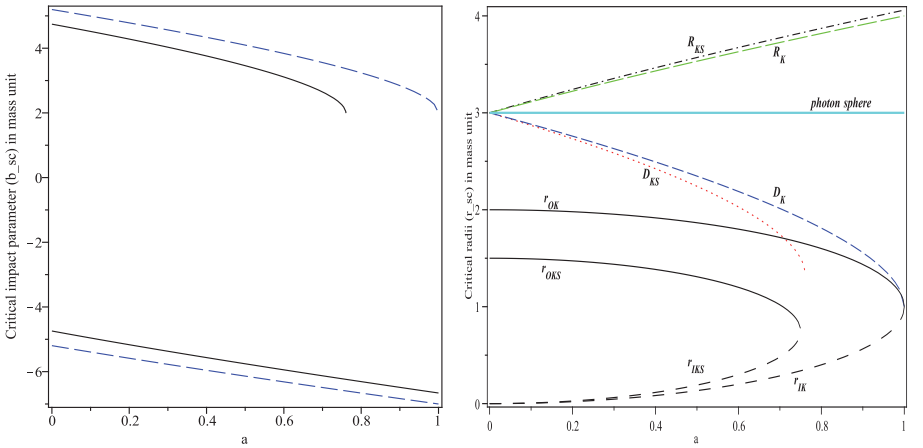

Fig. 1. ***Left Panel:*** Here solid and dashed lines represent the critical impact parameter (in mass unit) for KSBH and KBH respectively with $x = 0.5$ for KSBH; further upper portion of the plot corresponds to $b_{+c}$ solutions while the lower portion of the plot corresponds to the $b_{-c}$ solutions; ***Right Panle:*** Variation of critical radii in mass units with spin parameter $a$. Here $D_K$ and $D_{KS}$ depict the corresponding radii for direct orbits and $R_K$ and $R_{KS}$ depict the corresponding radii for retro orbits of KBH and KSBH respectively. Lower portion of the plot represents inner and outer horizons for KBH and KSBH.

$$b_{sc} = -a + 2s\sqrt{3M(3M-x)}\cos\left[\frac{1}{3}\arccos\left(\frac{-3sa}{3M-x}\sqrt{\frac{3M}{3M-x}}\right)\right]. \tag{14}$$

and

$$r_{sc} = x + \frac{2}{3}(3M-x)\left[1+\cos\left(\frac{2}{3}\arccos\left(\frac{-3sa}{3M-x}\sqrt{\frac{3M}{3M-x}}\right)\right)\right]. \tag{15}$$

## 4. Bending Angle of Light Rays

Now if one considers a light ray starting in an asymptotic region and approaching a BH, with $r_0$ as distance of its closest approach. The exact expression for the bending angle can easily be expressed in terms of elliptical integrals of third kind[5] as,

$$\alpha = -\pi + \frac{4}{1-\omega_s}\sqrt{\frac{r_0}{Q}}\Big\{\Omega_+\Big[\Pi(n_+,k) - \Pi(n_+,\psi,k)\Big] + \Omega_-\Big[\Pi(n_-,k) - \Pi(n_-,\psi,k)\Big]\Big\}. \tag{16}$$

where $\Pi(n_\pm,k)$ and $\Pi(n_\pm,\psi,k)$ are the complete and the incomplete elliptic integrals of the third kind respectively. The argument $k^2$ is defined through the elliptic integral as usual in the range $0 \le k^2 \le 1$. The other variables in the above expression are defined as, $\Omega_\pm = \frac{C_\pm}{u_\pm - u_1}$, $k^2 = \frac{Q-P+6M}{2Q}$, $\psi = \arcsin\sqrt{\frac{Q+2M-P}{Q+6M-P}}$ and $n_\pm = \frac{u_2-u_1}{u_\pm-u_1}$.

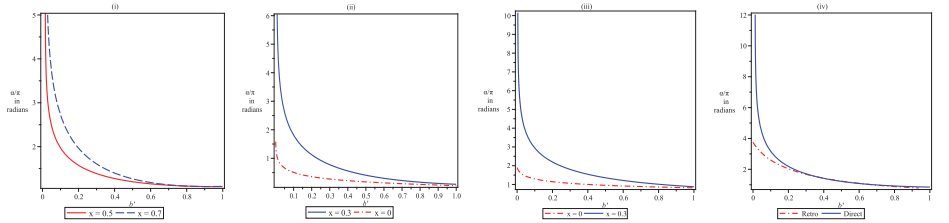

Fig. 2. Exact deflection angle as a function of normalised impact parameter with spin parameter value $a = 0.5$. Left section of the above plots where $b' \to 0$ corresponds to the strong deflection limit while the right section where $b' \to 1$ corresponds to weak deflection limit.

## 5. Summary and Conclusions

We have studied the GL for a KSBH in its equatorial plane and derived an exact expression for the bending angle of light. The effect of frame-dragging on the bending angle of photons in such cases has previously been discussed for KBH[5]. The additional charge parameter behaves similar to the spin parameter for direct orbiting photons but oppositely for retrograde orbiting photons as the bending angle increases in either case on increasing the numerical value of the charge parameter. Though this increment is still much larger for direct orbiting photons. This difference in the bending angle can clearly be visible through the shifts of the corresponding relativistic images. In order to study this shift in relativistic images, one needs to study the series expansion of the bending angle in weak as well as strong deflection limits. Hence, as a further work we will derive the series expansion of the above obtained bending angle formulas in both the strong and weak field limits. This will allow an easier comparison with similar results obtained for other BH types.

## Acknowledgments

The authors RU and HN would like to thank Science and Engineering Research Board (SERB), New Delhi for financial support through grant no. EMR/2017/000339. The authors RU and HN are also thankful to IUCAA, Pune (where a part of the work was completed) for support in form of academic visits under its Associateship programme. RU and HN would also like to thank Prof. Philippe Jetzer for the study visit to Physik-Institut, University of Zurich, Switzerland (where a part of this work was initially carried out) and for the hospitality during the stay there.

# Reconstructing the metric of the local Universe from number counts observations

Sergio Andrés Vallejo Peña[1,3,†] and Antonio Enea Romano[1,2,3]

[1] *Instituto de Fisica, Universidad de Antioquia, A.A.1226, Medellin, Colombia*

Number counts observations available with new surveys such as the Euclid mission will be an important source of information about the metric of the Universe. We compute the low red-shift expansion for the density contrast using an exact spherically symmetric solution in presence of a cosmological constant. At low red-shift the expansion is more precise than linear perturbation theory prediction. We then use the local expansion to reconstruct the metric from the monopole of the density contrast. We test the inversion method using numerical calculations and find a good agreement within the regime of validity of the red-shift expansion. The method could be applied to observational data to reconstruct the metric of the local Universe with a level of precision higher than the one achievable using perturbation theory.

*Keywords*: Number counts, density contrast, redshift, metric, local Universe.

## 1. Introduction

The standard cosmological model is based on the assumption that the Universe is homogeneous and isotropic on sufficiently larges scales, and is confirmed by different observations such as for example the cosmic microwave background (CMB) radiation[1] or of galaxy catalogues. However the presence of structure at smaller scales can affect local observations as it was shown in Ref. 2, and it is therefore important to understand its consequences. The effects of inhomogeneities on cosmological observables have been studied in different cases, such as dark energy, the luminosity distance[3–5] or the expansion scalar.[6] These effects are due to the fact that spatial inhomogeneities change the energy of photons, modifying the cosmological red-shift due to the Universe expansion. As a consequence some errors are produced in the estimation of parameters based on homogeneous cosmological models.

One important source of information about the Universe are galaxy catalogues since they allow to map the local density field. Since we can only measure the red-shift of astrophysical objects for which other distance measurement methods such as stellar parallax cannot be applied, it is important to take into account the effects of these inhomogeneities on the metric in order to compute self-consistently the density in red-shift space. This is particularly important when trying to determine the metric of the Universe.

## 2. Modeling the local Universe

In order to model the monopole component of the local structure we use the LTB solution[7–11]

$$ds^2 = -dt^2 + \frac{R'(t,r)^2}{1+2\,E(r)}dr^2 + R(t,r)^2 d\Omega^2\,, \tag{1}$$

where $E(r)$ is an arbitrary function of $r$, and $R'(t,r) = \partial_r R(t,r)$. The analytical solution of Einstein's equations can be derived[12,13] if we introduce a new function $k(r)$, and a new coordinate $\eta = \eta(t,r)$ given by

$$\frac{\partial\eta}{\partial t}|_r = \frac{r}{R} = \frac{1}{a}\,, \quad k(r) = -\frac{2E(r)}{r^2}\,. \tag{2}$$

The Einstein equations imply

$$\left(\frac{\partial a}{\partial \eta}\right)^2 = -k(r)a^2 + \frac{\rho_0(r)}{3}a + \frac{\Lambda}{3}a^4\,, \tag{3}$$

where $\rho_0(r)$ is an arbitrary function of $r$, and we adopt a system of units in which $c = 8\pi G = 1$. Without any loss of generality we adopt the coordinate system in which $\rho_0(r)$ is a constant, which is known as the FLRW gauge. The solution to the above equation can be written in the form[14]

$$a(\eta,r) = \frac{\rho_0}{k(r) + 3\wp(\frac{\eta}{2}; g_2(r), g_3(r))}\,. \tag{4}$$

where $\wp(x; g_2, g_3)$ is the Weierstrass elliptic function and

$$g_2(r) = \frac{4}{3}k(r)^2\,, \quad g_3(r) = \frac{4}{27}\left(2k(r)^3 - \Lambda\rho_0^2\right). \tag{5}$$

The relation between $t$ and $\eta$ can be found by integrating Eq. (2) and is given by[6]

$$t(\eta,r) = \frac{2\rho_0}{3\wp'\left(\wp^{-1}\left(-\frac{k(r)}{3}\right)\right)}\left[\ln\left(\frac{\sigma\left(\frac{\eta}{2} - \wp^{-1}\left(-\frac{k(r)}{3}\right)\right)}{\sigma\left(\frac{\eta}{2} + \wp^{-1}\left(-\frac{k(r)}{3}\right)\right)}\right) + \eta\zeta\left(\wp^{-1}\left(-\frac{k(r)}{3}\right)\right)\right].$$

The radial null geodesic equations take the form[15]

$$\frac{d\eta}{dz} = -\frac{\partial_r t(\eta,r) + G(\eta,r)}{(1+z)\partial_\eta G(\eta,r)}\,, \qquad \frac{dr}{dz} = \frac{a(\eta,r)}{(1+z)\partial_\eta G(\eta,r)}\,, \tag{6}$$

where

$$G(\eta,r) \equiv \frac{R'(t(\eta,r),r)}{\sqrt{1-k(r)r^2}}\,.$$

The density profile is given by

$$\rho(\eta,r) = \rho(t(\eta,r),r) = \frac{\rho_0}{a(\eta,r)^2 R'(t(\eta,r),r)}\,. \tag{7}$$

The background density of the universe is given by the sub-horizon volume average of $\rho$ on constant time slices

$$\overline{\rho}(t) = \frac{\int_V \rho(t,r)dV}{\int_V dV} = \frac{\int_0^{r_{Hor}(t)} \rho(t,r)\frac{R(t,r)^2 R'(t,r)}{\sqrt{1-k(r)r^2}}dr}{\int_0^{r_{Hor}(t)} \frac{R(t,r)^2 R'(t,r)}{\sqrt{1-k(r)r^2}}dr}\,, \tag{8}$$

where the upper limit of the integrals $r_{Hor}(t)$ is the comoving horizon as a function of time, and determines the region of space causally connected with the central observer at time $t$. We can then evaluate $\overline{\rho}(t)$ at the time $t(z)$ corresponding to a given redshift $z$, i.e. the time along null radial geodesics, and define the background value of $\rho$ at redshift $z$ as $\overline{\rho}(z) \equiv \overline{\rho}(t(z))$. We can then define the density contrast

$$\delta(z) = \frac{\rho(z)}{\overline{\rho}(z)} - 1\,. \tag{9}$$

If the size of the local inhomogeneity is sufficiently smaller than the volume over which the integral in Eq. (8) is performed then $\overline{\rho}$ will get most of its contribution from the asymptotically homogeneous region and the average density will be well approximated by the asymptotic density

$$\overline{\rho}(z) = 3(H_0^b)^2\Omega_M^b(1+z)^3\,; \quad H_0^b = \overline{H}(0)\,, \quad \Omega_M^b = \frac{\overline{\rho}(0)}{3(H_0^b)^2}\,, \tag{10}$$

where the upper-script $^b$ stands for background and $H$ is the expansion scalar $H(t,r)$[6].

## 3. Reconstruction of the local metric

In order to reconstruct the metric of the local universe from the density contrast we expand the curvature function $k(r)$ as

$$k(r) = k_0 + k_1 r + k_2 r^2 + \cdots\,. \tag{11}$$

We also expand the solution of the geodesic equations according to

$$r(z) = r_1 z + r_2 z^2 + r_3 z^3 + \cdots\,, \quad \eta(z) = \eta_0 + \eta_1 z + \eta_2 z^2 + \cdots\,. \tag{12}$$

We expand $t(\eta, r)$ as

$$t(\eta,r) = t_0(r) + a(\eta_0,r)(\eta-\eta_0) + \frac{1}{2}\partial_\eta a(\eta_0,r)(\eta-\eta_0)^2 + \cdots\,, \tag{13}$$

where $t_0(r) \equiv t(\eta_0, r)$. We now define the dimensionless parameters $K_n \equiv k_n(a_0H_0)^{-(n+2)}$ and applying the chain rule to $t_0'(0)$ and $t_0''(0)$ we find

$$t_0'(0) = \frac{\partial t_0(r)}{\partial k}\frac{\partial k}{\partial r}|_{r=0} = a_0\alpha K_1\,, \quad t_0''(0) = a_0(a_0H_0)(\beta K_1^2 + 2\alpha K_2)\,, \tag{14}$$

where $\alpha$ and $\beta$ are dimensionless parameters.

We will consider the case in which $k_0 = 0$, which is enough to understand qualitatively the effects of the inhomogeneity, since this term corresponds to the homogeneous component of the curvature function $k(r)$. Expanding the density contrast up to second order we find

$$\delta(z) = \delta_0 + \delta_1 z + \delta_2 z^2 \,, \tag{15}$$

$$\delta_0 = \left(\frac{H_0}{H_0^b}\right)^2 \left(\frac{\Omega_M}{\Omega_M^b} - 1\right) \,, \tag{16}$$

$$\delta_1 = \left(\frac{H_0}{H_0^b}\right)^2 \frac{4K_1\,(3\alpha\Omega_M + 1)}{3\Omega_M^b} \,, \tag{17}$$

$$\begin{aligned}\delta_2 = &-\left(\frac{H_0}{H_0^b}\right)^2 \frac{1}{36\Omega_\Lambda\Omega_M\Omega_M^b}\Bigg[18K_1\Omega_\Lambda\Omega_M^2\,(3\alpha\Omega_M + 2) \\ &+ K_1^2\Bigg\{\Omega_\Lambda\Big(-18\left(25\alpha^2 - 4\alpha + 5\beta\right)\Omega_M^2 + 81\alpha^2\Omega_M^3 - 300\alpha\Omega_M - 40\Big) \\ &+ 20\,(\Omega_M - \zeta_0)\Bigg\} - 60K_2\Omega_\Lambda\Omega_M\,(3\alpha\Omega_M + 1)\Bigg] \,.\end{aligned} \tag{18}$$

From these equations we can finally obtain

$$k(r) \approx K_1(a_0H_0)^3 r + K_2(a_0H_0)^4 r^2 \,, \tag{19}$$

$$K_1 = \left(\frac{H_0^b}{H_0}\right)^2 \frac{3\Omega_M^b\delta_1}{4\,(3\alpha\Omega_M + 1)} \,, \tag{20}$$

$$\begin{aligned}K_2 = &\left(\frac{H_0^b}{H_0}\right)^4 \frac{3\Omega_M^b}{320\Omega_\Lambda\Omega_M\,(3\alpha\Omega_M + 1)^3}\Bigg[8\Omega_\Lambda\Omega_M\,(3\alpha\Omega_M + 1)\Bigg\{9\alpha\delta_1\Omega_M^2 \\ &+ 6\,(4\alpha\delta_2 + \delta_1)\,\Omega_M + 8\delta_2\Bigg\} + \delta_1^2\Omega_M^b\left(\frac{H_0}{H_0^b}\right)^2\Bigg\{\Omega_\Lambda\Big(-18\left(25\alpha^2 - 4\alpha\right. \\ &\left. + 5\beta\right)\Omega_M^2 + 81\alpha^2\Omega_M^3 - 300\alpha\Omega_M - 40\Big) + 20\,(\Omega_M - \zeta_0)\Bigg\}\Bigg] \,.\end{aligned} \tag{21}$$

In the above equations we have introduced the parameters $a_0$, $H_0$, $\Omega_M$, $\Omega_\Lambda$, $T_0$ and $\zeta_0$ according to their corresponding definitions given in Refs. 14, 6.

## 4. Testing the accuracy of the method

In order to test the formulae we have derived we chose models defined by the spatial curvature function $k(r)$ according to

$$k(r) = \pm(a_0H_0)^2\frac{a_0H_0r}{5}\Big[1 - \tanh\left(2a_0H_0r\right)\Big] \,. \tag{22}$$

We also compare our formula for the density contrast with the linear perturbation theory prediction that around a flat homogeneous background[16]

$$\delta(z) \approx -3\delta H(z)(\Omega_M^b)^{-0.55} \,. \tag{23}$$

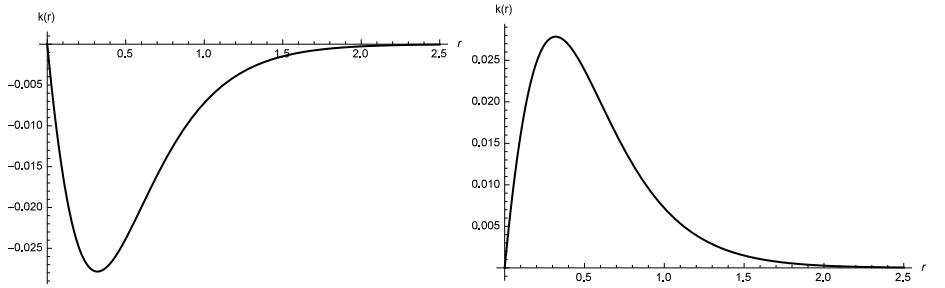

Fig. 1. The function $k(r)$ is plotted in units of $H_0^2$ as a function of the radial coordinate in units of $H_0^{-1}$.

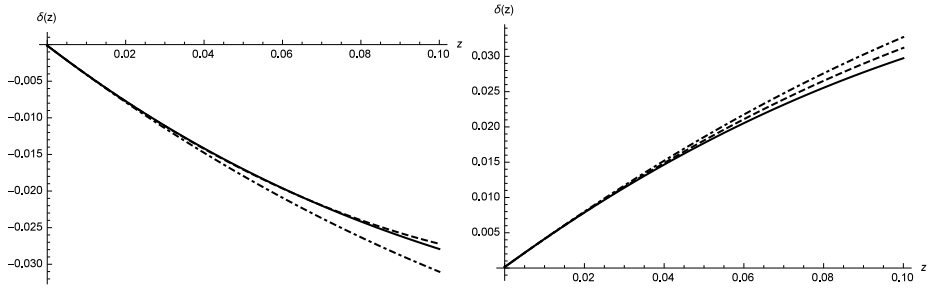

Fig. 2. The density contrast is plotted as a function of redshift. The left and right plots are for the inhomogeneities corresponding to Fig. 1. The solid lines correspond to the numerical solution, the dashed lines to the analytical formula we derived and the dot-dashed lines to the perturbation theory result.

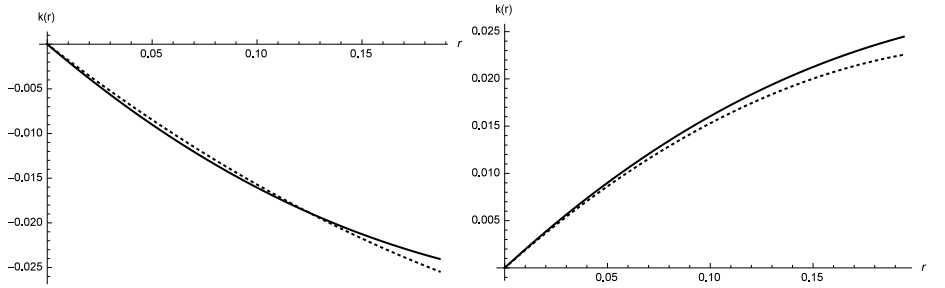

Fig. 3. The reconstructed metric function $k(r)$ is plotted in units of $H_0^2$ as a function of the radial coordinate in units of $H_0^{-1}$ for the inhomogeneities corresponding to Fig 1. The black solid line corresponds to the original $k(r)$ function and the black dotted line to the reconstructed one.

## 5. Conclusions

We have derived the low-redshift expansion for the monopole of the density contrast. At low red-shift the formula is in good agreement with numerical solutions and

is more accurate than the linear perturbation theory approximation. Using this formula we have then developed a new analytical inversion method to reconstruct the metric from the monopole of the density contrast. The inversion method could be applied to low red-shift observational data to determine the metric with a level of precision higher than the one achievable using perturbation theory.

For a full reconstruction of the metric beyond the monopole contribution other solutions of the Einstein equations could be used for the analytical approach, in order to accommodate more complex geometries. For a general numerical inversion able to reconstruct any type of metric more sophisticated methods in numerical relativity will be required.

We consider light propagation as a probe of non-metricity in area metric spacetimes, and find a deviation from the standard Etherington relation for linearized area metric Schwarzschild. This is joint work with Frederic P. Schuller (Erlangen University).

*Keywords*: Gravitational lensing; Etherington relation; constructive gravity; area metrics.

## 1. Introduction

Since the 1919 eclipse expeditions, whose centennial will be celebrated in the year following this Marcel Grossmann Meeting, gravitational lensing has provided important precision tests of the Lorentzian metric spacetimes of general relativity. This raises the question of how modified theories with *non-metric* spacetime structures may be probed by gravitational lensing.

The answer to this question requires, of course, knowledge of the gravitational theory of such non-metric spacetime kinematics, and the standard approach is to start by stipulating some modification of the Einstein-Hilbert action as the gravitational dynamics. However, recent work in geometrodynamics (cf. Refs. 1, 2) has shown that predictive gravitational dynamics can, in fact, be *derived* from the underlying spacetime kinematics, such that the theory is predictive by construction. Hence, this new approach is called *constructive gravity*, and session AT5 of this meeting is dedicated to it.

Here, we describe the first concrete example of how constructive gravity can be employed to derive a prediction for gravitational lensing in a non-metric spacetime. Specifically, we consider area metric geometry for which a perturbative Schwarzschild-like solution has been obtained, and find a deviation from the standard metric Etherington distance duality relation. This proceedings paper is based on Ref. 3 and references therein.

## 2. Geometrical background

### 2.1. *General kinematics*

We begin by discussing general spacetime kinematics and the notion of predictivity, following Ref. 4. Consider a smooth 4-dimensional manifold $M$ endowed with smooth tensor fields $G$ and $F$, which we refer to as *geometry* and its *test matter*,

respectively, governed by a general linear field PDE,

$$\left[\sum_{d=1}^{k} D^{\bar{\mu}\nu_1\dots\nu_d}_{\bar{\lambda}}(G)\frac{\partial}{\partial x^{\nu_1}}\dots\frac{\partial}{\partial x^{\nu_d}}\right] F_{\bar{\mu}} = 0\,, \tag{1}$$

where $\nu_i \in \{0,\dots,3\}$ denote general spacetime coordinates, $\bar{\mu}$ multi-indices of test matter fields components, and $i \in \{1,\dots,d\},\ d \in \{1,\dots,k\}$ partial derivative order where $k$ is highest. Now, causal properties of Eq. (1) are governed by its principal polynomial, which emerges from the eikonal approximation: letting

$$F_{\bar{\mu}}(x,\epsilon) = e^{\frac{\mathrm{i}S(x)}{\epsilon}}\sum_{j=0}^{\infty} F_{\bar{\mu}j}(x)\epsilon^j\,, \quad \text{and} \quad \epsilon \to 0\,,$$

where $S$ is the eikonal (phase) function, then from (1),

$$e^{\frac{\mathrm{i}S(x)}{\epsilon}}\left(\frac{\mathrm{i}}{\epsilon}\right)^k\left[D^{\bar{\mu}\nu_1\dots\nu_k}_{\bar{\lambda}}(x)\frac{\partial S}{\partial x^{\nu_1}}\dots\frac{\partial S}{\partial x^{\nu_k}}\right]F_{\bar{\mu}0}(x) + \text{ lower terms in } \frac{1}{\epsilon} = 0\,,$$

whence the first term stemming from the highest derivative order remains in the limit, and for this equation to have non-trivial solutions, the determinant of the square bracketed term needs to vanish. This yields the principal polynomial of Eq. (1) $P : T^*M \to \mathbb{R}$, reducing repeated powers,

$$P(x,p) = w_G \det\left[D^{\bar{\mu}\nu_1\dots\nu_k}_{\bar{\lambda}}(x)p_{\nu_1}\dots p_{\nu_k}\right] = P^{\nu_1\dots\nu_{\deg P}}p_{\nu_1}\dots p_{\nu_{\deg P}}\,, \tag{2}$$

where $P^{\nu_1\dots\nu_{\deg P}}$ is the totally symmetric principal polynomial tensor, and $w_G$ some appropriate weight function to render $P$ a scalar. Thus, the general *null cone* (or, null dispersion relation) at $x \in M$ becomes

$$N_x = \{p \in T^*_x M \ :\ P(x,p) = 0\}\,. \tag{3}$$

We are interested in causal kinematics of the generalized spacetime $(M, G, F)$, which is determined by the Cauchy problem. Given (1) and initial data, the Cauchy problem is well-posed if there is a unique solution depending continuously on the initial data, so $P$ is necessarily hyperbolic.

So far, we have only considered covectors, or particle momenta. However, we also need the dual vectors for particle trajectories. Now it turns out that if $P$ is hyperbolic, then its dual polynomial $P^\sharp : TM \to \mathbb{R}$ exists, although hyperbolicity of $P$ does not imply hyperbolicity of $P^\sharp$. But for predictivity in the sense of distinguishing future and past, or the sign of particle energies, $P^\sharp$ needs to be hyperbolic as well. This is called *bihyperbolicity*, and is the geometric requirement for predictive kinematics.

**Example: standard Maxwell.** In $M = \mathbb{R}^4,\ x^\nu = (t, \mathbf{x})$, consider Maxwell's equations in vacuum, in suitable units. Then we have two constraint equations $\nabla \cdot \mathbf{E} = 0,\ \nabla \cdot \mathbf{B} = 0$, and two dynamical equations,

$$\frac{\partial \mathbf{E}}{\partial t} - \nabla \times \mathbf{B} = 0\,, \qquad \frac{\partial \mathbf{B}}{\partial t} + \nabla \times \mathbf{E} = 0\,.$$

Introducing $F_{\bar{\mu}} = (-\mathbf{E}, \mathbf{B})$, $\bar{\mu} \in \{1, \ldots, 6\}$, they can be recast as test matter field equations in the form of Eq. (1) to obtain

$$D^{\bar{\mu}\nu}_{\bar{\lambda}} \frac{\partial F_{\bar{\mu}}}{\partial x^{\nu}} = 0\,.$$

Now according to Eq. (2), the corresponding principal polynomial is computed from

$$\det[D^{\bar{\mu}\nu}_{\bar{\lambda}} p_\nu] = \det \begin{bmatrix} -p_0 & 0 & 0 & 0 & p_3 & -p_2 \\ 0 & -p_0 & 0 & -p_3 & 0 & p_1 \\ 0 & 0 & -p_0 & p_2 & -p_1 & 0 \\ 0 & p_3 & -p_2 & p_0 & 0 & 0 \\ -p_3 & 0 & p_1 & 0 & p_0 & 0 \\ p_2 & -p_1 & 0 & 0 & 0 & p_0 \end{bmatrix} = p_0^2(-p_0^2 + p_1^2 + p_2^2 + p_3^2)^2\,,$$

whence, after reducing repeated powers, we read off the principal polynomial,

$$P(x,p) = -p_0^2 + p_1^2 + p_2^2 + p_3^2 = P^{\mu\nu} p_\mu p_\nu = \eta^{\mu\nu} p_\mu p_\nu\,,$$

identifying the principal polynomial tensor as the inverse Minkowski metric.

### 2.2. *Area metric spacetimes*

We can now specialize the previous discussion to test matter defined by general linear electromagnetism, which has the Lagrangian

$$L = -\frac{1}{8} \mathcal{G}^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma}\,, \tag{4}$$

where $F_{\mu\nu} = -F_{\nu\mu}$ is the electromagnetic tensor, and $\mathcal{G}$ is called constitutive tensor density, describing the properties of the optical medium. This is the structure defining pre-metric electromagnetism (see, e.g., Ref. 5), although in the standard Maxwell vacuum we consider $\mathcal{G}$ to be induced by a Lorentzian spacetime metric $g$. However, more generally, $\mathcal{G}$ is an area metric structure.

An *area metric* is a smooth 4th order tensor field $G$ with symmetries such that

$$G_{\mu\nu\rho\sigma} = G_{\rho\sigma\mu\nu}\,,\; G_{\mu\nu\rho\sigma} = -G_{\nu\mu\rho\sigma}\,,\; G_{\mu\nu\rho\sigma} = -G_{\mu\nu\sigma\rho}\,,$$

and we define an area metric induced by a metric $g$ as follows,

$$(G_g)_{\mu\nu\rho\sigma} = g_{\mu\rho} g_{\nu\sigma} - g_{\mu\sigma} g_{\nu\rho} - \sqrt{\det g}\; \epsilon_{\mu\nu\rho\sigma}\,.$$

The name stems from its area measuring property.[a] Now *vacuum* electromagnetism on an area metric background can be described like Eq. (4) with $F$ subject to

$$L = -\frac{1}{8} \mathcal{G}^{\mu\nu\rho\sigma} F_{\mu\nu} F_{\rho\sigma} \quad \text{with} \quad \mathcal{G}^{\mu\nu\rho\sigma} = \omega_G G^{\mu\nu\rho\sigma}\,, \tag{5}$$

[a] To see this, consider two vectors $X, Y$ and a Riemannian metric $g$, then

$$G_g(X,Y,X,Y) = (X \cdot X)(Y \cdot Y) - (X \cdot Y)^2 = |X|^2 |Y|^2 \sin^2 \angle(X,Y) = |X \wedge Y|^2\,,$$

that is, the squared area spanned by $X, Y$.

where $\omega_G^{-1} = \frac{1}{4!}\epsilon_{\mu\nu\rho\sigma}G^{\mu\nu\rho\sigma}$. Thus, an area metric spacetime with predictive kinematics in the sense of Sec. 2.1 can be defined as the triple $(M, G, F)$ with a corresponding bihyperbolic principal polynomial $P$.

## 3. Gravitational lensing

### 3.1. *Light propagation*

Let us know proceed to study light propagation on such an area metric spacetime $(M, G, F)$. As discussed in general in Sec. 2.1, we can apply the eikonal approximation to the field equations of Eq. (5) to define geometrical optics. The null cone (3) in this case is, of course, found to be *quartic* ($\deg P = 4$),

$$P(x, p) = P(G)^{\alpha\beta\gamma\delta}p_\alpha p_\beta p_\gamma p_\delta = 0\,,$$

with the principal polynomial tensor constructed from the area metric $G$. It is clear, then, that light rays in such a spacetime are, in general, subject to *birefringence*.

However, since observationally any such effect would necessarily be very small, we shall from now on investigate a perturbation about an effective Minkowski spacetime. Then the (inverse) area metric is given by

$$G^{\mu\nu\rho\sigma} = \eta^{\mu\rho}\eta^{\nu\sigma} - \eta^{\mu\sigma}\eta^{\nu\rho} - \epsilon^{\mu\nu\rho\sigma} + H^{\mu\nu\rho\sigma}\,,$$

where $H$ is small. In this case, the principal polynomial tensor and its dual are found to be merely *quadratic*,

$$P^{\mu\nu} = \eta^{\mu\nu} + H^{\mu\nu}\,, \quad P^\sharp_{\mu\nu} = \eta_{\mu\nu} - H_{\mu\nu}\,, \tag{6}$$

where $H^{\mu\nu} = \frac{1}{2}H^{\alpha\mu\beta\nu}\eta_{\alpha\beta} - \frac{1}{4!}\epsilon_{\alpha\beta\gamma\delta}H^{\alpha\beta\gamma\delta}\eta^{\mu\nu}$. Hence, there is an *effective* Lorentzian metric $P^\sharp_{\mu\nu}$ for light rays, and standard ray optical arguments for light rays apply. This fact, however, does not eliminate effects of the non-metricity of this spacetimes entirely: one result important for our later discussion is that energy-momentum conservation (for the general case, cf. Ref. 6) implies that the photon current $N^\mu$ obeys the conservation law

$$(\omega_G N^\mu)_{,\mu} = 0\,, \tag{7}$$

which corresponds to the well-known result for metric spacetimes (see, e.g., Eq. (3.26) of Ref. 7), except that the volume measure here, $\omega_G$, is area metrical.

### 3.2. *Linearized gravity*

Having established our non-metric spacetime kinematics, we need gravitational dynamics next in order to obtain a concrete prediction for light propagation. But rather than stipulating a modification of general relativity, contructive gravity can be employed to derive it.

This geometrodynamical technique originates in Ref. 8, which treats the Lorentzian metric case, but has been extended recently to any tensorial background

(see Refs. 1 and 2). Briefly, the idea is that a bihyperbolic spacetime kinematics yields a generalized ADM split with lapse and shift, defining a hypersurface deformation algebra. Recognizing that kinematical deformation and dynamical evolution coincide, the constraint algebra with supermomentum and superhamiltonian can be determined, resulting eventually in a PDE system for the gravitational Lagrangian.

The gravitational dynamics for area metric kinematics can, so far, be derived perturbatively. The solution for a point mass $M$, that is, the linearized area metric Schwarzschild, is

$$\begin{aligned} G^{0a0b} \equiv& -\gamma^{ab} + H^{0a0b} = -\gamma^{ab} + (2A - \tfrac{1}{2}U + \tfrac{1}{2}V)\gamma^{ab}\,, \\ G^{0bcd} \equiv& \epsilon^{bcd} + H^{0bcd} = \epsilon^{bcd} + \left(\tfrac{3}{4}U - \tfrac{3}{4}V - A\right)\epsilon^{bcd}\,, \\ G^{abcd} \equiv& \gamma^{ac}\gamma^{bd} - \gamma^{ad}\gamma^{bc} + H^{abcd} = (1 + 2U - V)(\gamma^{ac}\gamma^{bd} - \gamma^{ad}\gamma^{bc})\,, \end{aligned}$$

with Euclidean metric $\gamma^{ab}$, Euclidean distance $r$ of the unperturbed background, Levi-Civita symbol $\epsilon^{abc}$, and scalar perturbations

$$A = -\frac{M}{8\pi r}\left(\kappa - \lambda\eta e^{-\mu r}\right)\,,\ U = -\frac{M}{4\pi r}\eta e^{-\mu r}\,,\ V = \frac{M}{4\pi r}\left(\kappa - \tau\eta e^{-\mu r}\right)\,,$$

where $\eta, \kappa, \lambda, \mu, \tau$ are constants.

### 3.3. *Modified Etherington relation*

Finally, we are ready to study light propagation in this non-metric spacetime under the influence of gravity. One fundamental kinematical property of *any* Lorentzian metric spacetime is the Etherington distance duality relation, originally derived in Ref. 9, which connects the luminosity distance, angular diameter distance and redshift. Thus, we naturally expect this relation to be broken for a non-metric spacetime, such as our area metric spacetime, possibly even in a way such that the result is no longer merely kinematical but dynamical, that is, dependent on the gravity theory. This turns out to be the case here, as we shall see in the following.

First of all, recall from Sec. 3.1 that, at leading order in geometrical optics, area metric light propagation is essentially metric, so the standard ray optical derivation of the Etherington relation (e.g., Ref. 7, ch. 3) largely applies, yielding

$$D_L = \frac{(1+z)^2 D_A}{\sqrt{1+\Delta}}\,, \tag{8}$$

where $D_L,\ D_A,\ z$ are luminosity distance, angular diameter distance and redshift, respectively, as usual, and $\Delta$ is the photon excess fraction in a ray bundle domain $\mathcal{D}$ from the light source to the observer obeying

$$\Delta \cdot N = \int_{\mathcal{D}} \mathrm{d}^4x \sqrt{-\det P^\sharp}\ N^\mu{}_{;\mu}\,, \tag{9}$$

where the covariant derivative is with respect to metric $P^\sharp$ of (6), $N$ is the photon number and $N^\mu$ the photon current, as before. In standard metric theory, photon conservation implies the vanishing of $N^\mu{}_{;\mu}$ in Eq. (9) whence $\Delta = 0$ in Eq. (8), and

we recover the standard Etherington relation. However, in the area metric case, although conservation law (7) applies, the $N^{\mu}{}_{;\mu}$ does not vanish whence $\Delta \neq 0$, and we find a modification of the Etheringon relation. Concretely, for linearized area metric Schwarzschild of Sec. 3.2, Yukawa-type corrections emerge,

$$D_L = (1+z)^2 D_A \left(1 + \frac{3\kappa M}{8\pi}\left(\frac{e^{-\mu r_s}}{r_s} - \frac{e^{-\mu r_o}}{r_o}\right)\right),$$

with Euclidean distances $r_o, r_s$ between the mass $M$ and the observer and light source, respectively. Thus, although at the optical geometry (and hence image positions and time delays) is the same as for metric Schwarzschild at leading order in $M$, the area metric volume measure implies a difference in the image magnification.

## 4. Concluding remarks

The constructive gravity approach allows the derivation of predictive gravitational dynamics from bihyperbolic kinematics. This enables the study of spacetimes beyond metric geometry without additional assumptions about the modified gravity theory. Thus, qualitatively new gravitational lensing effects due to non-metricities can be derived to provide possible observational tests. The first concrete example of this was described here, resulting in a modified Etherington relation for the linearized area metric Schwarzschild spacetime. The interested reader is also referred to session AT5 *Constructive Gravity* of this Marcel Grossmann Meeting.

# Review of tokamak physics and a way to get big bang GW conditions before the $10^{-26}$ reduction in frequency seen today, confirming *e*-fold values of 60 for inflation

Andrew Walcott Beckwith

*Physics Department, Chongqing University, Chongqing 401331, People's Republic of China*
*E-mail: Rwill9955b@gmail.com; abeckwith@uh.edu*
*english.cqu.edu.cn*

We reconstruct early-universe GW conditions, before the onset of inflation. The idea is as follows. e-Fold expansion of the universe due to inflation is of the order of $10^{26}$. Hence, the goal is to produce relic gravitational waves with a device having a signal with frequencies around $10^{10}$ Hz, which is in line with todays theoretical GW frequencies of $10^{16}$ Hz for relic big-bang GW detected in the present era. Measuring $10^{10}$ Hz in a laboratory would be a proof of the calculated e-fold value of, say, 60.

*Keywords*: Tokamak Physics, Plasma Confinement Time, GW Amplitude, Drift Current.

## 1. Introduction

The main justification of our work is that we could, with due diligence, reconstruct GW radiation from the start of inflationary physics. First, there is the question of what sort of polarization would be produced in initial processes. Second, if we were able to produce $10^{10}$ Hz gravitational waves via our laboratory arrangements and if we were later able to confirm, say, the existence of $10^{-16}$ Hz GW frequencies via LISA in the present era, this would be a stunning proof of the big-bang hypothesis. So, we summarize what this inquiry may answer.

(1) Determination of the fidelity of the e-fold value of 60 in the big bang.
(2) Determination if a drop of say $10^{-2}$ in strain value, $h$, for GW, from the initial configuration of the big bang, to our present era, is supportable.
(3) Unknown initial GW polarization from the start of the big bang. Knowing (1) and (2), we could at least say which GW polarization states may be permitted.

## 2. Comparison with Grishchuk and Sazhin Results

Russian physicists obtained the amplitude of a Gravitational wave (GW) in a plasma as $A = h \sim \frac{G}{c^4} \cdot E^2 \cdot \lambda_{\rm GW}^2$.[1] Note that a simple model of how to provide a current, $I$, in the Toroid is provided by a transformer core using the simple Ohm's Law derivation referred to in the first part of the text. Here, $E$ is the electric field whereas $\lambda_{\rm GW}$ is the gravitational wavelength for GW generated by the tokamak in our model. In the original Grishchuk model, we would have very small strain values, which requires the following relationship between GW wavelength and resultant frequency. Note, $\omega_{\rm GW} \sim 10^6$ Hz $\Rightarrow \lambda_{\rm GW} \sim 300$ m, so we will be assuming $\omega_{\rm GW} \sim 10^9$ Hz $\Rightarrow \lambda_{\rm GW} \sim 0.3$ m as a baseline measurement for GW detection above the tokamak.

Furthermore,

$$A \sim h \sim \frac{G \cdot W_E \cdot V}{c^4 \cdot \widetilde{a}} \tag{1}$$

where $W_E$ is the energy density, $V$ is the volume, and $\widetilde{a}$ is the toroid's inner radius.

Equation (1) is due to the two-part strain's first term, with the strain's second term significantly larger than the first term and due to ignition of the tokamak plasma. The strain's first term is largely due to Grishchuk and Sazhin's calculations.[1] The plasma-fusion contribution is due to nonequilibrium contributions to plasma ignition, which we will elaborate. Note that the first term in the strain derivation is due to the electric field within the toroid, not Plasma fusion, and we will first of all discuss how to obtain the requisite strain for the electric-field contribution to the current inside a tokamak via Ohm's Law.

## 3. Derivation of Strain Generated by an Electric Field

We examine the would-be electric field, contributing to small strain values similar in part to Ohm's Law. A generalized Ohm's Law ties in well.

$$J = \sigma \cdot E \tag{2}$$

To obtain an electric field detectable by 3DSR,[4,5] we use generalized Ohm's Law (see Ref. 3, p. 146), where $E$ and $B$ are electric and magnetic fields, and $v$ is velocity.

$$E = \sigma^{-1} J - v \times B \tag{3}$$

The term $v \times B$ in Eq. (3) deserves special commentary. If $v$ is perpendicular to $B$, as occurs in a simple equilibrium case, then of course, Eq. (3) would be, simply put, Ohm's Law, and spatial equilibrium averaging would then lead to

$$E = \sigma^{-1} J - v \times B \xrightarrow[v \text{ perpendicular to } B]{} E = \sigma^{-1} J. \tag{4}$$

What saves the contribution of Plasma burning as a contributing factor to the tokamak generation of GW, with far larger strain values, is that the ion velocity in the plasma is not perpendicular to $B$ in the beginning of tokamak generation. It is, fortunately for us, a nonequilibrium initial process, with thermal irregularities leading to both terms in Eq. (3) contributing to the electric field values. We will be looking for an application for radial free-electric fields being applied (see Ref. 3, p. 120).

$$n_j e_j \cdot (E_{\mathrm{r}} + v_{\perp j} B) = -\frac{\mathrm{d}P_j}{\mathrm{d}r} \tag{5}$$

Here, $n_j$ is ion density of the $j^{\mathrm{th}}$ species, $e_j$ is ion charge of the $j^{\mathrm{th}}$ species, $E_{\mathrm{r}}$ is the radial electric field, $v_{\perp j}$ is the perpendicular velocity of the $j^{\mathrm{th}}$ species, $B$ is the magnetic field, and $P_j$ is the pressure of the $j^{\mathrm{th}}$ species. The results of Eq. (3) and Eq. (5) are

$$\frac{G}{c^4} \cdot E^2 \cdot \lambda_{\mathrm{GW}}^2 \sim \frac{G}{c^4} \cdot \left(\frac{C}{R}\right)^2 \cdot \lambda_{\mathrm{GW}}^2 + \frac{G}{c^4} \cdot \left(\frac{J_b}{n \cdot e} + v_{\mathrm{r}}\right)^2 \lambda_{\mathrm{GW}}^2 = (\text{first}) + (\text{second}) \tag{6}$$

Here, the first term is due to $\nabla \times E = 0$, and the second term is due to $E_{\rm n} = \frac{{\rm d}P_j}{{\rm d}x_{\rm n}} \cdot \frac{1}{n_j \cdot e_j} - (v \times B)_{\rm n}$ with the first term generating $h \sim 10^{-38}$–$10^{-30}$ in terms of GW amplitude strain 5 m above the tokamak. In contrast, the second term has a strain of $h \sim 10^{-26}$ in terms of GW amplitude above the tokamak. The article has contributions from amplitude from the first and second terms separately. The second part will be tabulated separately from the first contribution assuming a minimum temperature of $T \sim 10$ keV.[3]

## 4. GW *h* Strain Values When the First Term of Eq. (6) Is Used

We now look at what we can expect with the simple Ohm's Law calculation for strain values. As it is, the effort led to unusable GW amplitude values of up to $h \sim 10^{-38}$–$10^{-30}$ for GW wave amplitudes 5 m above a tokamak, and $h \sim 10^{-38}$–$10^{-28}$ in the center of a tokamak. This would be the tokamak-generated GW amplitude using the first term of Eq. (6) to obtain the following value[1]

$$h_{\rm 1st} \sim \frac{G}{c^4} \cdot E^2 \cdot \lambda_{\rm GW}^2 \sim \frac{G}{c^4} \cdot \left(\frac{J}{\sigma}\right)^2 \cdot \lambda_{\rm GW}^2. \tag{7}$$

We summarize the results for when $\omega_{\rm GW} \sim 10^9$ Hz $\Rightarrow \lambda_{\rm GW} \sim 0.3$ m and with conductivity $\sigma \sim 10$ m$^2$/s and with the following provisions as to initial values. We observe is a range of tokamak values that are, even in the case of ITER (not yet built) beyond the reach of any technological detection devices in the coming decade. These results, assuming fixed conductivity values $\sigma \sim 10$ m$^2$/s as well as $\lambda_{\rm GW} \sim 0.3$ m, are why the author expects the second term of Eq. (3) to dominate the results for the Chinese tokamak in Hefei.[6]

$$h_{\rm 2nd} \sim \frac{G}{c^4} \cdot E^2 \cdot \lambda_{\rm GW}^2 \sim \frac{G}{c^4} \cdot \left(\frac{J}{n \cdot e} + v_{\rm r}\right)^2 \cdot \lambda_{\rm GW}^2, \tag{8}$$

or values 10000 larger than the results in ITER due to Eq. (6).

We are setting $\lambda_{\rm GW} \sim 0.3$ m and $\sigma \sim 10$ m$^2$/s, using Eq. (6) above for GW amplitude. What makes the second term of Eq. (4) mandatory is that even in the case of ITER, 5 m above the tokamak ring, the GW amplitude is $\frac{1}{10000}$ the size of any reasonable GW detection device, including the new 3DSR technology.[4,5] Hence, we need to come up with a better estimate, which the second term of Eq. (6) provides.

## 5. Enhancing GW Strain Amplitude via a Burning Plasma Drift Current: Eq. (4)

We next examine the normal-to-surface induced electric field contribution (see Ref. 3, p. 120):

$$E_{\rm n} = \frac{{\rm d}P_j}{{\rm d}x_{\rm n}} \cdot \frac{1}{n_j \cdot e_j} - (v \times B)_{\rm n}. \tag{9}$$

If one has for $v_{\rm r}$ as the radial velocity of ions in the tokamak from tokamak center to its radial distance, $R$, from center, and $B_\theta$ as the direction of a magnetic

field in the "face" of a Toroid containing the plasma, in the angular $\theta$ direction from a minimal toroid radius of $R = a$, with $\theta = 0$, to $R = a + r$ with $\theta = \pi$, one has $v_{\rm r}$ for radial drift velocity of ions in the tokamak, and $B_\theta$ having a net approximate value of with $B_\theta$ not perpendicular to the ion velocity, so then [3]

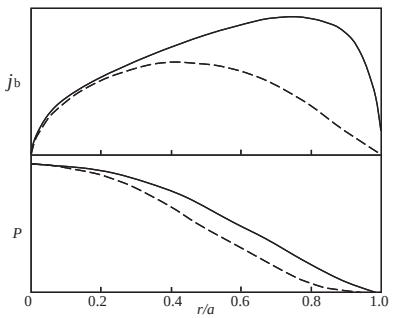

Fig. 1. Typical bootstrap currents with a shift due to $\frac{r}{a}$ where $r$ is the radial direction of the tokamak, and $a$ is the inner radius of the Toroid This figure is reproduced from Wesson. [3]

$$(v \times B)_{\rm r} \sim v_{\rm r} \cdot B_\theta. \tag{10}$$

Also, spatial change in pressure denoted (see Ref. 3, p. 167)

$$\frac{{\rm d}P_j}{{\rm d}x_{\rm n}} = -B_\theta \cdot j_b. \tag{11}$$

Here the drift current, using $\xi = \frac{a}{R}$, and drift current $j_b$ for plasma charges, is

$$j_b \sim -\frac{\xi^{\frac{1}{2}}}{B_\theta} \cdot T \cdot \frac{{\rm d}n_{\rm drift}}{{\rm d}r}. \tag{12}$$

Figure 1 introduces the role of the drift current, in terms of a tokamak. [3]

Then one has

$$B_\theta^2 \cdot \left(\frac{j_b}{n_j \cdot e_j}\right)^2 \sim \frac{B_\theta^2}{e_j^2} \cdot \frac{\xi^{\frac{1}{4}}}{B_\theta^2} \cdot \left(\frac{1}{n_{\rm drift}} \cdot \frac{{\rm d}n_{\rm drift}}{{\rm d}r}\right)^2 \sim \frac{\xi^{\frac{1}{4}}}{e_j^2} \cdot \left(\frac{1}{n_{\rm drift}} \cdot \frac{{\rm d}n_{\rm drift}}{{\rm d}r}\right)^2. \tag{13}$$

Now, the behavior of the numerical density of ions grows in the radial direction, so [3]

$$n_{\rm drift} = n_{\rm drift}|_{\rm initial} \cdot {\rm e}^{\widetilde{\alpha} \cdot r}. \tag{14}$$

This exponential behavior then will lead to the second term in Eq. (6) having in the center of the tokamak, for an ignition temperature of $T \geq 10$ keV a value of

$$h_{\rm 2nd} \sim \frac{G}{c^4} \cdot B_\theta^2 \cdot \left(\frac{j_b}{n_j \cdot e_j}\right)^2 \cdot \lambda_{\rm GW}^2 \sim \frac{G}{c^4} \cdot \frac{\xi^{\frac{1}{4}} \widetilde{\alpha} T^2}{e_j^2} \cdot \lambda_{\rm GW}^2 \sim 10^{-25}. \tag{15}$$

There is a critical ignition temperature [3] at its lowest point of the curve having $T \geq 30$ keV as an optimum value of the tokamak ignition temperature for $n_{\rm ion} \sim 10^{20}$ m$^{-3}$, with a still permissible temperature value of $T|_{\rm safe\ upper\ bound} \approx 100$ keV with a value of $n_{\rm ion} \sim 10^{20}$ m$^{-3}$ (see Ref. 3, p. 11). The relationship of Eq. (16), where $\tau_E$ is a tokamak confinement-of-plasma time of about one to three seconds. [3] Then $n_{\rm ion} \cdot \tau_E > 0.5 \times 10^{20}$ m$^{-3}$s. Also, if $T|_{\rm safe\ upper\ bound} \approx 100$ keV, then one could have at the tokamak center, even the Hefei-based tokamak, [3,6]

$$h_{\rm 2nd}|_{T \geq 100\ {\rm keV}} \sim \frac{G}{c^4} \cdot \frac{\xi^{\frac{1}{4}} \widetilde{\alpha} T^2}{e_j^2} \cdot \lambda_{\rm GW}^2 \sim 10^{-25}\text{–}10^{-26}. \tag{16}$$

This would lead to, for a GW reading 5 meter above the tokamak, [3,6]

$$\left[h_{\rm 2nd}|_{T \geq 100\ {\rm keV}}\right]_{\rm 5\ m\ above\ tokamak} \sim \frac{G}{c^4} \cdot \frac{\xi^{\frac{1}{4}} \widetilde{\alpha} T^2}{e_j^2} \cdot \lambda_{\rm GW}^2 \sim 10^{-25}\text{–}10^{-26}. \tag{17}$$

Note that the support for up to 100 keV for temperature can yield more stability in terms of thermal plasma confinement

## 6. Restating the Energy Density and Power

$$W_E \cdot V \sim \widetilde{\alpha} \cdot \lambda_{\mathrm{GW}}^2 \cdot \frac{\xi^{\frac{1}{4}} \widetilde{\alpha} T_{\mathrm{plasma}}^2}{e_j^2} \tag{18}$$

The temperature for plasma fusion burning is between 30 and 100 keV.[3] The corresponding power is then, for the tokamak,[3]

$$P_\Omega = E \cdot J \leq \frac{E}{\mu_0} \cdot \frac{B_\phi}{R} \tag{19}$$

The tie in with Eq. (18) by Eq. (20) can be seen by first setting the $E$ field as related to the $B$ field, via $E$ (electrostatic) $\approx 10^{12} V$ m$^{-1}$ as equivalent to a magnetic field $B \approx 10^4$ T.[2] In a one-second interval, if we use the input power as an experimentally supplied quantity, then the effective $E$ field is

$$E_{\mathrm{applied}} \sim \frac{\xi^{\frac{1}{8}} \cdot \widetilde{\alpha}}{e_j} \times T_{\mathrm{plasma}} \tag{20}$$

What is found is, that if Eq. (19) and Eq. (20) hold, then if $Z_{\mathrm{effective}} \sim 1.5$, $q_a Q_0 \sim 1.5$, and $\frac{R}{\widetilde{a}} \approx 3$, then the temperature of a tokamak, to a good approximation, would be between 30 and 100 keV (see Ref. 3, pp. 242–243). Then one has[3]

$$B_\phi^{\frac{4}{5}} \sim 0.87 \cdot (\widetilde{T} = T_{\mathrm{plasma}}). \tag{21}$$

Then the power for the tokamak is

$$P_\Omega = \frac{\xi^{\frac{1}{8}} \cdot \widetilde{\alpha}}{\mu_0 \cdot e_j \cdot R} \times \frac{T_{\mathrm{plasma}}^{\frac{9}{4}}}{0.87^{\frac{5}{4}}} \tag{22}$$

Then, $n$ $10^{-34}$ eV gravitons are produced per second, as, if $\widetilde{a} = \frac{R}{3}$:

$$n \propto \frac{3 \cdot \hbar \cdot e_j}{\mu_0 \cdot R^2 \cdot \xi^{\frac{1}{8}} \cdot \widetilde{\alpha}} \times \frac{T_{\mathrm{plasma}}^{\frac{1}{4}}}{0.87^{\frac{5}{4}} \cdot \lambda_{\mathrm{g}}^2 \cdot m_{\mathrm{g}}} \sim \frac{1}{\lambda_{\mathrm{g}}^2} \text{ scaling.} \tag{23}$$

## 7. Conclusion

Further elaboration of this matter in the experimental detection of experimental data sets for massive gravity lies in the viability of the expression derived, namely Eq. (19). $h \sim 10^{-27}$ for a GW detected 5 m above a tokamak represents a decrease in strain by a factor of about 100,[7] whereas in the center of the tokamak, we would have, say, $h_{2\mathrm{nd}} \sim 10^{-26}$–$10^{-27}$, a difference of two orders of magnitude. We state that our rough estimate is that we would see about the same strain values. In the initial starting point of the universe, we would have, say $h \approx 10^{-25}$ decreasing

to $h_{2\mathrm{nd}} \sim 10^{-26}$–$10^{-27}$ today, a comparatively small change in strain amplitude. Contrast this with e-folding issues,[8] wherein we would have a difference of $10^{26}$ in frequency magnitude, with $10^{10}$ Hz initially, for GW at the start of the big bang, decreasing to $10^{-16}$ Hz, due to inflation.[8] If we confirm that last statement observationally, we have confirmed the e-folding prediction.[8]

*E-mail: obukhov@ibrae.ac.ru*

A unified approach to the study of classical and quantum spin in external fields is developed. Understanding the dynamics of particles with spin and dipole moments in arbitrary gravitational, inertial and electromagnetic fields is important in astrophysics and high-energy and heavy-ion experimental physics.

*Keywords*: Spin, dipole moments, nonminimal interactions.

## 1. Projection method for spin in arbitrary external fields

One can develop a natural extension of the classic Frenkel-Thomas spin model which is based on the definition of the "magnetic" and "electric" components of the relativistic forces and moments of forces acting on a particle (hence it is natural to call this approach a projection method). Let us recall that in Maxwell's theory, electrodynamic phenomena are described by the field strength tensor $F_{\alpha\beta}$, and the magnetic and electric fields can be introduced in a covariant way as the longitudinal and transversal projections on the velocity $U^\alpha$:

$$E_\alpha := F_{\alpha\beta}U^\beta, \qquad B^\alpha := \frac{1}{2c}\eta^{\alpha\mu\nu\beta}F_{\mu\nu}U_\beta. \tag{1}$$

Here $\eta_{\alpha\beta\mu\nu}$ is the totally antisymmetric Levi-Civita tensor. Thereby one gets an unique representation of the electromagnetic field strength tensor in terms of its projections (electric and magnetic fields):

$$F_{\alpha\beta} = \frac{1}{c^2}\left(E_\alpha U_\beta - E_\beta U_\alpha + c\eta_{\alpha\beta\mu\nu}U^\mu B^\nu\right). \tag{2}$$

In the model of a classical particle with internal degrees of freedom (the generalized Frenkel-Thomas model), the motion of a test particle is characterized by the 4-velocity $U^\alpha$ and the 4-vector of spin $S^\alpha$, which satisfy the normalization $U_\alpha U^\alpha = c^2$ and the orthogonality condition $S_\alpha U^\alpha = 0$. In general, the dynamic equations for these variables can be written as

$$\frac{dU^\alpha}{d\tau} = \mathcal{F}^\alpha, \qquad \frac{dS^\alpha}{d\tau} = \Phi^\alpha{}_\beta S^\beta. \tag{3}$$

External fields of different physical nature (electromagnetic, gravitational, scalar, etc.) determine the forces $\mathcal{F}^\alpha$ acting on the particle, as well as the spin transport matrix $\Phi^\alpha{}_\beta$ which affects the spin. Normalization and orthogonality of the velocity and spin vectors impose conditions on the right-hand sides of (3):

$$U_\alpha\mathcal{F}^\alpha = 0, \qquad U_\alpha\Phi^\alpha{}_\beta S^\beta = -S_\alpha\mathcal{F}^\alpha. \tag{4}$$

The spin transport matrix must be skew-symmetric, $\Phi_{\alpha\beta} = -\Phi_{\beta\alpha}$, which automatically guarantees $S_\alpha S^\alpha$ =const. The relativistic 4-velocity vector $U^\alpha$ is conveniently parametrized via the spatial velocity 3-vector $\widehat{v}^a$ and the Lorentz factor $\gamma$:

$$U^\alpha = \begin{pmatrix} \gamma \\ \gamma\widehat{v}^a \end{pmatrix}, \qquad \gamma = \frac{1}{\sqrt{1-\widehat{v}^2/c^2}}, \qquad \widehat{v}^2 = \delta_{ab}\widehat{v}^a\widehat{v}^b. \tag{5}$$

The vector of the generalized force $\mathcal{F}^\alpha$ acting on a particle has only a transversal projection, according to (4). As for the spin transport matrix $\Phi_{\alpha\beta}$, like any bivector, we can decompose it into a pair of 4-vectors. Namely, by analogy with (1), we define "electric" and "magnetic" projections

$$N_\alpha := \Phi_{\alpha\beta}U^\beta, \qquad Q^\alpha := \frac{1}{2c}\eta^{\alpha\mu\nu\beta}\Phi_{\mu\nu}U_\beta. \tag{6}$$

By construction, these 4-vectors are orthogonal to the velocity of the particle,

$$U_\alpha N^\alpha = 0, \qquad U_\alpha Q^\alpha = 0, \tag{7}$$

and the relations (4) are then recast into

$$U_\alpha \mathcal{F}^\alpha = 0, \qquad S_\alpha N^\alpha = S_\alpha \mathcal{F}^\alpha. \tag{8}$$

As a result, we have an unique decomposition analogous to (2):

$$\Phi_{\alpha\beta} = \frac{1}{c^2}\left(N_\alpha U_\beta - N_\beta U_\alpha + c\eta_{\alpha\beta\mu\nu}U^\mu Q^\nu\right). \tag{9}$$

The orthogonality conditions (7) can be resolved so that

$$N^0 = \frac{1}{c^2}(\boldsymbol{N}\cdot\widehat{\boldsymbol{v}}), \tag{10}$$

where as usual $\widehat{\boldsymbol{v}} = \{\widehat{v}^a\}$ and $\boldsymbol{N} = \{N^a\}$. Accordingly, we find in components:

$$\Phi^a{}_0 = \gamma\left(N^a - \widehat{v}^a N^0 - \epsilon^a{}_{bc}Q^b\widehat{v}^c\right), \tag{11}$$

$$\Phi^0{}_a = \frac{\gamma}{c^2}\left(N_a - \widehat{v}_a N^0 - \epsilon_{abc}Q^b\widehat{v}^c\right), \tag{12}$$

$$\Phi^a{}_b = \frac{\gamma}{c^2}\left(\widehat{v}^a N_b - \widehat{v}_b N^a\right) - \gamma\epsilon^a{}_{bc}\left(Q^c - \widehat{v}^c Q^0\right). \tag{13}$$

The physical spin, as an "internal angular momentum" of a particle, is defined with respect to particle's rest frame system, in which $u^\alpha = \delta^\alpha_0$. The transition to this system is carried out by the Lorentz transformation $U^\alpha = \Lambda^\alpha{}_\beta u^\beta$, where

$$\Lambda^\alpha{}_\beta = \left(\begin{array}{c|c} \gamma & \gamma\widehat{v}_b/c^2 \\ \hline \gamma\widehat{v}^a & \delta^a_b + \frac{\gamma-1}{\widehat{v}^2}\widehat{v}^a\widehat{v}_b \end{array}\right). \tag{14}$$

Therefore, the dynamic equation for the *physical spin* $s^\alpha = (\Lambda^{-1})^\alpha{}_\beta S^\beta$ reads:

$$\frac{ds^\alpha}{d\tau} = \Omega^\alpha{}_\beta s^\beta, \tag{15}$$

where the tensor of angular precession of spin is constructed as

$$\Omega^\alpha{}_\beta = (\Lambda^{-1})^\alpha{}_\gamma \Phi^\gamma{}_\delta \Lambda^\delta{}_\beta - (\Lambda^{-1})^\alpha{}_\gamma \frac{d}{d\tau}\Lambda^\gamma{}_\beta. \tag{16}$$

The 0th component of (15) vanishes, which is equivalent to the second condition (4). As a result, the spin evolution equation (15) reduces to the 3-vector form

$$\frac{ds^a}{d\tau} = \Omega^a{}_b s^b, \qquad \text{or} \qquad \frac{d\boldsymbol{s}}{d\tau} = \boldsymbol{\Omega} \times \boldsymbol{s}. \tag{17}$$

Here the components of 3-vectors are introduced through $\boldsymbol{s} = \{s^a\}$ and $\boldsymbol{\Omega} = \left\{-\frac{1}{2}\epsilon^{abc}\Omega_{bc}\right\}$. A direct calculation gives the precession angular velocity in terms of the magnetic and electric projections of the spin transport matrix:

$$\boldsymbol{\Omega} = \gamma\left\{\boldsymbol{Q} - \widehat{\boldsymbol{v}}\,Q^0 + \frac{\gamma}{\gamma+1}\frac{1}{c^2}\left[\widehat{\boldsymbol{v}}\,(\widehat{\boldsymbol{v}}\cdot\boldsymbol{Q}) - \widehat{v}^2\boldsymbol{Q}\right]\right\} + \frac{\gamma}{\gamma+1}\frac{\boldsymbol{\mathcal{F}}\times\widehat{\boldsymbol{v}}}{c^2}. \tag{18}$$

It is worthwhile to note that $\boldsymbol{\Omega}$ actually depends only on the transversal part of the "magnetic" vector, namely $Q^\alpha_\perp = Q^\alpha - \frac{1}{c^2}U^\alpha U_\beta Q^\beta$. Explicitly in components

$$Q^0_\perp = \frac{\gamma^2}{c^2}\left[\widehat{\boldsymbol{v}}\cdot\boldsymbol{Q} - \widehat{v}^2 Q^0\right], \qquad Q^a_\perp = Q^a + \frac{\gamma^2}{c^2}\left[\widehat{\boldsymbol{v}}\cdot\boldsymbol{Q} - c^2 Q^0\right]\widehat{v}^a, \tag{19}$$

and by a direct computation one can check that

$$\boldsymbol{Q}_\perp - \widehat{\boldsymbol{v}}\,Q^0_\perp = \boldsymbol{Q} - \widehat{\boldsymbol{v}}\,Q^0, \qquad \widehat{\boldsymbol{v}}\,(\widehat{\boldsymbol{v}}\cdot\boldsymbol{Q}_\perp) - \widehat{v}^2\boldsymbol{Q}_\perp = \widehat{\boldsymbol{v}}\,(\widehat{\boldsymbol{v}}\cdot\boldsymbol{Q}) - \widehat{v}^2\boldsymbol{Q}. \tag{20}$$

From (19) one then finds

$$Q^0_\perp = \frac{1}{c^2}\,\widehat{\boldsymbol{v}}\cdot\boldsymbol{Q}_\perp, \tag{21}$$

and therefore we recast (18) into a final form

$$\boldsymbol{\Omega} = \boldsymbol{Q}_\perp - \frac{\gamma}{\gamma+1}\frac{\widehat{\boldsymbol{v}}\,(\widehat{\boldsymbol{v}}\cdot\boldsymbol{Q}_\perp)}{c^2} - \frac{\gamma}{\gamma+1}\frac{\widehat{\boldsymbol{v}}\times\boldsymbol{\mathcal{F}}}{c^2}. \tag{22}$$

The new general equations (22), (17) are valid for a particle with spin that interacts with arbitrary external fields. The actual dynamics of the physical spin depends on the forces acting on the particle and on the spin transport law.

## 2. Application: Spin in the gravitational and electromagnetic fields

In order to consider the most general case, we assume that the gravitational field is described by an arbitrary coframe and an (independent) local Lorentz connection $(e_i^\alpha, \Gamma_i{}^{\alpha\beta} = -\Gamma_i{}^{\beta\alpha})$, whereas the electromagnetic field as usual is represented by the vector potential $A_i = (-\Phi, \boldsymbol{A})$. The corresponding field strengths are the torsion $T_{ij}{}^\alpha = \partial_i e_j^\alpha - \partial_j e_i^\alpha + \Gamma_{i\beta}{}^\alpha e_j^\beta - \Gamma_{j\beta}{}^\alpha e_i^\beta$, the curvature $R_{ij}{}^{\alpha\beta} = \partial_i\Gamma_j{}^{\alpha\beta} - \partial_j\Gamma_i{}^{\alpha\beta} + \Gamma_{i\gamma}{}^\beta\Gamma_j{}^{\alpha\gamma} - \Gamma_{j\gamma}{}^\beta\Gamma_i{}^{\alpha\gamma}$, and the Maxwell tensor $F_{ij} = \partial_i A_j - \partial_j A_i$. Accordingly, the spacetime geometry in general carries the Riemann-Cartan structure with the metric $g_{ij} = e_i^\alpha e_j^\beta g_{\alpha\beta}$ and the nontrivial torsion. The "deviation" of the spacetime geometry from the Riemannian structure can be conveniently measured by the contortion tensor which is defined in terms of the difference of the local Lorentz connection $\Gamma_i{}^{\alpha\beta}$ and the Riemannian (Levi-Civita or Christoffel) connection $\tilde{\Gamma}_i{}^{\alpha\beta}$:

$$K_i{}^{\alpha\beta} = \tilde{\Gamma}_i{}^{\alpha\beta} - \Gamma_i{}^{\alpha\beta}. \tag{23}$$

### 2.1. *Quantum spinning particle*

A fermion particle with spin $\frac{1}{2}$, charge $q$ and mass $m$ is described by the relativistic Dirac theory. The spinor field $\psi$ dynamics is determined by the Lagrangian

$$L = \frac{i\hbar}{2}\left(\overline{\psi}\gamma^{\alpha}D_{\alpha}\psi - D_{\alpha}\overline{\psi}\gamma^{\alpha}\psi\right) - mc\overline{\psi}\psi + \frac{1}{2c}M_{\alpha\beta}\,\overline{\psi}\sigma^{\alpha\beta}\psi + \frac{i\hbar\nu'}{12}\check{T}^{\alpha}\,\overline{\psi}\gamma_{\alpha}\gamma_{5}\psi, \quad (24)$$

where the spinor covariant derivative is defined as (with $\sigma_{\alpha\beta} = i\gamma_{[\alpha}\gamma_{\beta]}$)

$$D_{\alpha}\psi = e^{i}_{\alpha}\left(\partial_{i}\psi - \frac{iq}{\hbar}\,A_{i}\psi + \frac{i}{4}\Gamma_{i}{}^{\beta\gamma}\sigma_{\beta\gamma}\psi\right). \quad (25)$$

The first two terms in (24) describe minimal coupling of the spinor field to electromagnetism and gravity encoded in (25). In addition, we assume possible nonminimal interactions, which are described by two Pauli-type terms in (24), where

$$M_{\alpha\beta} = \mu' F_{\alpha\beta} + c\delta'\,\frac{1}{2}\,\eta_{\alpha\beta\mu\nu}F^{\mu\nu}, \quad (26)$$

is the generalized polarization tensor, and the axial torsion is defined as

$$\check{T}^{\alpha} = -\,\frac{1}{2}\,\eta^{\alpha\mu\nu\beta}T_{\mu\nu\beta} = \left\{\check{T}^{0}, \check{\boldsymbol{T}}\right\}. \quad (27)$$

The parameters $\delta', \mu', \nu'$ characterize the strength of nonminimal couplings.

### 2.2. *Classical spinning particle*

The classical theory of spin was developed soon after the concept of spin was proposed in particle physics (see Ref. 1 for introduction and history). This theory underlies the analysis of the dynamics of polarized particles in accelerators and storage rings.

Neglecting second-order spin effects[2], the dynamical equations for a spinning particle in external electromagnetic and gravitational fields are written as

$$\frac{DU^{\alpha}}{d\tau} = -\,\frac{q}{m}\,F^{\alpha}{}_{\beta}\,U^{\beta}, \quad (28)$$

$$\frac{DS^{\alpha}}{d\tau} = -\,(\nu'-2)\,U^{i}K_{i\beta}{}^{\alpha}S^{\beta} - \frac{q}{m}\,F^{\alpha}{}_{\beta}S^{\beta} - \frac{2}{\hbar}\left[M^{\alpha}{}_{\beta} + \frac{1}{c^{2}}U^{\gamma}\left(U^{\alpha}M_{\beta\gamma} - U_{\beta}M^{\alpha}{}_{\gamma}\right)\right]S^{\beta}. \quad (29)$$

Here we follow the notations and conventions introduced in the previous sections.

### 2.3. *Application of the projection method*

Comparing the system (28)–(29) with (3), we find explicitly the generalized force and the spin transport matrix:

$$\mathcal{F}_{\alpha} = -\,\frac{q}{m}\,\mathbb{F}_{\alpha\beta}\,U^{\beta}, \qquad \Phi_{\alpha\beta} = -\,\frac{q}{m}\,\mathbb{F}_{\alpha\beta}, \quad (30)$$

where we introduced the combined external field

$$\mathbb{F}_{\alpha\beta} = F_{\alpha\beta} + \frac{2m}{q\hbar}\,M^{\perp}_{\alpha\beta} - \frac{m}{q}\,U^{i}\Gamma_{i\alpha\beta}. \quad (31)$$

As we see, $\Phi_{\alpha\beta}U^\beta = \mathcal{F}_\alpha$. Here we denoted

$$M^\perp_{\alpha\beta} = \Big(\delta^\mu_\alpha - \frac{1}{c^2}U_\alpha U^\mu\Big)\Big(\delta^\nu_\beta - \frac{1}{c^2}U_\beta U^\nu\Big)M_{\mu\nu}. \tag{32}$$

The components of this tensor read explicitly

$$M^\perp_{0a} = \frac{\gamma^2}{c}\left\{-v^2\mathcal{P}_a + \widehat{v}_a(\widehat{\boldsymbol{v}}\cdot\boldsymbol{\mathcal{P}}) + c[\widehat{\boldsymbol{v}}\times\boldsymbol{\mathcal{M}}]_a\right\}, \tag{33}$$

$$M^\perp_{ab} = \epsilon_{abc}\frac{\gamma^2}{c^2}\left\{c^2\mathcal{M}^c - \widehat{v}^c(\widehat{\boldsymbol{v}}\cdot\boldsymbol{\mathcal{M}}) + c[\widehat{\boldsymbol{v}}\times\boldsymbol{\mathcal{P}}]^c\right\}. \tag{34}$$

Here we identify $c\boldsymbol{\mathcal{P}}_a = \{M_{\widehat{01}}, M_{\widehat{02}}, M_{\widehat{03}}\}, \boldsymbol{\mathcal{M}}^a = \{M_{\widehat{23}}, M_{\widehat{31}}, M_{\widehat{12}}\}$ as the polarization and magnetization 3-vectors, respectively.

Now we use the projection method developed above and extract the "electric" and "magnetic" vectors from the artificial electromagnetic field (31)

$$\mathbb{E}_\alpha := \mathbb{F}_{\alpha\beta}U^\beta, \qquad \mathbb{B}^\alpha := \frac{1}{2c}\eta^{\alpha\mu\nu\beta}\mathbb{F}_{\mu\nu}U_\beta, \tag{35}$$

which yields an unique representation

$$\mathbb{F}_{\alpha\beta} = \frac{1}{c^2}\left(\mathbb{E}_\alpha U_\beta - \mathbb{E}_\beta U_\alpha + c\eta_{\alpha\beta\mu\nu}U^\mu\mathbb{B}^\nu\right). \tag{36}$$

Comparing (6) with (9), we thus identify

$$N_\alpha = -\frac{q}{m}\,\mathbb{E}_\alpha, \qquad Q^\alpha = -\frac{q}{m}\,\mathbb{B}^\alpha. \tag{37}$$

Let us define effective "electric" and "magnetic" fields

$$\mathfrak{E}^{\rm eff}_a = \{\mathbb{F}_{\widehat{10}}, \mathbb{F}_{\widehat{20}}, \mathbb{F}_{\widehat{30}}\}, \qquad \mathfrak{B}^a_{\rm eff} = \{\mathbb{F}_{\widehat{23}}, \mathbb{F}_{\widehat{31}}, \mathbb{F}_{\widehat{12}}\}. \tag{38}$$

Or in compact form: $\mathfrak{E}^{\rm eff}_a = \mathbb{F}_{a0}$, and $\mathfrak{B}^a_{\rm eff} = \frac{1}{2}\epsilon^{abc}\mathbb{F}_{bc}$.

Consequently from (35) and (37) we derive the components

$$N^0 = \gamma\,\frac{q\widehat{\boldsymbol{v}}\cdot\mathfrak{E}_{\rm eff}}{mc^2}, \qquad \boldsymbol{N} = \gamma\,\frac{q}{m}\left(\mathfrak{E}_{\rm eff} + \widehat{\boldsymbol{v}}\times\mathfrak{B}_{\rm eff}\right), \tag{39}$$

$$Q^0 = -\gamma\,\frac{q\widehat{\boldsymbol{v}}\cdot\mathfrak{B}_{\rm eff}}{mc^2}, \qquad \boldsymbol{Q} = -\gamma\,\frac{q}{m}\Big(\mathfrak{B}_{\rm eff} - \frac{1}{c^2}\widehat{\boldsymbol{v}}\times\mathfrak{E}_{\rm eff}\Big). \tag{40}$$

By construction, $\boldsymbol{Q}_\perp = \boldsymbol{Q}$, and moreover we have $\boldsymbol{\mathcal{F}} = \boldsymbol{N}$. Inserting (39) and (40) into (22), we obtain the precession angular velocity (22)

$$\boldsymbol{\Omega} = \frac{q}{m}\left(-\mathfrak{B}_{\rm eff} + \frac{\gamma}{\gamma+1}\,\frac{\widehat{\boldsymbol{v}}\times\mathfrak{E}_{\rm eff}}{c^2}\right) \tag{41}$$

as a function of external fields which enter via the effective variables:

$$\mathfrak{E}_{\rm eff} = \mathfrak{E} - \frac{2m}{q\hbar}\,\gamma^2\,\widehat{\boldsymbol{v}}\times\boldsymbol{\Delta} + \frac{m}{q}\,\boldsymbol{\mathcal{E}}, \tag{42}$$

$$\mathfrak{B}_{\rm eff} = \mathfrak{B} + \frac{2m}{q\hbar}\,\gamma^2\Big[\boldsymbol{\Delta} - \frac{1}{c^2}\,\widehat{\boldsymbol{v}}\,(\widehat{\boldsymbol{v}}\cdot\boldsymbol{\Delta})\Big] + \frac{m}{q}\,\boldsymbol{\mathcal{B}}. \tag{43}$$

Recall that the components of the true electric and magnetic fields are introduced as $\mathfrak{E}_a = \{F_{\widehat{1}\widehat{0}}, F_{\widehat{2}\widehat{0}}, F_{\widehat{3}\widehat{0}}\}, \mathfrak{B}^a = \{F_{\widehat{2}\widehat{3}}, F_{\widehat{3}\widehat{1}}, F_{\widehat{1}\widehat{2}}\}$. The generalized polarization current,

$$\boldsymbol{\Delta} = \boldsymbol{\mathcal{M}} + \frac{1}{c}\,\widehat{\boldsymbol{v}} \times \boldsymbol{\mathcal{P}}, \tag{44}$$

accounts in the spin precession (41)–(43) for the electromagnetic nonminimal coupling effects, whereas the gravitoelectric and gravitomagnetic fields

$$\boldsymbol{\mathcal{E}} = \widetilde{\boldsymbol{\mathcal{E}}} - \frac{\gamma c(3-\nu')}{6}\,\widehat{\boldsymbol{v}} \times \check{\boldsymbol{T}}, \qquad \boldsymbol{\mathcal{B}} = \widetilde{\boldsymbol{\mathcal{B}}} + \frac{\gamma c(3-\nu')}{6}\,\big(\check{\boldsymbol{T}} - \widehat{\boldsymbol{v}}\check{T}^0\big) \tag{45}$$

encompass general-relativistic Riemannian gravitoelectric $\widetilde{\boldsymbol{\mathcal{E}}}$ and gravitomagnetic $\widetilde{\boldsymbol{\mathcal{B}}}$ contributions, as well as the post-Riemannian terms due to the spacetime torsion.

## 3. Discussion and conclusion

The classical and quantum spin dynamics are fully consistent. The physical contents of the relativistic quantum theory (24) is revealed when we recast the Dirac equation into a Schrödinger form and go to the Foldy-Wouthuysen (FW) representation. In the Schwinger gauge, the coframe is parametrized by the functions $V, \boldsymbol{K}, W^{\widehat{a}}{}_b$:

$$e_i^{\widehat{0}} = V\,\delta_i^0, \qquad e_i^{\widehat{a}} = W^{\widehat{a}}{}_b\,\big(\delta_i^b - cK^b\,\delta_i^0\big), \qquad a = 1,2,3, \tag{46}$$

and the resulting FW Hamiltonian in the semiclassical approximation then reads

$$\mathcal{H}_{FW} = \beta mc^2 V\gamma + q\Phi + \frac{c}{2}\,(\boldsymbol{K}\cdot\boldsymbol{\pi} + \boldsymbol{\pi}\cdot\boldsymbol{K}) + \frac{\hbar}{2}\boldsymbol{\Sigma}\cdot\boldsymbol{\Omega}. \tag{47}$$

Here the Lorentz factor (5) operator $\gamma$ and the precession velocity (41) operator $\boldsymbol{\Omega}$ are both expressed in terms of the velocity operator $\widehat{\boldsymbol{v}}$ which is related to the momentum operator $\boldsymbol{\pi} = -i\hbar\boldsymbol{\nabla} - q\boldsymbol{A}$ via $\beta\,W^b{}_{\widehat{a}}\pi_b = m\gamma\widehat{v}_a$.

The analysis of the spin dynamics in electromagnetic, inertial and gravitational fields is fundamentally important for the study of the geometrical structure of spacetime[3], as well as in the high-energy physics experiments[4], in the search of gravitational waves[5], in the neutrino physics in matter[6], and in the heavy-ion collisions[7].

There is an ever growing number of proposals for high precision experiments to measure gravitational effects, from simple Newtonian gravity to gravitational waves and even precision tests of general relativity (GR). In particular, more and more researchers from the fields of quantum optics and quantum opto-mechanics are becoming interested in GR and propose metrological experiments. Usually, such proposals rely heavily on a notion of length. However, in GR, as coordinates have no physical meaning, there is no unique concept for the length of a matter system. In this proceedings article, we summarize the article [24], where the conceptual problem of length is addressed for a subset of experimental proposals. In particular, the effect of gravitational fields and acceleration on the frequency spectrum of an optical resonator is discussed in the framework of GR. The optical resonator is modeled as a deformable rod of matter connecting two mirrors. Explicit expressions for the frequency spectrum are given for the case of a small perturbation. Example situations are discussed and a connection is obtained to a relativistic concept of rigidity.

*Keywords*: Optical cavity, Fabry-Pérot, gravitational field, rigid body, elastic body.

## 1. Introduction

In general relativity (GR), as coordinates have no physical meaning, there is no unique concept for the length of a matter system. Some notion of length can be covariantly defined using geometrical quantities or properties of matter. The ambiguity in the notion of length poses a problem for high accuracy metrological

experiments, where gravitational fields or acceleration play a significant role. For example, the frequency spectrum of a resonator depends on its dimensions and hence knowledge of the precise values of these dimensions is of utmost importance. Cases in which the effects of gravitational fields and acceleration must be considered include those in which the gravitational field is to be measured, such as in proposals for the measurement of gravitational waves with electromagnetic cavity resonators[6,9,10,20–22,27] or other extended matter systems[1,7,8,12,18,25,26], tests of GR[3,11] or the expansion of the universe[13,14]. Other situations are those in which the metrological system is significantly accelerated[16,17,23]. A fundamental limit for the precision of a light cavity resonator as a metrological system can even be imposed by the gravitational field of the light inside the cavity[4].

The two most important concepts of length are the proper distance and the radar distance. The proper distance is a geometrical quantity usually associated with the length of a rod that is rigid in the sense of that given by Born[2]. The radar distance is the optical length that can be measured by sending light back and forth between two mirrors and taking the time between the two events as a measure of distance. It is this radar length that gives the resonance frequency spectrum of an optical resonator for large enough wave numbers. However, the resonators that are part of the metrological systems described in Refs. 1, 3, 4, 6–14, 16–18, 20–23, 25–27 are confined by solid matter systems, and therefore, the notion of proper length plays also a role.

We assume that all effects on the optical resonator can be described as small perturbations. We use a specific coordinate system $x^{\mathcal{M}}$ valid in a region around the world line of the resonator's support in which the spacetime metric takes the form $g_{\mathcal{MN}} = \eta_{\mathcal{MN}} + h_{\mathcal{MN}}$, where $\eta_{\mathcal{MN}} = \mathrm{diag}(-1, 1, 1, 1)$ is the Minkowski metric and $h_{\mathcal{MN}}$ is a perturbation. $h_{\mathcal{MN}}$ is considered as small in the sense that $|h_{\mathcal{MN}}| \ll 1$ for all $\mathcal{M}, \mathcal{N}$.

## 2. Frequency spectrum

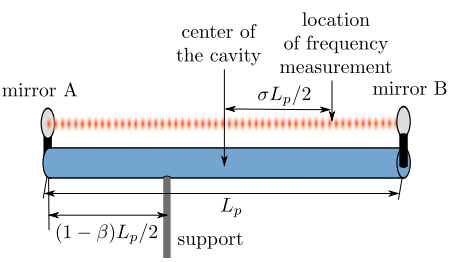

Fig. 1. Illustration of our model of an optical resonator consisting of two mirrors that are attached to the ends of a rod. We assume that the resonator is moved along a trajectory $\gamma(\varrho)$ by a support which is attached at a distance $(1-\beta)L_p/2$ from mirror A, where $L_p$ is the length of the rod without gravity or acceleration. Since proper time depends on the position in the gravitational field so does the measured frequency of a resonator mode. We assume the frequency to be measured at a distance $\sigma L_p/2$ from the center of the resonator towards mirror B.

In Ref. 24, we consider two fundamental models of an optical resonator. In both cases, there is a rod which is supported at a certain point along its length. In one model, the rod itself is the optical resonator. For example, it could consist of a homogeneous isotropic dielectric. The other model assumes two mirrors attached to the ends of the rod. The latter model is the focus of this article, and it is illustrated in Fig. 1. For both cases, we derived an expression for the resonance frequencies of the optical resonator in Ref. 24. As we are dealing with an extended object in GR, the obtained resonance frequencies are ambiguous as we cannot give a proper time to the whole resonator; the frequencies of the modes must depend on the point in the resonator where they are observed. Using the short wavelength expansion, we find that the frequencies of the modes of the resonator measured by an observer inside the cavity is given as

$$\omega_{\gamma,n} = \frac{cn\pi}{R_\gamma}\,, \tag{1}$$

where $R_\gamma$ is the radar distance which is defined as $c/2$ times the proper time for a round trip of a light pulse in the resonator as it would be measured by an observer at a fixed proper distance from the support of the resonator. It is clear that this is an approximate value; the notion of frequency means the rate of repetition of a signal. For this notion to make sense, it has to be constant at least for a few repetition cycles. Hence, the gravitational field has to change slowly in comparison to the round trip time $2R_\gamma/c$.

## 3. Rigid resonators

In GR, there exist different notions of rigidity as it turns out to be less than straightforward to formulate this basic concept of Newtonian mechanics in a relativistic way. Here, we use, as our starting point, a definition of a rigid rod that is Born rigid, and we undertake a perturbative analysis for small length scales, small accelerations, small velocities and small gravitational fields. We show that two types of effects are found; those due to spacetime properties alone and those due to small deformations of the rod which correspond to small deviations from Born rigidity. Since all effects can be considered as small, we remain in the linear regime, where the different effects are assumed to be independent.

Let us assume that we have a rod of very small diameter in comparison to its length, which means it is effectively 1-dimensional. We assume that the world lines of the segments of the rod form a family of curves $\gamma_\varsigma(\varrho)$ parametrized by $\varsigma$ which we assume to be in the interval $\varsigma \in [a, b]$. The end points of the rod are $\gamma_a(\varrho)$ and $\gamma_b(\varrho)$. The spacetime surface $F(\varrho, \varsigma) = \gamma_\varsigma(\varrho)$ can be called the world sheet of the rod. We assume that the curve parameter $\varrho$ is chosen so that the curves $s_\varrho(\varsigma) := F(\varrho, \varsigma)$ are space-like geodesics. We say that the rod is rigid if the proper distance between every two points on the curve $s_\varrho(\varsigma)$ is independent of the parameter $\varrho$.

In Ref. 24, we derive the resonance frequencies of a Born rigid resonator in terms of its constant proper length. For this purpose, we choose to work in a particular

coordinate system, the proper detector frame which is defined along the world line of the support of the optical cavity. In these coordinates, the spacetime metric seen by a non-rotating observer can be given simply in terms of the Riemann curvature tensor along the world line of the resonator's support $\gamma(\tau)$ denoted as $R_{\mathcal{MNKL}}(\tau)$ (caligraphic captical indeces run from 0 to 3) and the non-gravitational or proper acceleration with respect to a local freely falling frame, represented by the spatial vector $a^J$ $(J \in 1, 2, 3)$.

The proper detector frame of a non-rotating observer is accurate for proper distances much smaller than $l_{\text{var}}$, the length scale on which the properties of spacetime vary. Therefore, we assume that the proper length of the resonator in the absence of gravity and acceleration $L_p$ is small in comparison to the scale $l_{\text{var}}$. We consider $\gamma(\tau)$ to be the world line of the point at which the rod of the resonator is supported. We assume that this point is somewhere inside the resonator. We also assume that the resonator is not rotating in the frame of the observer. We orient the spatial geodesic representing the rigid rod along the $z$-direction at $\gamma(\tau)$ in the proper detector frame, i.e. $s'_\tau(\varsigma) = (0, 0, 0, 1)$. By construction of the proper detector frame, the geodesics $s_\tau(\varsigma)$ run along the $z$-coordinate. We consider only first order contributions of the proper acceleration, which means that we can consider the metric in the proper detector frame as a linearly perturbed flat spacetime metric.

To obtain the frequency of the rigid resonator measured by an observer at coordinates $(0, 0, z_0)$ in the proper detector frame based on Eq. (1), we have to calculate the corresponding radar distance between the mirrors. Then, the relative change of the resonance frequencies measured at $z_0 = (\sigma + \beta)L_p/2$ is given as

$$\delta_{\omega,\sigma} := \frac{\omega_n}{\bar{\omega}_n} - 1 \approx -\frac{a^z(\tau)}{2c^2}\sigma L_p - \frac{R_{0z0z}(\tau)}{24}\left(3\sigma^2 + 6\sigma\beta - 1\right)L_p^2\,, \tag{2}$$

where $\bar{\omega}_n = cn\pi/L_p$ is the $n$-th resonance frequency of the resonator for vanishing acceleration and curvature. We find that the only linear contribution of the acceleration $a^z$ to the resonance frequency spectrum in Eq. (2) is via a position-dependent red shift. It vanishes for $\sigma = 0$, which corresponds to a frequency measurement in the center of the resonator. The term $3\sigma^2$ corresponds to a pure red shift with respect to the center of the cavity. The term $6\beta\sigma$ is due to the displacement of the resonator's support from its center.

## 4. Deformable resonators

A realistic rod can never be rigid. Therefore, we consider the first order deviations from the rigid rod by taking the deformation of the rod due to small inertial and gravitational forces into account. In the proper detector frame, every segment of the rod has a world line with constant spatial components. The relative acceleration of a segment of the rod at $\mathbf{x} = (c\tau, 0, 0, z)$, in comparison to a freely falling test particle initially at rest at the same position as that segment, can be derived from the geodesic equation.

We consider the effect of relative acceleration on the resonator's end mirrors and the resulting deformation of the rod to be negligible in comparison to the direct effect of relative acceleration on the rod. Then, we obtain the inertial and tidal forces on the rod by multiplication with the mass density $\rho$. These forces give rise to stresses within the rod, represented by the stress tensor $\sigma_{KL}$. For static forces and forces that change very slowly, the stresses are related to the strain via Hooke's law. After an analysis of the resulting forces, we give conditions that have to be fulfilled for the longitudinal deformation of the rod to be the dominant effect on the frequency spectrum of the resonator. We find for the relative change of the resonance frequencies of the deformable resonator

$$\delta_{\omega,\sigma} \approx \frac{\mathbf{a}^z(\tau)}{2c^2}\left(\frac{c^2}{c_s^2}\beta - \sigma\right) L_p + \frac{R_{0z0z}(\tau)}{24}\left(2\frac{c^2}{c_s^2}(3\beta^2+1) - 3\sigma^2 - 6\sigma\beta + 1\right) L_p^2 \,. \tag{3}$$

We obtain the result in Eq. (2) for the Born rigid rod from Eq. (3) if the speed of sound $c_s$ in the material is infinite. This coincides with the observation that a Born rigid rod violates causality, as its segments would need to interact with an infinite speed. A more realistic definition of a rigid rod, which we call a causal rigid rod, was given in Ref. 19 as a rod in which the speed of sound is equivalent to the speed of light. In the appendix of Ref. 24, we show that the approach of Ref. 19 leads to Eq. (3) with the speed of sound replaced by the speed of light.

The speed of sound $c_s$ in every realistic material is always much smaller than the speed of light: for example the speed of sound in aluminum is of the order $5 \times 10^3$m/s. To date, the material with the highest ratio of Young's modulus and density $Y/\rho = c_s^2$ is carbyne, with a value of the order of $10^9 \mathrm{m}^2/\mathrm{s}^2$ [15], which would correspond to a speed of sound of the order of $3 \times 10^4$m/s. Therefore, we find that the effect of the deformation of matter is by far the most dominant and the rod is far from rigid (may it be Born rigid or causal rigid) in all realistic situations. However, the relativistic effect of gravitational redshift gives a fundamental limit on the definition of the frequency spectrum of an optical resonator as a property of the resonator alone; when resonance frequencies of an optical resonator are to be specified with a precision of the order of this relativistic effect, the position of the frequency measurement has to specified.

## 5. Example applications

To illustrate the applicability of our results, we consider some examples. A particularly straightforward example is the situation of a non-rotating resonator that is uniformly accelerated along the optical axis. We find

$$\delta_{\omega,\sigma} \approx \left(\frac{\beta}{c_s^2} - \frac{\sigma}{c^2}\right)\frac{a^z L_p}{2} \,. \tag{4}$$

For $\beta = \pm 1$, a length of the resonator of $L_p \sim 2\,\mathrm{cm}$, an acceleration of the order of $10\,\mathrm{ms}^{-2}$, which is similar to the gravitational acceleration of the Earth, and a

speed of sound in the rod of the order of $10^3\,\mathrm{ms}^{-1}$ (similar to the speed of sound in aluminum), we obtain a relative frequency shift of the order of $10^{-7}$. This frequency shift is given only by the first term in Eq. (4) as the second term is smaller by about 11 orders of magnitude. Since the first term is due to the deformation of the resonator it is a Newtonian effect. The second term is the gravitational red shift, which was already measured on the length scale of about 2 cm in the gravitational field of the Earth[5] and therefore for the acceleration in the example. The effect of gravitational red shift gives a limit on the validity of the concept of the frequency spectrum as a property of the optical resonator itself.

Our results are not limited to spacetimes that only bear weak gravitational effects. It is the spacetime metric seen by the optical resonator in its proper detector frame that has to be a linearized metric. This is ensured by the condition $l_{\mathrm{var}} \gg L_p$. To illustrate the applicability of our results to spacetimes with strong gravitational fields, we consider the situation of a non-rotating resonator that falls into a non-rotating black hole. For a vertically oriented causal rigid resonator supported at its center, we find the relative frequency shift at its center

$$\delta_{\omega,0}(\tau) \approx -\frac{r_S L_p^2}{8r(\varrho)^3}\,. \tag{5}$$

Note that there is no effect due to the crossing of the event horizon at $r_S$. This result can be applied as well to an optical resonator falling towards the Earth. For a distance from the center of the Earth of the same order as its radius, we find that the relative frequency shift in Eq. (5) is of the order of $10^{-27}$ for an optical resonator of 2 cm length. This relativistic effect is mostly gravitational red shift due to curvature. It is far from being observable with state of the art technology. However, it gives a fundamental limit of the validity of the concept of frequency spectrum as a property of the optical resonator without any reference as discussed above.

We discuss the interaction of gravitational waves with spinning particle. To obtain physically measurable quantities, we make use of Fermi coordinates and we show that, using these coordinates, the magnetic-like (or gravitomagnetic) part of the gravitational field of the wave is emphasized. Eventually, we evaluate the magnitude of the effects induced by the waves on spinning particles, and discuss some measurement possibilities.

*Keywords*: Gravitational waves; spin; gravitomagnetism.

## 1. Introduction

The observation of gravitational wave (GW) signals[1,2] is just one of the latest successes of Einstein's theory of gravitation, General Relativity (GR): as a matter of fact, its prediction were verified with great accuracy during last century, even though challenges to the Einsteinian paradigm come from cosmological observations[3]. Einstein's theory is based on the principle of general covariance, which requires physics laws to be expressed by tensorial equations in space-time; accordingly, physical measurements are meaningful only when the observer and the object of the observations are unambiguously identified[4]. Roughly speaking, the measurement process can be summarised as follows: (i) observers possess their own space-time, in the vicinity of their world-lines; (ii) covariant physics laws are then projected onto local space and time; (iii) predictions for the outcome of measurements in the local space-time of the observers are obtained. In practice, it is convenient for an observer to use a quasi-Cartesian coordinates system in his neighborhood to describe the effects of gravitation; a continuous set of quasi-Cartesian coordinates associated with the observer's world-line defines the so called Fermi coordinates. These coordinates have a concrete meaning, since they are the coordinates an observer would naturally use to make space and time measurements in the vicinity of his world-line. The definition of these coordinates is relevant to define measurements performed in the space-time of a gravitational wave, even though in current literature the interaction between gravitational waves and detectors is described in terms of a transverse and traceless tensor, which allows to introduce the so-called TT coordinates (see e.g. Ref. 5 and references therein for a thorough discussion on the various coordinates

used to describe the interaction with gravitational waves). Motion of spinning particles in the weak gravitational plane wave space-time has been investigated in the past [6]; indeed, gravitational waves carry angular momentum and, hence, spinning particles interact with gravitational waves differently from non spinning ones. In particular, writing the gravitational waves space-time using Fermi coordinate emphasizes these features, since gravitomagnetic terms are present in the metric (see e.g. Ref. 7): the term *gravitomagnetic* refers to the magnetic-like part of the gravitational field, which originates from the angular momentum of the sources. It is a well known fact (see e.g. Ref. 8) that Einstein equations, in weak-field approximation (small masses, low velocities), can be written in analogy with Maxwell equations for the electromagnetic field, where the mass density and current play the role of the charge density and current, respectively. Once that a set of coordinates adapted to the observer world-line is chosen, gravitomagnetic effects are determined by the off-diagonal terms in the space-time metric. Actually, these effects are very small, but there were many proposals in the past (see Ref. 8) and also more recently to test them (see e.g. Refs. 9, 10, 11, 12, 13, 14). Starting from the results described in Ref. 7, it is possible to test the effects of the gravitomagnetic field of a gravitational wave on a bunch of spinning particles; in particular, we are going to show that the response of a such a system to the interaction with the wave could lead to macroscopic measurable quantities.

## 2. Spinning Particles in the Gravitational Wave Space-Time

Using the transverse - traceless gauge (TT) the space-time metric of a gravitational wave propagating along the $x$ axis is given by the following line element:

$$ds^2 = -dt^2 + dx^2 + (1 - h_+)dy^2 + (1 + h_+)dz^2 - 2h_\times dydz\,, \tag{1}$$

where[a] the functions $h_{+,\times}$ depend on $t - x$. In particular, if we consider monochromatic waves with frequency $\omega$, we have

$$h_+(t-x) = A_+ \sin\omega\,(t-x)\ , \quad h_\times(t-x) = A_\times \cos\omega\,(t-x) \tag{2}$$

In what follows, analysis is carried out up to linear order in $h_+$, $h_\times$. It is easy to show [5] that in the TT metric (1) the geodesics are such that an inertial mass initially at rest remains at rest indefinitely; however the $x, y, z, t$ coordinates have no operational meaning, since they are not directly related to physical quantities: in fact, two masses at rest in the TT with (constant) coordinate distance $\Delta y$, have a physical distance varying with time $\ell = \Delta y \left(1 + \frac{h_+}{2}\right)$. In order to give a physical meaning to coordinates, we need to use a set of Fermi coordinates in the space-time of the gravitational wave. The transformation from TT coordinates $x, y, z, t$ to Fermi $X, Y, Z, T$ coordinates is given by [7]:

[a] We use units such that $c = 1$, however physical units are used to evaluate the order of magnitude of the effects; the space-time signature is (-1,1,1,1).

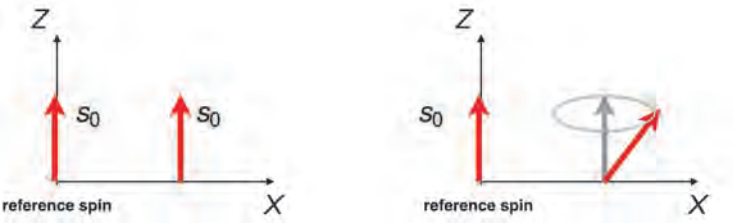

Fig. 1. Left: the reference spin and the other one before the passage of the wave; right: the two spin after the passage of the wave.

$$
\begin{aligned}
t &= T - \frac{1}{2}A_+\left\{\frac{Y^2-Z^2}{X}\left[\frac{\cos(\omega(T-X))-\cos(\omega T)}{\omega X}-\sin(\omega T)\right]\right.\\
&\quad \left.+\,\omega(S_2^0 Z + S_3^0 Y)[\cos(\omega T)-1]\right\}\\
&\quad +A_\times\left\{\frac{YZ}{X}\left[\frac{\sin(\omega(T-X))-\sin(\omega T)}{\omega X}+\cos(\omega T)\right]-\frac{1}{2}\omega(S_2^0 Y - S_3^0 Z)\sin(\omega T)\right\}\\
x &= X - \frac{1}{2}A_+\frac{Y^2-Z^2}{X}\left[\frac{\cos(\omega(T-X))-\cos(\omega T)}{\omega X}-\sin(\omega T)\right]\\
&\quad +A_\times\frac{YZ}{X}\left[\frac{\sin(\omega(T-X))-\sin(\omega T)}{\omega X}+\cos(\omega T)\right],\\
y &= Y + A_+\left\{Y\left[\frac{\cos(\omega(T-X))-\cos(\omega T)}{\omega X}-\frac{1}{2}\sin(\omega T)\right]-\frac{1}{2}S_3^0[\sin(\omega T)-\omega T]\right\}\\
&\quad -A_\times\left\{Z\left[\frac{\sin(\omega(T-X))-\sin(\omega T)}{\omega X}+\frac{1}{2}\cos(\omega T)\right]-\frac{1}{2}S_2^0[\cos(\omega T)-1]\right\},\\
z &= Z - A_+\left\{Z\left[\frac{\cos(\omega(T-X))-\cos(\omega T)}{\omega X}-\frac{1}{2}\sin(\omega T)\right]+\frac{1}{2}S_2^0[\sin(\omega T)-\omega T]\right\}\\
&\quad -A_\times\left\{Y\left[\frac{\sin(\omega(T-X))-\sin(\omega T)}{\omega X}+\frac{1}{2}\cos(\omega T)\right]+\frac{1}{2}S_3^0[\cos(\omega T)-1]\right\}.
\end{aligned}
\tag{3}
$$

The above expressions are obtained in the vicinity of the world-line of the spinning particle. It is based on the study of the motion of the particle and the evolution of its spin vector components in the gravitational field of the wave. It has been supposed that, before the passage of the wave, the particle is at rest with associated spin vector aligned along a given direction with constant magnitude; $S_i^0$ $(i = 1, 2, 3)$ are the initial values of the coordinate components of the particle's spin. In order to compare the spin of two different spinning particles, the deviation equation has been solved together with a suitable transport equation for the spin vector between two neighbouring world-lines. The space-time metric in Fermi coordinates, up to

the second order, is then given by

$$
\begin{aligned}
g_{TT} &= -1 - \left[S_2^0 Z + S_3^0 Y - \frac{1}{2}(Y^2 - Z^2)\right]\omega^2 A_+ \sin(\omega T) \\
&\quad + \left[S_2^0 Y - S_3^0 Z + YZ\right]\omega^2 A_\times \cos(\omega T) + O(3)\,, \\
g_{TX} &= -\frac{1}{3}\omega^2\left[(Y^2 - Z^2)A_+ \sin(\omega T) + 2YZA_\times \cos(\omega T)\right] + O(3)\,, \\
g_{TY} &= \frac{1}{3}\omega^2 X\left[YA_+ \sin(\omega T) + ZA_\times \cos(\omega T)\right] + O(3)\,, \\
g_{TZ} &= \frac{1}{3}\omega^2 X\left[-ZA_+ \sin(\omega T) + YA_\times \cos(\omega T)\right] + O(3)\,, \\
g_{XX} &= 1 + \frac{1}{6}\omega^2\left[(Y^2 - Z^2)A_+ \sin(\omega T) + 2YZA_\times \cos(\omega T)\right] + O(3)\,, \\
g_{XY} &= -\frac{1}{2}g_{TY} + O(3)\,, \qquad g_{XZ} = -\frac{1}{2}g_{TZ} + O(3)\,, \\
g_{YY} &= 1 + \frac{1}{6}\omega^2 X^2 A_+ \sin(\omega T) + O(3)\,, \qquad g_{YZ} = \frac{1}{6}\omega^2 X^2 A_\times \cos(\omega T) + O(3)\,, \\
g_{ZZ} &= 1 - \frac{1}{6}\omega^2 X^2 A_+ \sin(\omega T) + O(3)\,. \qquad (4)
\end{aligned}
$$

In particular, we see that the gravitomagnetic terms $g_{TX}, g_{TY}, g_{TZ}$ are not null, since a gravitational wave transports angular momentum. The world-line of a spinning particle and the evolution of its spin vector can be found in Ref. 7. Notice that, by inspection of the $g_{TT}$ component, we see that clocks at rest in the laboratory measure different time due to their spin. Let us suppose that a test body is spinning around the Z-axis before the passage of the wave with constant spin $S_1^0 = 0, S_2^0 = 0, S_3^0 = s_0$. Due to the passage of the wave, the particle spin vector has non-vanishing spatial components varying with time and displacements along the three spatial directions; in particular, close to the reference spinning particle, the spin vector components turn out to be:

$$
\begin{aligned}
\tilde{S}^X &= -\frac{1}{2}\omega s_0[YA_\times \sin(\omega T) + ZA_+ \cos(\omega T)] + O(2) \\
\tilde{S}^Y &= \frac{1}{2}\omega s_0 X A_\times \sin(\omega T) + O(2) \\
\tilde{S}^Z &= \frac{1}{2}\omega s_0 X A_+ \cos(\omega T) + O(2)
\end{aligned}
$$

If we consider a second spinning particle at coordinates (X,0,0) (see Figure 1) with the same spin vector of the reference one, the passage of the GW induces a relative precession:

$$
\tilde{S}^X = 0, \quad \tilde{S}^Y = \frac{1}{2}\omega s_0 X A_\times \sin(\omega T), \quad \tilde{S}^Z = \frac{1}{2}\omega s_0 X A_+ \cos(\omega T).
$$

To estimate the effect, we write the magnitude of the component of the spin vector on the wave front $\tilde{S}^\perp = \sqrt{(\tilde{S}^Y)^2 + (\tilde{S}^Z)^2} = \frac{1}{2}s_0 h\omega X$, where we set $A_+ = A_\times = h$. If the two spin vectors (for instance in two laboratories) are separated by a

distance $L$, we have: $\tilde{S}^{\perp}(L) = \frac{1}{2} s_0 h \omega L$, provided that $\omega L/c \lesssim 1$, that is to say the wavelength should be far greater than $L$. Then, measuring $\tilde{S}^{\perp}(L)$ allows to get information on the product of the amplitude $h$ and frequency $\omega$ of the GW. In summary, the passage of the GW induces the relative spin variation

$$\frac{\Delta S}{S} = \frac{\tilde{S}^{\perp}(L)}{s_0} \simeq h \frac{\omega L}{c} \simeq h \frac{L}{\lambda_{GW}} \tag{5}$$

Since $h \simeq 10^{-21}$, the effect can be increased by using a large separation $L$ (which needs to be in any case smaller than $\lambda_{GW}$). For instance, for terrestrial laboratories $L = 10^7$ m, so that $\lambda_{GW} = 10^8$ m or greater could be suitable (corresponding to $\omega \simeq 1$ Hz, which is out of the terrestrial interferometers range). Accordingly, we get the following estimate for the relative spin variation:

$$\frac{\Delta S}{S} = 10^{-22} \tag{6}$$

Possibile candidates for measuring such a small effect could be the optical magnetometers: in particular GNOME[15] (Global Network of Optical Magnetometers for Exotic Physics) is based on synchronous measurements of optical-magnetometer signals from several devices operating in magnetically shielded environments in distant locations: by synchronously detecting and correlating magnetometer signals, transient events of global character may be identified. These devices are accurate magnetic field sensors, and their measurements can be related to spin dynamics. Another possibility is the use of a ferromagnetic sample: in fact since the passage of the GW induces a spin variation, the magnetization due to electron spins in two ferromagnetic samples will change after the passage of the GW. Eventually, if we consider mechanical gyroscopes, in terms of angles, the gravitational wave induces a precession angle of $10^{-22}$ rad; by comparison, remember that in the Gravity Probe B mission[10] the (1-year) Lense-Thirring effect was $10^{-9}$ rad, hence it seems very hard to use these devices to measure the effect of the gravitational waves.

## 3. Conclusions

We have discussed the interaction between spinning particles and gravitational waves. To this end, we have used Fermi coordinates, because of their operational meaning in terms of space and time measurements. As a consequence, we have reported the expression of the spacetime metric in Fermi coordinates adapted to the world-line of a spinning particle. The form of the metric emphasizes the transport of angular momentum by gravitational waves, as it testified by the presence of gravitomagnetic terms. Hence, this approach allow to explicitly calculate the gravitomagnetic effects in the gravitational field of the wave; it is important to point out that current interferometers are not sensitive to these effects. In particular, the interaction with gravitational waves causes spinning particles to change their spin. Consequently, spinning particles could be used as a probe to measure the gravitomagnetic effects of gravitational waves. Furthermore, we showed also that clocks at rest in the laboratory measure different time due to their spin. Indeed, these

effects are very small, as it usually happens when dealing with gravitational waves, however in our very preliminary analysis we have suggested that magnetometers or ferromagnetic samples could be uses to explore these effects.

# Atom Interferometry with the Sr optical clock transition for gravity measurements

Leonardo Salvi, Liang Hu*, Jonathan Tinsley, Enlong Wang, Nicola Poli†, and Guglielmo M. Tino‡

*Dipartimento di Fisica e Astronomia and LENS - Università di Firenze, INFN - Sezione di Firenze, Via Sansone 1, I-50019 Sesto Fiorentino, Italy*

Inertial sensors based on atom interferometers have demonstrated extremely high levels of sensitivity thus allowing for accurate measurements of gravitational interactions. Most such sensors employ multi-photon transitions induced by laser fields to manipulate the atomic wavepackets that enter an interferometer. However, this approach cannot totally suppress the contribution of the laser phase noise to the gravitational signal when two sensors are separated by a large distance. In this article, a proof-of-principle experiment for an interferometer operating on the single-photon clock transition of strontium atoms is described. This configuration can suppress the effect of laser phase noise and therefore provides a promising condidate for the detection of low-frequency gravitational waves.

*Keywords*: Atom interferometry; gravity measurements; gravitational waves; optical clock transition.

## 1. Introduction

Recent advances in the manipulation of atomic ensembles have made it possible to exploit the wave nature of matter to build interferometers that are highly sensitive to many fundamental interactions[1]. In particular, due to massive nature of atoms, these devices are sensitive to gravitational interactions and can be configured to measure, for example, gravitational acceleration[2,3], gravity gradients[4,5], gravity curvature[6], and can provide tests of general relativity at the quantum level[7–9]. As compared to macroscopic masses, atomic probes offer a number of key advantages. For example, it is possible to accurately manipulate their motion by using the interaction with laser light. This allows for the construction of analogues to beam splitters and mirrors for matter, thereby allowing for the implementation of atom interferometers. Moreover, atoms are made to travel in vacuum and are therefore immune to undesired forces such as friction or vibrations. Other parasitic effects such as electromagnetic interactions can also be largely suppressed by a careful choice of the atomic species and of the atomic levels employed. Finally, atoms are quantum objects and therefore allow for the testing of gravity in the broad context of quantum mechanics where gravitational effects are usually negligible.

Atom interferometers are also good candidates for the detection of gravitational waves. Indeed, while optical interferometers such as LIGO and Virgo are sensitive to gravitational waves with frequencies larger than about 10 Hz due to seismic noise affecting the motion of the interferometer mirrors, atomic sensors are expected

*Also at Shanghai Jiao Tong University, Minhang, Shanghai, China.
†Also at CNR-INO, Firenze, Italy.
‡Also at CNR-IFAC, Sesto Fiorentino, Italy.

to be sensitive in the 1 mHz-10 Hz band, where new interesting sources, such as the coalescence of intermediate and massive black holes and of neutron stars, are expected to appear [10].

Generally, the beam splitters and mirrors of atom interferometers are implemented through multi-photon transitions induced by a couple of counterpropagating laser fields. In a gradiometric configuration, where the gravity difference between two locations is measured by two simultaneous interferometers, the phase noise of the two lasers is largely common mode and is therefore very highly suppressed by the differential configuration. However, when the separation between the two sensors is large, the atomic clouds will sense two counterpropagating fields emitted at different times. During this interval, noise is accumulated in the gradiometer which cannot be canceled and which puts stringent requirements on the laser frequency stability and on the laser platform vibrations. Indeed, it can be shown [11] that the amplitude spectral density of the laser fractional frequency fluctuations $\sqrt{S_f}$ should be at most of the order of the gravitational-wave-induced strain $h$, or $\sqrt{S_f} \leq h/2$. Based on the predicted gravitational wave amplitudes, the relative frequency fluctuations should not exceed $10^{-21}$. Comparing this requirement with the state of the art of lasers locked to ultrastable cavities [12], where $\sqrt{S_f} = 10^{-16}/\sqrt{\text{Hz}}$ at the Fourier frequency of 1 Hz, one can conclude that an improvement of five orders of magnitude in laser frequency stability would be required.

The effects of laser phase noise can be largely suppressed from the output of the interferometer if the transitions are driven by a single laser. Intuitively, this immunity arises because the photon phase does not acquire additional noise in the path between the two sensors. In this situation, a single-photon transition connecting two optically separated stable states must be used. In principle, if an interferometer was operated on such a transition, the low frequency limit of the strain sensitivity would only be set by the coherence time of the transition [13,14]. Such an interferometer would therefore measure the gravitational-wave-induced shift of the time required to travel the distance between the two interferometers and record this interval as a phase shift, via the internal atomic oscillation. Even though there are in principle many atomic species that can fulfill the requirement of having two long-lived states connected by an optical transition, only a few cases have the required immunity to external perturbations. It follows that the atoms usually employed to realize optical atomic clocks, such as Sr or Yb, should also be suitable for this application. However, despite the phase noise immunity of gradiometers operated on a clock transition, several challenges emerge in terms of the required laser system. For example, in order to fully address the atoms in the interferometer, the interrogation laser must have a high frequency stability. Additionally, because the atoms are in free flight, the Doppler effect from different atomic velocities will cause a broadening of the transition so that a high efficiency of the interferometer pulses can only be attained with large optical power.

In this article, a proof-of-principle experiment of a gravimeter and a gravity gradiometer operating on the single-photon $^1S_0$-$^3P_0$ transition of $^{88}Sr$ is described[15]. In Section 2, the main experimental configuration, including the laser cooled and trapped ensemble of strontium atoms in a vacuum chamber and the interferometry laser, as well as the interferometer sequence, will be described. In Section 3, the main experimental results regarding the gravimeter and the gradiometer will be provided. The amount of observable interferometry laser frequency noise cancellation in the gradiometer will be established. Finally, in Section 4 conclusions and future perspectives for this new kind of sensor will be provided.

## 2. Experimental setup and sequence

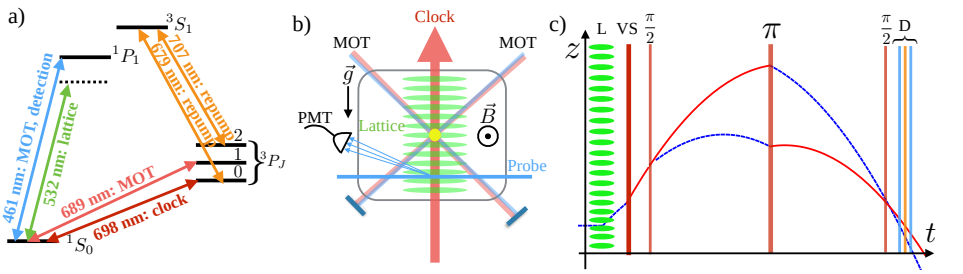

Fig. 1. a) Strontium level diagram showing the main optical transitions for cooling, trapping, interferometry, repumping and detection. b) Simplified drawing of the chamber, PMT: photomultiplier tube, MOT: magneto-optical trap, $\vec{B}$: applied magnetic field. c) Interferometer trajectories with the launch (L), velocity selection (VS), Mach-Zehnder interferometer ($\pi/2 - \pi - \pi/2$) and detection (D) consisting of probing on the blue transition and repumping (orange). The blue dashed (red) lines indicate atoms in the ground $^1S_0$ state (excited $^3P_0$ state).

In our experiment, the starting point is the ensemble of $^{88}Sr$ atoms. The atoms are laser cooled and trapped in a two-stage magneto-optical trap (MOT) first performed on the dipole-allowed $^1S_0$-$^1P_1$ transition and then on the $^1S_0$-$^3P_1$ intercombination transition (see Fig. 1(a)). This sequence produces almost $10^7$ atoms at a temperature of 1.2 $\mu$K with typical size of 100 $\mu$m at full width at half maximum.

While in the fermionic isotope of strontium, $^{87}Sr$, the clock transition is naturally allowed, in the $^{88}Sr$ boson it is strictly forbidden but can be induced with a static magnetic field. As a result, the laser cooled atoms are loaded in a 1D vertical optical lattice at 532 nm, where they are held for 65 ms. During this time, the current of one of the MOT coils, originally in the anti-Helmholtz configuration, is inverted to produce a homogeneous magnetic field of 330 G used to induce the clock transition. The lattice light is generated by a Coherent Verdi V6 laser which can deliver about 1 W of optical power to the atoms. When collimated to a beam waist of 350 $\mu$m, this laser yields a trap depth of $9E_r$, where $E_r = (k_B/2) \times 0.8$ $\mu$K is the recoil energy. This depth allows the atoms to be held and launched by accelerating the lattice

with reduced losses due to Landau-Zener tunneling. When a single interferometer is implemented, we load the atoms in the lattice and accelerate at $3g$ ($g$ is the gravitational acceleration) the cloud upwards by chirping the frequency of one of the lattice beams (Fig. 1(c)). In our gradiometer experiments, after launching a first cloud, the residual losses are used for a second launch at a slightly different final velocity.

The launching stage produces about $2.5 \times 10^5$ atoms in each cloud with a velocity difference $\Delta v = 8.5$ mm/s.

After the cloud preparation, the light from the interferometry (clock) laser is delivered to the atoms. The clock laser light, resonant with the $^1S_0$-$^3P_0$ transition at 698 nm, is produced by a grating-stabilized laser diode which is prestabilized by locking to an intermediate finesse ($F = 10000$) optical cavity and stabilized by locking to a high-finesse ($F = 500000$) ultrastable cavity with an ultra-low expansion spacer. When locked, this laser has a fast linewidth of 1 Hz and an estimated drift on the order of 1 Hz/s[16]. The light from the clock laser is preamplified by optically injecting another diode laser and finally amplified by a tapered amplifier. The light is then coupled into a 10-m single-mode polarization-maintaining fiber which can deliver up to 80 mW of light to the atoms. As opposed to multi-photon Raman or Bragg accelerometers, a single interferometer operated on the clock transition is sensitive to the single laser beam phase imprinted onto the atoms, rather than the phase difference of two counterpropagating beams. As a result, both the intrinsic laser noise and the optical components' vibrations will affect the gravimeter noise. The 10 m-long fiber contributes a large fraction of the noise which we can suppress with a fiber noise cancellation setup[17].

When we operate the gradiometer, we drive an acousto-optic modulator on the clock laser path with two frequency components in order to match the velocity difference of the two clouds after the double lattice launch. This method has the advantage of allowing the two clouds to be addressed separately and imprints a differential phase shift which can be used to characterize the gradiometer sensitivity.

The clock laser is first used to select a narrow velocity class of $10^4$ atoms, corresponding to an effective temperature of 1 nK[18]. Following velocity selection, the atoms undergo a Mach-Zehnder $\pi/2 - \pi - \pi/2$ sequence performed through clock laser pulses. A simplified view of the setup of the laser beams for the experiment is shown in Fig. 1(b) while the sequence for a single interferometer is shown in Fig. 1(c).

The interferometer output is detected by collecting the fluorescence induced by a thin sheet of light resonant with the $^1S_0$-$^1P_1$ transition onto a photomultiplier tube. In order to count the atoms in the excited $^3P_0$ state, two repumping lasers (Fig. 1(a)) are shone onto the atoms that transfer the population to the ground $^1S_0$ state where they are detected again by fluorescence collection.

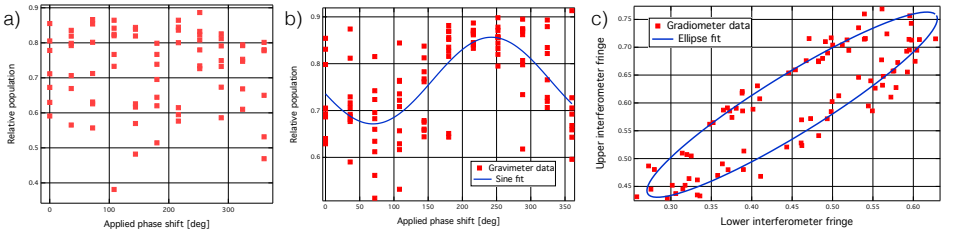

Fig. 2. Gravimeter and gradiometer results for interferometer durations of $2T = 10$ ms. a) Single interferometer fringe without the fiber noise cancellation b) Single interferometer fringe with fiber noise cancellation active. c) Plot of the upper interferometer fringe versus the lower one in the gradiometer configuration. The data show a clear correlation between the two fringes despite the presence of laser phase noise.

## 3. Gravimeter and gradiometer results

After releasing the atoms from the green optical lattice, we performed some preliminary measurements of the efficiency of the laser pulses resonant with the clock transition for untrapped atoms. The Rabi oscillations between the two interferometer states were measured by shining the clock laser onto velocity-selected atoms for a variable duration and then detecting the population of the two states. With our maximum optical power, we reached a Rabi frequency of $\Omega = 2\pi \times 750$ Hz and observed a damping time of 1.2 ms, with an efficiency limited to about 50% mainly due to the finite velocity distribution width. The consequence of this limited efficiency is a fringe contrast of 30%, which was measured to be constant as a function of the duration of the interferometer up to a time $2T = 10$ ms.

When gravimeter experiments were performed, using the sequence depicted in Fig. 1(c), we compared the fringe visibility with and without the fiber noise cancellation. As shown in Figs. 2(a) and (b), the phase noise induced by the fiber contributes a large amount of noise which can completely wash out the fringe for $2T = 10$ ms. The fringe acquires a clear visibility when the fiber noise cancellation is active. The remaining noise is due to the intrinsic laser frequency fluctuations and to the vibrations of the optical components in the laser's path from the source to the atoms. Although these noise sources appear relatively hard to suppress, it is in principle possible to improve these results by using a laser with better frequency stability and by reducing the vibrations of the optical components.

The potential of interferometry on the optical clock transition should appear in the gradiometer configuration, where a large suppression of the laser phase noise is expected. However, the relatively small separation of the two clouds and the small $T$ of our experiment would yield a negligible signal from the Earth's gradient. As already anticipated, the small velocity difference of the two clouds allows them to be addressed separately and to set an artificial differential phase shift. Using this feature, we performed gradiometric measurements with durations of $2T = 10$ ms. Plotting the upper interferometer fringe against the lower one displays the expected

correlation, as shown in Fig. 2(c). With a cycle time of 2.4 s, averaging this signal for $\tau = 400$ s results in an Allan deviation decaying as $\tau^{-1/2}$, an indication of white phase noise. The level of the recorded phase uncertainty lies only a factor of five above the estimated atom shot noise fluctuations. We estimate that this excess noise arises from detection noise.

## 4. Conclusions and perspectives

In this article, interferometry on the optical clock transition is presented. Results for the gravimeter show the expected sensitivity of the interference fringes to laser phase noise, while in the gradiometer configuration, the expected immunity to laser phase noise is established and operation close to the atom shot noise limit is observed. By further cooling the atoms, by using higher clock laser power and by using the fermion $^{87}$Sr for which the clock transition is naturally allowed, this scheme provides a potentially interesting avenue for the detection of low-frequency gravitational waves. Further improvements might include the implementation of large momentum transfer and of atomic squeezing to increase the sensitivity. Other applications are possible with this interferometer such as, for example, the test of the weak equivalence principle for atoms in coherent superpositions of optically separated states.

Large ring lasers have improved significantly in recent years, such that we are now in the position to separate and mitigate error sources that are not directly related to the rotation sensing process from the Sagnac interferogram. As a result, we are now able to reduce the measurement error of the 16 $m^2$ G ring laser of the Geodetic Observatory Wettzell by a factor of two. Improvements in the measurement of the relevant parameters for the backscatter correction remove most of the sensor drift effects, so that the backscatter induced coupling is no longer a real concern. Now that we can separate the mechanisms of the error contributors much better, we can mitigate them in a more effective way. In this paper we report on the latest progress.

## 1. Introduction

The rotation rate of the Earth and the orientation of the rotational axis of the Earth in space are the quantities which link the terrestrial (ITRF) and the celestial (ICRF) reference frames. Until now, the only way of obtaining the rotational velocity of the Earth as well as the variation of the orientation of the respective rotational axis with sufficient accuracy has been to interferometrically observe a set of radio sources - quasars at the perimeter of the observable universe form an external set of stable markers. This can be used to link the respective reference frames together. Today residuals of about 10 $\mu$s for the measurement of the Length of Day (LoD) and 0.5 nrad (0.1 milli-arc-seconds) for measurement of the pole position are achieved by a network of VLBI radio telescopes and GNSS observations[1,2]. These efforts are carried out by the services of the International Association of Geodesy (IAG). The operation of such a large network requires a significant number of radio telescopes and a very substantial maintenance and processing effort. Huge amounts of data of up to 1 Tb of volume per radio telescope are recorded in each of the 24h measurement sessions, which until recently required physical transport over large intercontinental distances to perform the correlation process in the analysis centers. Data latency, combined with the fact that there is no continuous measurement coverage, suggests that complementary methods for the accurate estimation of Earth rotation and polar motion should be explored. Optical Sagnac interferometry offers an independent technical approach. This is desirable in order to identify any technique related biases if they exist. Large ring lasers are potential candidates for such an alternative measurement technique. This technology is widely used in inertial aircraft navigation and can measure angular velocities absolutely, i.e. independent

from an external reference frame. The beat note, $\delta$f, of two counter propagating mono-mode laser beams in the ring cavity is proportional to the experienced rate of rotation $\Omega$ of the entire apparatus and is described by the ring laser equation

$$\delta f = \frac{4A}{\lambda P}\mathbf{n} \cdot \mathbf{\Omega}, \tag{1}$$

where $A$ is the area circumscribed by the laser beams, $P$ the corresponding perimeter, $\lambda$ the optical wavelength and $\mathbf{n}$ the normal vector on the plane of the laser beams. However, the demands on such instruments for the application in geodesy are extremely high, and cannot be met by existing commercial devices. These requirements can be summarized as below:

- sensitivity to angular motion of less than 0.1 $prad/s$ over an integration time of about 1 h
- sensor stability of 1 part in $10^9$ over several months (requirement for the measurement of the Chandler and Annual Wobble with high temporal resolution)
- resolution for the sensor orientation of approximately 1 $nrad$, corresponding to a polar motion effect of around 1 cm at the pole

All these requirements demand a substantial improvement of ring laser technology over existing navigational instrumentation in all aspects of the sensor design. A significant upscaling of the physical parameters of the Sagnac interferometer is the most promising approach in order to make ring lasers a viable technique for applications in space geodesy. The design of the large ring laser gyro G (Grossring), located at the Geodetic Observatory Wettzell in eastern Bavaria is one way of approaching these demands[3]. This single axis gyro is a 16 meter perimeter square ring laser with a length of 4 m on each side, which utilizes a mixture of helium and neon as a gain medium, similar in many ways to the well established systems used in aircraft navigation. However, the vastly increased size of the G ring laser with a Q factor well in excess of $5 \times 10^{12}$ provides a measurement sensitivity to angular velocities, much higher than any other rotation sensing instrument on the ground. A nearly monolithic sensor block design from the low thermal expansion material ZERODUR located in an underground laboratory provides the necessary passive mechanical stability of the G ring laser body for the desired level of performance. The ring laser G has now matured to the point where small geophysical signals with very long periods such as the Chandler and Annual wobble of the rotating Earth are measurable[4]. This has not been achieved through higher sensitivity but rather through considerable improvements in the overall cavity stability[5]. Such long-term laser stabilization is one of the key requirements for the proposed terrestrial measurements of general relativistic phenomena such as the Lense–Thirring (or frame-dragging) effect[6–8].

## 2. Backscatter Correction

The most important contributor to the sensor drift arises from the backscatter coupling between the two counter-propagating laser beams, causing frequency pulling and pushing. This quantity is not constant over time, but strongly depends on the phase of the laser beam as it hits each mirror. Variations in ambient temperature and atmospheric pressure cause a tiny change in mirror separation and hence a slow variation in the backscatter coupling. While atmospheric pressure variations can be controlled with the installation of a pressure stabilizing vessel, isolating the ring laser from the rest of the laboratory, changes in temperature are not well enough controlled for a structure as large as G. While the temperature inside the ring laser vessel only varies at a level of 3 – 5 mK per day following the annual temperature cycle of the seasons, this is enough to cause a significant drift of the observed interferometer beat note. By observing the amount of backscattered light in each of the laser beams, a correction value $\Delta f_S$ can be computed according to Ref. 9 as

$$\Delta f_S = \frac{1}{2} f_S m_1 m_2 \cos\varphi, \tag{2}$$

where $f_S$ is the observed beat note, $m_1$ and $m_2$ are the fractional beam modulations and $\varphi$ the phase angle between them. For a given mirror quality, $m_1$ and $m_2$ scale approximately as $L^{-2.5}$ for a cavity of linear size $L$. The ratio of the correction to the observed interferometer beat note to the beat note itself scales approximately as $L^{-5}$. This shows how important it is to make the ring laser cavity as large as possible, while sufficient mechanical stability of the entire structure has still to be maintained. In the absence of active control mechanisms it appears that a symmetrical construction with a length of 6 – 10 m on a side seems to be feasible for a large ring laser structure.

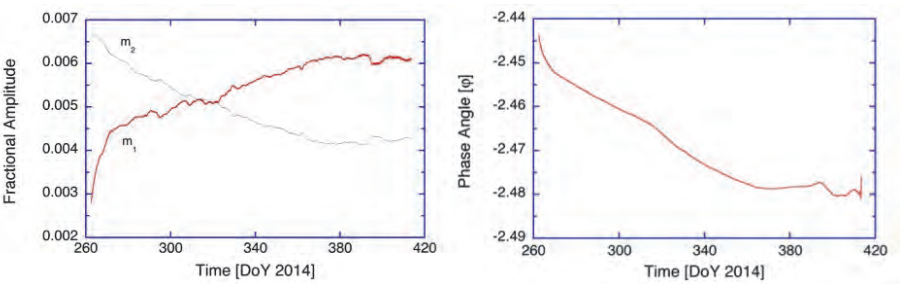

Fig. 1. The parameters $m_1$, $m_2$ and $\varphi$ of the backscatter correction (Eq. (2)) of a time series of 130 days of length. Due to the mechanically monolithic construction of the G ring laser and the active pressure stabilized environment of the gyroscope, there are only small changes in the backscatter pulling observable.

Figure 1 shows the observed variation of the fractional beam modulations and the phase angle between them over a period of more than 130 day. Since this dataset was taken with the atmospheric pressure stabilizing vessel in operation, the

observed variations of the correction quantities $m_1$, $m_2$ and $\varphi$ are entirely caused by temperature variation. When these corrections are applied to the gyro observations, we are able to remove the backscatter induced drift in the observation of the Earth rotation signal. However, some short-term fluctuations and some irregular steps still remain in the measurement signal. This signature compares well with the tiltmeter readings obtained from a high resolution tilt sensor, placed on top of the ring laser structure. Figure 2 depicts the observed Earth rotation rate after the backscatter correction has been applied to the full 130 days of observation.

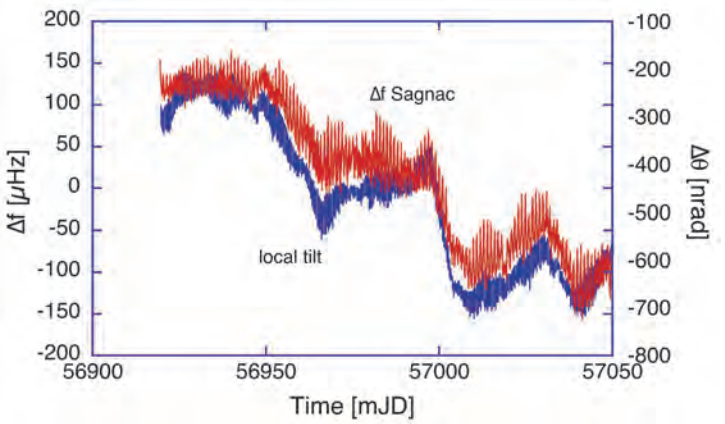

Fig. 2. 130 days of ring laser observation of Earth rotation velocity. After the backscatter correction procedure has been performed, the effects of a number of geophysical signals, like local tilt, diurnal polar motion, solid Earth tides, the Chandler and the Annual wobble remain.

The lower (blue) curve, corresponding to the variation of local $g$ over the same period of time, shows the changes experienced in the North/South tilt of the ring laser monument. The step like drops in $\Delta\Theta$ after day 56950 and around 57000 correspond to the response of the ring laser monument to significant rain falls at the observatory. The response of the tiltmeter corresponds well with the trend in the observed gyro signal represented in the same diagram in the upper (red) curve. After the tilt correction we have computed the known geophysical signals, which cause a change of the projection of $\Omega$ on the area vector of our Sagnac interferometer. Figure 3 represents the combined effect of all known signals over the length of the measurement. The section between the two dashed lines is shown enlarged in the inset in order to emphazise the fine structure of the signals. $\Delta\Omega$ is expressed in the units of the observed beat note in accordance with Eq. (1).

Once all the model corrections (diurnal polar motion, solid Earth tides, ocean loading and the variation of latitude) are applied, the Chandler and the Annual wobble, as measured by VLBI are also reduced from the data. The result is a continuous dataset of the rotation rate of the Earth with a spacing of 1 hour between

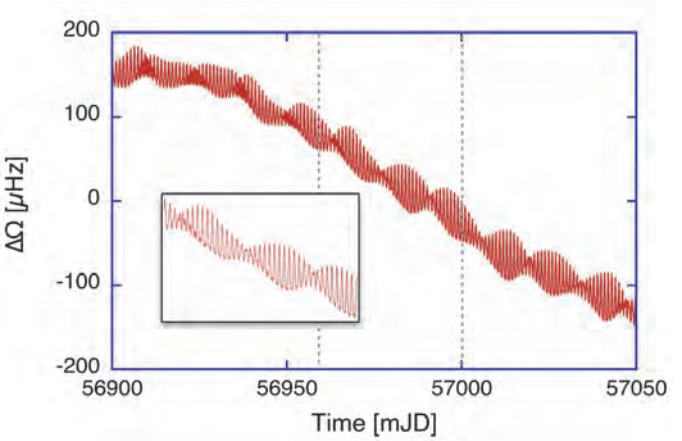

Fig. 3. The combined effect of the known geophysical signals, which have an effect on the North - South projection of the instantaneous Earth rotation vector onto the area vector of the laser gyro. The abscissa shows the variation of the measured angular velocity, expressed as a variation in the beat note of the Sagnac interferogram, derived from Eq. (1). The area between the two dashed lines is shown enlarged in the inset.

the data points as shown in Fig. 4. Although some small short-term variations at the level of less than 1 part in $10^7$ remain, a stable rotation rate is obtained over the full span of 130 days. The successful observation of a continuous long dataset of

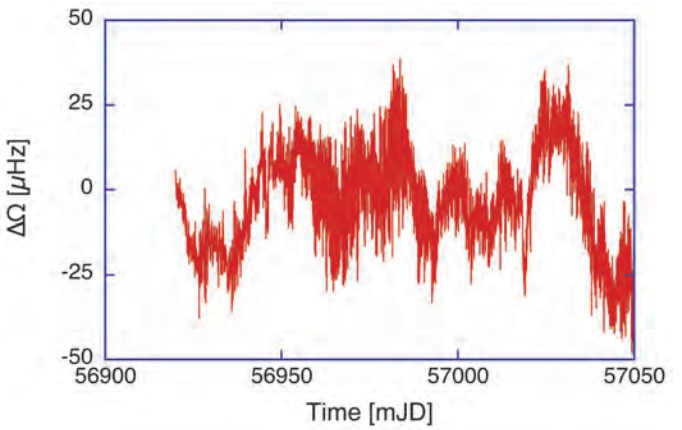

Fig. 4. The backscatter corrected Earth rotation rate over 130 days of observation. Each data point was averaged over 1 hour and the known geophysical signals have been removed from the measurements. The abscissa shows the variation of the measured angular velocity expressed as a variation in the beat note of the Sagnac interferogram, derived from Eq. (1).

high resolution ring laser observations of the Earth rotation velocity over 130 days marks a great progress in the application of Sagnac interferometers on geodetic

observations. We note in particular the stability of the measurements. Despite getting close to the target of a gyroscopic observation of the variations in the length of day (LoD), we are not quite there. However the short-term variation is within a factor of two of the order of the typical amplitude of LoD variations. It would appear that small variable non-reciprocal effects are playing a role.

## 3. Conclusion

Although the application of the backscatter correction has improved the long-term stability of our G ring laser to $\Delta\Omega/\Omega \leq 10^{-7}$ over the entire measurement series, we still consider this work in progress. We have identified the tiltmeters as one weak link in our correction process for a single component ring laser. In addition, the backscatter correction procedure itself will have limitations. The long term stability for the measurement of the fractional amplitudes as well as the corresponding phase angle, remains to be proven. In order to use laser gyros for fundamental physics, it is important to have a three component ring laser of sufficient size in operation. Furthermore it appears to be desirable to locate this gyro in a deep underground facility, such that seasonal temperature variations, excessive noise from the interaction between wind and the top soil and the variability of the hydrology are considerably reduced. Since the Lense-Thirring frame dragging effect appears as a DC quantity, it is also necessary to determine the absolute scale factor of the instrument in order to contribute to fundamental physics. However this ambitious goal appears to be much more practical now than several years ago.

# LAGRANGE: How to measure the angular momentum of the galactic dark halo

Angelo Tartaglia

*OATO, INAF, Strada Osservatorio 20*
*Pino Torinese, 10125, Italy*
**E-mail: angelo.tartaglia@inaf.it*
*www.oato.inaf.it*

The Lagrange points of the Sun/Earth pair form an interesting reference frame corotating with the Earth around the barycenter of the pair. Here we propose to use them as a base for a "rigid" physical loop allowing for the propagation of electromagnetic signals along a closed contour. If a gravito-magnetic field is concatenated with the loop, it produces an asymmetry of the times of flight in opposite directions, just as for the classical Sagnac effect. Due to the large scale of the loop, an experiment based on these premises could allow for a measurement of the angular momentum of the Sun and also the detection of the angular momentum of the dark halo of the Milky Way, if it exists.

*Keywords*: Gravito-magnetism; Sagnac effect; Lagrange points; Dark halo.

## 1. Introduction

Dark matter is today accepted as one of the ingredients that make up the universe as far as we can observe it. The need for more mass than that people could directly observe was recognized long time ago. Letting aside some early remarks going back even to the $19^{th}$ century, in 1932 Oort [1] observed that the Milky Way needed more mass than that of the visible stars in order to justify its internal kinematics. One year later Fritz Zwicky [2], studying the Coma galaxy cluster concluded that it had to be hundreds of times more massive than suggested by its appearance. The ensuing open problem was that of the "missing mass"; later the mysterious ingredient was named "dark matter". Today the evidence in favor of the existence of dark matter is multiple and varied: at the cosmological scale, observations tell us that dark matter in the universe should be approximately 5.5 times more massive than ordinary matter [3]; the temperature of the plasma trapped in the globular clusters is too high to be consistent with stability and suggests a deeper gravitational potential well; rotation curves of the stars in spiral galaxies correspond to peripheral speeds higher than the values deduced from the visible mass distribution [4]; often observed gravitational lensing and microlensing indicate mass distributions which do not manifest themselves in any other way.

In parallel with the search for evidence of dark matter a continuous theoretical investigation has been and is under way for conjecturing what kind of particles could be the constituents of dark matter. The main conviction of the present paper is, however, that an important task, before speculating on the nature of dark matter, should be to fully characterize its gravitational effects and, since the standard theory used to describe gravity is general relativity (GR), to explore all effects of that theory at the scale of the dark matter phenomenology. The simplest explanation for the

observed rotation curves of galaxies is to assume that the whole galaxy (including ours) is immersed into a huge dark matter halo[5]. Such halo extends beyond the visible disk of the galaxy, since we see that the anomalously high rotation speeds continue outside the disk, as shown by the radiation emitted by neutral hydrogen. The halo is more massive than the galaxy and we may also infer that it should also rotate together with the stars. If so, GR predicts that the dark halo, besides an additional gravitational pull on visible matter, should also generate a *gravito-magnetic* (GM) field, depending on its angular momentum; that GM field would in turn influence the motion of freely falling bodies within it. Why then not try and look for effects of that sort?

This is the simple idea which is the starting point of this work. An experiment at the scale of the internal solar system will be illustrated, aimed at evidencing possible GM effects of the angular momentum of the dark halo of the Milky Way.

## 2. Gravito-magnetism

A generic form for the metric of a curved space-time in arbitrary coordinates may be written:

$$ds^2 = g_{00}c^2dt^2 + 2g_{0i}cdtdx^i + g_{ij}dx^idx^j \tag{1}$$

The usual conventions have been adopted: index 0 is for time, Latin indices denote space variables; Einstein convention on index summation is applied.

The mixed components of the metric tensor, $g_{0i}$, tell us that the source of gravity is moving with respect to the observer. If the movement is a rotation no coordinate change can globally make the $g_0i$'s disappear and those terms correspond to physical effects we may hope to detect by suitable experiments.

In weak field conditions, i.e. when the difference between the actual metric tensor and Minkowski metric is very small (almost everywhere in the universe), the mixed space-time components of the metric tensor may be interpreted as the components of an ordinary vector potential similar to the one of Maxwell electromagnetism (EM)[6]:

$$cg_{0i} = h_i \tag{2}$$

Correspondingly we may describe the gravitational interaction as due to a *gravito-electric* field, causing the usual gravitational attraction, and a *gravito-magnetic* field, $\overline{B}_g$ stemming out of the $\overline{h}$ vector potential as in the case of electromagnetism:

$$\overline{B}_g = \overline{\nabla} \wedge \overline{h} \tag{3}$$

The influence of the GM field on freely falling particles is the analogue of the effect of a magnetic field on moving charges.

### 2.1. *Gravito-magnetism and Sagnac*

When describing EM signals, their line element is null and (1) may be read as a second order equation whose unknown is $cdt$:

$$0 = g_{00}c^2dt^2 + 2g_{0i}cdtdx^i + g_{ij}dx^idx^j \tag{4}$$

The coordinated time interval for the propagation of EM signals over a space displacement expressed by the $dx^i$'s is then:

$$cdt = -\frac{g_{0i}}{g_{00}}dx^i \pm \frac{1}{g_{00}}\sqrt{(g_{0i}dx^i)^2 - g_{00}g_{iy}dx^idx^j} \tag{5}$$

If now, by some appropriate device, we force the EM signal to move along a closed route (in the given reference frame) and come back at the starting point, we may calculated the proper time of flight $\tau$ integrating (4) along the whole path. What happens is that, like in the typical Sagnac measurement, right-handed and left-handed travels along the same circuit require different times. The proper time asymmetry $\delta\tau_G$ is[7]:

$$\delta\tau_G = 2\sqrt{g_{00}}\oint\frac{g_{0i}dx^i}{g_{00}} \tag{6}$$

## 3. LAGRANGE

The Lagrange points (L-points) of the Sun-Earth pair occupy positions which stay fixed with respect to the Earth, thus forming a natural co-rotating reference frame at the scale of the inner solar system. Their configuration is shown in Fig. 1.

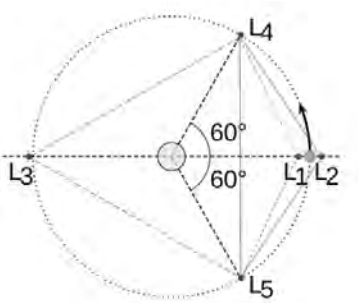

Fig. 1. Location of the Lagrange points of the Sun-Earth pair, along the terrestrial orbit. The straight lines outline possible closed paths for the EM signals of the LAGRANGE experiment.

Locating transponders in the $L$-points would allow to implement the closed paths required for a wide scale Sagnac-like experiment: let us call it LAGRANGE. Not considering $L_3$, which is beyond the Sun, a possible choice would be the triangle $L_2 - L_5 - L_4$. The typical scale of such configuration is the astronomic unit (AU), i.e. $1.5 \times 10^{11}$m: the sides $L_4 - L_2$ and $L_2 - L_5$ are just 1 AU long.

### 3.1. *Measuring the angular momentum of the Milky Way*

As written in the introduction, if the Milky Way (as the other spiral galaxies) is immersed in a huge dark halo and the latter, as it is reasonable to expect, rotates at the same rate as the visible stars, the solar system is in turn immersed into the GM field originated by the rotating halo.

The distance of the Sun from the center of the Milky Way, $R_G$, is 8 kpc i.e. $\sim 2.5 \times 10^{20}$m. The diameter of the orbit of the Earth, $D_E$, is $\sim 3 \times 10^{11}$m: as we see, the ratio $D_E/R_G$ is $\sim 10^{-9}$. We may then infer that the relative change of the galactic GM field met by the Lagrangian triangle during the year will reasonably be proportional to $10^{-9}$: in practice we are allowed to treat $\overline{B}_G$ as constant and uniform across the inner solar system.

The assumption above, together with Stokes theorem, simplifies the calculation of the formula for the time of flight (tof) asymmetry along the Lagrangean triangle:

$$\delta\tau_G = \frac{2}{c}\oint \overline{h}\cdot d\bar{l} = \frac{2}{c}\int_S \overline{B}_G \cdot \hat{u}_n dS \cong \frac{2}{c} B_G S\cos\alpha \tag{7}$$

Here of course $d\bar{l}$ is the elementary displacement vector along the trajectory of the EM signal; $\hat{u}_n$ is the unit vector perpendicular to the plane of the trajectory; $S$ is the contoured area. The EM analogy and the symmetry tell us that on the galactic plane $\overline{B}_G$ is perpendicular to the plane; angle $\alpha$ is the inclination of the ecliptic plane with respect to the galactic plane.

In order to fix orders of magnitude, consider that for the $L_2 - L_5 - L_4$ triangle it is $S_{425} \approx 9.9 \times 10^{21}\ m^2$ and $\alpha \approx 62.6°$. Assuming a sensitivity of the measurement of the tof asymmetry in the order of $10^{-15}$s, from (7) we deduce a lower limit for the weakest detectable GM field, as big as $3 \times 10^{-29}\ m^{-1}$. For comparison, I recall that the terrestrial GM field, at the surface of the planet, is $\sim 10^{-30}\mathrm{m}^{-1}$.

### 3.2. *Measuring the angular momentum of the Sun*

We have discussed above the (dark) GM field of the Milky Way, but we should not forget that LAGRANGE would also be sensible at least to one more contribution: the GM field of the Sun.

In the case of our star, the weak field approximation for the line element in a non-rotating reference frame and polar coordinates may be written:

$$ds^2 = (1-2\frac{GM}{c^2 r})c^2dt^2 - (1+2\frac{GM}{c^2 r})dr^2 - r^2 d\theta^2 - r^2\sin^2\theta d\phi^2 + 4\frac{GJ\sin\theta}{c^3 r^2}(cdt)(r\sin\theta d\phi) \tag{8}$$

Here $M$ is the mass of the Sun and $J$ its angular momentum; $\overline{J}$ is assumed to be perpendicular to the ecliptic plane. If motion (then the corresponding space part of the line element) is contained in the ecliptic plane, it is $\theta = \pi/2 =$ constant. It is also convenient to refer to $m = \frac{GM}{c^2}$ $(= 1475\mathrm{m})$ and $j = \frac{GJ}{c^3}$ $(= 4.71 \times 10^6\mathrm{m}^2)$. This simplified line element cannot be used in the case of the galactic dark halo, because there we are *inside* the mass distribution, whereas here we assume to be in vacuo[8].

The view point for the LAGRANGE measurement would be the one of a terrestrial observer, which means that we have to pass to a co-rotating reference frame at the orbital angular velocity of the Earth $\Omega$. At the approximation level we are using, the orbital velocity of the Earth (and the $L$-points) can be assumed to be Keplerian:

$$\Omega = c\sqrt{\frac{m}{r^3}} \tag{9}$$

Putting all the above assumptions together, we see that the line element for the terrestrial observer (co-moving with the LAGRANGE triangle) is:

$$ds^2 \approx (1-3\frac{m}{r})c^2dt^2 - (1+2\frac{m}{r})dr^2 - r^2d\phi^2 + 2(2\frac{j}{r^2} - \sqrt{\frac{m}{r}})(cdt)(rd\phi) \tag{10}$$

.

As can be seen, the mixed time-space component of the metric tensor now contains a contribution due to the angular momentum of the Sun (proper GM term) and a kinematical contribution due to the rotation of the frame. Both terms concur to the GM field perceived by the rotating observer, then to the right/left tof difference along the Lagrangean triangle. The calculation is now a bit more complicated than in the case of the galactic halo effect, since now the field cannot be assumed to be constant along the trajectory. In principle we should also consider that the EM rays which physically form the sides of the triangle are not really straight because of the gravitational lensing effect that bends them. Luckily that effect, besides being very small, can safely be neglected because it is symmetric (it does not depend on the rotation sense), then cancels when subtracting the left and right tof from one another.

Eq. (6), preserving a consistent approximation level, is now:

$$\delta\tau \approx \frac{2}{c}\oint (2\frac{j}{r^2} - 3(\frac{m}{r})^{3/2} + \frac{3m}{2R}\sqrt{\frac{m}{r}} - \sqrt{\frac{m}{r}})rd\phi \tag{11}$$

$R$ is the average radius of the terrestrial orbit ($R \approx 1.495 \times 10^{11}$m). For $L_4$ and $L_5$ it is $r_{L_4} = r_{L_5} = R$; $L_2$ is a bit further: $r_{L_2} = R + a = 1.51 \times 10^{11}$m. To do the calculation, the sides are assumed to be straight and the typical equation is:

$$r = \frac{b}{\cos\phi - \phi_b} \tag{12}$$

The minimum approach to the origin (the barycenter of the Sun-Earth pair) is $b$; the corresponding azimuth is $\phi_b$. It is:

$$b_{45} = \frac{R}{2} \tag{13}$$

$$b_{42} = b_{25} = \frac{R}{2}\sqrt{\frac{3(R+a)^2}{R^2+Ra+a^2}} \tag{14}$$

Performing the calculation and inserting numbers, the purely gravito-magnetic contribution of the Sun, $\delta\tau_j$ is:

$$\delta\tau_j = \sqrt{3}\frac{8j}{c}\frac{R+2a}{R(R+a)} \approx 1.47 \times 10^{-12}\text{s} \tag{15}$$

The other kinematical terms appearing in Eq. (11) provide bigger contributions, which are, in the order from smallest to biggest:

$$\delta\tau_k \approx (5.35 \times 10^{-9} - 1.428 \times 10^{-8} - 0.36172)\text{s} \tag{16}$$

## 4. Discussion and conclusion

We have presented a principle experiment based on the typical Sagnac approach applied to a rotating closed path for EM signals having three Lagrange points of the Sun-Earth pair as vertices. The experiment could evidence the presence of a galactic GM field, dominated by the dark component in the halo incorporating the Milky Way, and could measure the angular momentum of the Sun inferred from its GM field. The signals of different origin would be superposed to kinematical contributions coming from the pure rotation of the Earth along its orbit. Numbers are indeed small and the proper GM terms are the smallest, however comparable and even easier to attain than the ambitious goals of other space missions, such as LISA. A possible strategy to mark interesting weak contributions could be to produce a time modulation, which could evidence them when exploring the cumulated data: this approach will be explored in further work now in preparation.

I have not discussed here the practical problems that LAGRANGE should surmount in order to be implemented, but I am confident that they are all within the possibilities of existing technologies. Both on the side of improving technologies and methods, and of reducing unitary costs, a global strategy would be to associate LAGRANGE to other experiments and missions under way or in preparation.

We describe how to create a measurable unbalanced gravitational acceleration using a gravitomagnetic field surrounding a superconducting toroid. Such a gravitomagnetic toroid has been experimentally quite impractical. However recent advances in nanorod superconducting wire technology has enabled a new class of SMES devices operating at current densities and magnetic field strengths sufficient to develop measurable gravitomagnetic fields, while still maintaining mechanical integrity. In the present paper an experimental SMES toroid configuration is proposed that uses an absolute quantum gravimeter to measure acceleration fields along the axis of symmetry of a toroidal coil, thus providing experimental confirmation of the additive nature of the gravitomagnetic fields, as well as the production of a linear component of the overall acceleration field.

## 1. Introduction

When Forward[1] first proposed a gravitomagnetic toroid for unbalanced gravitational force production in 1962, any experimental realization was quite impractical. However recent advances in high-temperature superconducting (HTSC) nanorod wire (nanowire) technology[2] has enabled a new class of superconducting magnetic energy storage (SMES) devices operating at current densities and magnetic-field strengths sufficient to develop measurable gravitomagnetic fields, while still maintaining mechanical integrity. In the present study, an experimental SMES toroid configuration is proposed that uses a quantum gravitometer to measure acceleration fields along the axis of symmetry of a toroidal coil, thus providing experimental confirmation of the additive nature of the gravitomagnetic fields, as well as the production of a linear component of the overall acceleration field. See Fig. 1 for details.

In Forward's gravitational generation coil described in this paper, superconducting electron flow provides the change in mass current in the toroid.

## 2. Background

We summarize enabling developments in high-current-density nanorod conductors and the overall design and use of SMES devices, which are emerging as an alternate approach to energy storage that does not require chemical energy technologies.

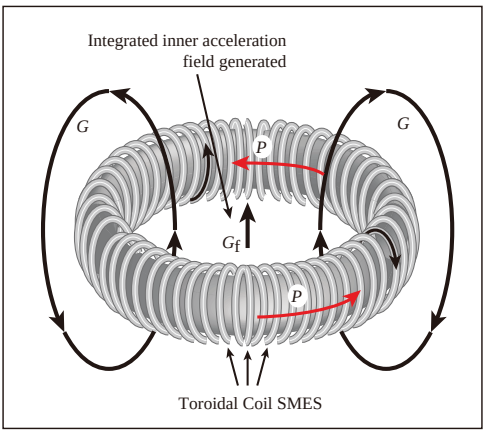

Figure 1. Gravitational force generation coil from Forward 1962 [1] with an inspiraling mass current, with a vector potential $P$, creating gravitomagnetic field $G$, which is additive in the center.

### 2.1. *Superconducting Nanorods*

New developments in superconductor nanomaterial processing [3] led to nanotubular superconductors [2] with a $T_c$ at 92 K. A uniqueness of the nanotubular and other geometric structures of HTSC makes for a practical wire form without using the melt texturing techniques which make for brittle thin films that are also difficult to shape into wire. Another aspect of these new HTSC materials is negation of post oxygenation at high temperatures. The elimination of this requirement makes room temperature forming and application of HTSC materials practical. The process has been demonstrated to be a low-cost and mass production method of superconductors which is scalable and without vacuum or cleanroom requirements. [2] These developments have led to the commercialization by True 2 Materials PTE, LTD (T2M) in Singapore, of a new HTSC wire using standard wire-making practices.

Although the critical temperature of the wire is 92 K, operation at 77 K in liquid nitrogen is more reasonable due to safety issues with gases and nitrogen's inertness, nonexplosive and nonflammable, as a cryogenic liquid. Currently T2M prototype wire is in the millimeter range and approaching the micron range. However, development of an HTSC wire, or filament at nanometer scale is on the roadmap [3] of T2M. The estimated diameter of the wire used in this study, currently theoretical, is 200 nm O.D. including insulation and a 30 nm O.D. HTSC core, with the total weight of the wire at approximately 0.001 $\frac{g}{m}$.

Individual wires make up a 19-nanofilament cable of 1 µm diameter as shown in Fig. 2, illustrating the compactness of the nanocable design. This allows the scaling up of the critical current limit, quenching aside, without adding significant weight to the toroidal coil. The individual nanofilament as described in Fig. 3 consists of a core (A), core sleeve (B), a highly insulated sleeve (C) with good heat-transport properties, and a high-strength gigapascal (GPa) outside sleeve (D), which also possesses

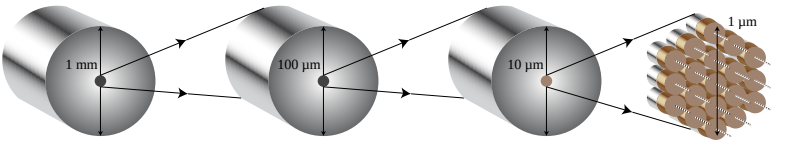

Figure 2. Representation of multiple filaments in a cable where each 1 $\mu$m yields 19 nanofilaments.

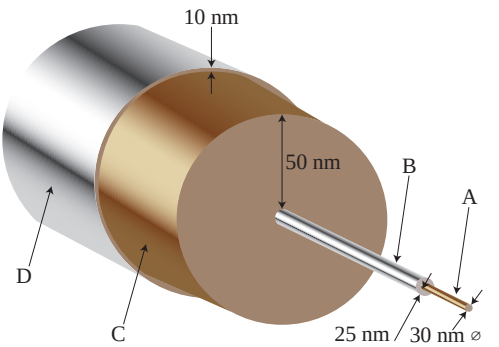

Figure 3. Detailed illustration of a nanowire filament.

good heat-transport properties at low temperatures. The main consideration for a candidate of the materials used in this study would be of carbon composition.

### 2.2. *Superconducting Magnetic Energy Storage*

SMES devices are an emerging battery replacement technology.[4] A typical application is shown in Fig. 4. The device is fed by a DC current, developing a magnetic field, typically in a toroidal geometry coil. When the need for emergency power is detected, an output switch is activated that provides DC current out, which may be converted to AC power by a power inverter.

Given the recent advances in nanowire technology, these devices are poised for remarkable improvements in capability in the very near term. With these coming improvements in this technology, and the similarity in geometry with the Forward design of Fig. 1, the present paper will study this technology at its limits for possible reapplication as a generator of an unbalanced DC gravitational force.

## 3. SMES Mass Current

The linear force, $G_{\mathrm{f}}$, developed by gravitomagnetic force in the mass flow toroid of Fig. 1 is given by Eq. (1):[1]

$$G_{\mathrm{f}} = \frac{\eta}{4\pi} \cdot \frac{N\dot{T}r^2}{R^2}, \tag{1}$$

where $G_{\mathrm{f}}$ = gravitomagnetic force, $\eta$ is gravitomagnetic permeability, $\eta = \eta_{\mathrm{o}}\eta_{\mathrm{r}}$, $\eta_{\mathrm{o}}$ = absolute gravitomagnetic permeability, $\eta_{\mathrm{r}}$ = relative gravitomagnetic permeability,

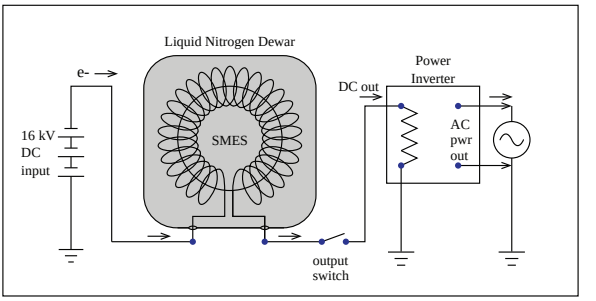

Figure 4. SMES in an energy-storage application.

$N$ = number of turns in the coil of the torus, $\dot{T}$ = change in mass flow, $r$ = the cross-sectional radius of the torus, and $R$ = the centerline radius of the torus.

Change in mass flow for a single electron flow is given by

$$\dot{T}_{\mathrm{e}} = \dot{p}_{\mathrm{e}} = a \times m_{\mathrm{e}} = (\Omega \times v) m_{\mathrm{e}}. \tag{2}$$

This is equivalent to a centripetal force of

$$\dot{T}_{\mathrm{e}} = F_{\mathrm{e}} = m_{\mathrm{e}} \frac{v^2}{r} = m_{\mathrm{e}} a_{\mathrm{e}} = m_{\mathrm{e}} (\omega^2 r), \tag{3}$$

We now attempt to estimate the possible mass currents enabled by emerging nanowire SMES technology as it relates to the core geometry constraints described by a torus geometry. We start with the assumptions needed to calculate the number of turns, $N$.

For the purposes of describing an idealized case with a realistic geometry, we develop a description of a device bounded by a 10 m toroid centerline diameter and with a cross-sectional core diameter of 1 m. We further assume a conductor winding depth of 0.5 m wound about the core. Assuming each nanowire conductor has a diameter $d_{\mathrm{c}} = 100\,\mu\mathrm{m}$, then the cross-sectional area of each conductor will be given by $A_{\mathrm{c}} = \pi r^2 = 7.854 \times 10^{-9}\,\mathrm{m}^2$. For packing the conductors described above to the winding depth described, it can be shown [5] that the total number of windings for the entire toroid can be as high as $N = 1.256 \times 10^9$.

What is $\dot{T}$ with the forgoing assumptions? In this idealized case electrons circulate about a coil of circumference $c_r$, or slightly larger, as described by $c_r = 2\pi r = 3.14\,\mathrm{m}$. Assume further a supply voltage of 16 kV, resulting in 16 keV of kinetic energy for each electron, which corresponds with the upper limit of a nonrelativistic case where, for idealized electron mobility, $v = 0.25c$, so that $\gamma = 1.06 \approx 1.0$. Then, from Eq. (3) for nonrelativistic circular motion, the vector change in DC current flow is

$$\dot{T}_{\mathrm{e}} = \frac{m_{\mathrm{e}} v^2}{r}, \tag{4}$$

which, for a single electron, has the following values: $m_{\mathrm{e}}$ = mass of the electron $= 9.11 \times 10^{-31}\,\mathrm{kg}$, $v$ = velocity of the electron $= 0.25c = 0.75 \times 10^8\,\frac{\mathrm{m}}{\mathrm{s}}$, $r = 0.5\,\mathrm{m}$

for the assumed geometry. The angular acceleration of the electron is

$$a_{\mathrm{e}} = \frac{v^2}{r} = 1.125 \times 10^{16}\,\frac{\mathrm{m}}{\mathrm{s}^2} \tag{5}$$

Thus, change in mass flow represents centripetal acceleration in the case of circular motion:

$$\dot{T}_{\mathrm{e}} = m_{\mathrm{e}} \times a_{\mathrm{e}} = 10.25 \times 10^{-15}\,\mathrm{N}. \tag{6}$$

Equation (6) corresponds to the change in mass flow for one electron in one loop of coil. Total mass-flow change is, therefore, the mass-flow change per electron times the number of electrons:

$$\dot{T} = \dot{T}_{\mathrm{e}} \times N_{\mathrm{e}}. \tag{7}$$

$N_{\mathrm{e}}$ in one loop can be described by the current $I$ times the period of a single-loop circulation $\Delta t$:

$$N_{\mathrm{e}} = I \times \Delta t, \tag{8}$$

where, for idealized mobility, the period of an orbit in a loop can be described by

$$\Delta t = \frac{c_r}{v} = 2\pi\frac{r}{v} = 41.89\,\mathrm{ns}. \tag{9}$$

What is the possible current inside the idealized device for the case where the entire winding is in series? We make the assumption about max current to stay below critical current density of 250 $\frac{\mathrm{MA}}{\mathrm{m}^2}$. Current is limited by the maximum permissible current density and the cross section of the conductor $t$:

$$I = J \times A_{\mathrm{c}} \tag{10}$$

where $J$ is material dependent. For the nanowire assumed in Ref. 2, $J = 250\,\frac{\mathrm{MA}}{\mathrm{m}^2}$. The assumed cross-sectional area $Ac = 7.85 \times 10^{-9}\,\mathrm{m}^2$ yields a maximum current of $I = 1.96\,\mathrm{A}$.

Expanding on Eq. (8), the number of electrons $N_{\mathrm{e}}$ in circulation in one loop may be calculated by noting that there are $6.24 \times 10^{18}$ electrons per Coulomb.

$$N_{\mathrm{e}} = \left(\frac{\mathrm{electrons}}{\mathrm{C}}\right) I \left(\frac{\mathrm{C}}{\mathrm{s}}\right) \times t = 5.12 \times 10^{11}\,\mathrm{electrons} \tag{11}$$

## 4. SMES Forces

Expressing Eq. (7) as force per electron times the number of electrons in motion in one loop:

$$\dot{T} = \dot{T}_{\mathrm{e}} \left(\frac{\mathrm{N}}{\mathrm{electrons}}\right) \times N_{\mathrm{e}}(\mathrm{electrons}) = 5.248\,\mathrm{mN}. \tag{12}$$

Thus, each loop experiences about 5 mN of integrated centripetal force ($\dot{T}$) due to the electrons in circulation within.

We now describe the scale factor to couple the centripetal force to the gravitomagnetic effect. Revisiting Eq. (1), which describes the overall linear force developed at the center of the toroidal coil, total gravitomagnetically developed force will be

$$G_{\mathrm{f}} = \eta_{\mathrm{o}}\eta_{\mathrm{r}} \cdot \frac{N\dot{I}r^2}{4\pi R^2} = \eta_{\mathrm{o}}\eta_{\mathrm{r}} \cdot 5{,}248\,\mathrm{N}. \tag{13}$$

grouping known variables on the right and unknown variables on the left. This raises the question, What are the correct values for $\eta_{\mathrm{o}}$ and $\eta_{\mathrm{r}}$? If $\eta_{\mathrm{o}}$ goes as $\frac{G}{c}$, as does gravitomagnetic potential (Ref. 6, Eq. (1.5)), then

$$\eta_{\mathrm{o}} = -\frac{G}{2c} = 1.11 \times 10^{-19}. \tag{14}$$

In this case $G_{\mathrm{f}} = 5.8 \times 10^{-16}\eta_{\mathrm{r}}$. Values of $\eta_{\mathrm{r}}$ are experimentally unknown at this time. However, if values of $\eta_{\mathrm{r}}$ track values of $\mu_{\mathrm{r}}$, then values as high as $\eta_{\mathrm{r}} = 10^6$ may be possible, yielding $G_{\mathrm{f}} = 5.8 \times 10^{-10}\,\mathrm{N} = 0.58\,\mathrm{nN}$.

Even with very sensitive quantum gravitometer, this would be a very difficult measurement. However, with additional current or winding count, a device scaled up from the idealized case considered in this paper may someday achieve a measurable DC gravitational field, even in the nonrelativistic case considered here.

## 5. Conclusion

An argument is made for using SMES to gravitomagnetically create an unbalanced force, possibly of measurable amplitude. Further research would be required to determine to what extent SMES devices could be operated into relativistic regimes to enhance relative mass flow change in the rest frame thus improving effect detectability.[5]

Light stable axions, originally proposed to solve the strong CP problem of quantum chromodynamics (QCD), emerge now as leading candidates of WISP dark matter. The axion-electron coupling, explicitly predicted by some models, can be exploited to envisage novel detectors complementary to the "Sikivie haloscope". In fact, due to the Earth motion with respect the dark matter halo, the interaction of relic axions with electron spins results in an effective magnetic field that inject power in magnetized media. In this proceeding we present the QUAX proposal of a ferromagnetic haloscope and the related ongoing experimental activity at the National Laboratories of Legnaro (Italy). The experimental parameters required to achieve cosmologically relevant sensitivity with our detector will be discussed. Some preliminary results on the operation of the QUAX prototype are eventually presented.

*Keywords*: Axion, Dark Matter.

## 1. Introduction

An impressive result of modern cosmology is that a major fraction of the mass content of the universe is composed of dark matter (DM), i.e. particles not interacting significantly with electromagnetic radiation, ordinary matter, not even self-interacting (cold dark matter). The DM existence is inferred from its gravitational influence on galaxies, clusters and Cosmic Microwave Background, which suggests it dominates by a ratio of 5:1 over ordinary matter described by the Standard Model (SM) of particle physics. In the era of precision cosmology an important threshold has been crossed: the issue nowadays is no longer the existence of particle dark matter, but its nature as new particle(s) Beyond SM (BSM models). Moreover, according to Big Bang cosmology, dark matter particles must be produced thermally similarly to SM particles. Hypothetical Weakly Interacting Massive Particles (WIMPs), e.g. 100 Gev particles from supersymmetric extension of SM, have been a prime DM candidate because of their self-annihilation cross section $\langle \sigma v \rangle \simeq 3 \times 10^{-26} \mathrm{cm}^3 \mathrm{s}^{-1}$, that guarantees the correct abundance of dark matter today ("WIMP miracle")[1]. Recently, the WIMP paradigm has started to look less as the obvious solution to the dark matter problem, and the spotlight passed over Weakly Interacting Sub-eV Particles (WISP), that are very light bosons characterized by sub-eV masses and large occupation numbers, such as axions, axion-like particles (ALP) and hidden photons. In particular, the axion, originally introduced in the SM by Peccei and Quinn to solve the strong CP problem of QCD, is a good candidate for DM. The axion is the pseudo-Goldstone boson associated to an additional symmetry of SM Lagrangian which is spontaneously broken at an extremely high energy scale $F_a$. Current literature favours invisible axion mechanism with $F_a \gg 250$ GeV (weak scale), which has two main implementations: the KSVZ (Kim-Shifman-Vainshtein-Zakharov) models and the DFSZ (Dine-Fischler-Srednicki-Zhitnitsky) models. For scales $F_a \simeq 10^{12}$ GeV, corresponding to typical mass values $m_a \simeq 1$ meV, axions may account for the totality of DM[2]. As a consequence, many different detectors have been proposed over the last decades to search for relic axions. Although theory do not fix the value of $F_a$, cosmological considerations and astrophysical observations provide boundaries on $F_a$ and suggest a favoured axion mass range $1\mu eV < m_a < 10meV$, i.e. over $10^{15}$ times smaller than WIMPs mass. In addition, lattice results on QCD topological susceptibility, based on reliable computations of the axion relic density, indicate a preferred window for the axion mass in the range of tens of $\mu$eV[3]. With such a small mass, we would expect $n_a \simeq 3 \times 10^{13} (10\ \mu eV/m_a)$ axions per cubic centimeter in our Solar System to account for the observed DM density $\rho_{DM} \sim 0.3$ GeV/$cm^3$. Most of axion detectors rely on the conversion of axions into photons in a resonant cavity in the presence of a static magnetic field, following the detection scheme proposed by P. Sikivie in 1983 – called axion haloscope – which is based on the inverse Primakoff effect[4]. In particular, the ADMX experiment reached the cosmologically relevant sensitivity to exclude the axion mass range $2.66 < m_a < 2.81$ $\mu$eV for DFSZ models and $1.9 < m_a < 3.7$ $\mu$eV for KSVZ models[5]. On the other hand, the axion-fermion coupling, explicitly predicted in DFSZ models[6], allows for

designing new detectors that exploit the interaction between axions and fermionic spins[7]. In fact, the motion of the Solar System through the DM cloud surrounding the Galaxy results in a gradient of the axion field $\boldsymbol{\nabla} a$ pointing in the motion direction, and one can demonstrate that the effect of $\boldsymbol{\nabla} a$ on spins in a magnetized material plays the rôle of an effective oscillating magnetic field $\boldsymbol{B}_a$ with amplitude, direction and frequency determined by $\rho_{DM}$, $\boldsymbol{\nabla} a$ and $m_a$, respectively. The QUAX detector is precisely based on the resonant interaction of $\boldsymbol{B}_a$ with the homogeneous magnetization mode in ferrimagnetic samples. In this proceeding we summarize the main ideas of the QUAX proposal[7] and report on some recent results regarding the cryogenic operation of a QUAX demonstrator[8].

## 2. Axion detection by resonant interaction with electron spin

Assuming standard cosmology, we calculate the effective magnetic field $\boldsymbol{B}_a$ with the aim of estimating the power released in a magnetized sample as a function of QUAX parameters. As the DFSZ axion models do not suppress the axion and electron coupling at the tree level, the Lagrangian reads

$$L = \bar{\psi}(x)(i\hbar\gamma^{\mu}\partial_{\mu} - m_e)\psi(x) - ig_{ae}a(x)\bar{\psi}(x)\gamma_5\psi(x), \tag{1}$$

where $\psi(x)$ is the spinor field of an electron with mass $m_e$. Here $\gamma^{\mu}$ are the 4 Dirac matrices, $\gamma^5 = i\gamma^0\gamma^1\gamma^2\gamma^3$, and $a(x)$ is coupled to matter by the dimensionless pseudo-scalar coupling constant $g_{ae}$. By taking the non-relativistic limit of $L$, the resulting interaction term can be written as

$$-\frac{g_{ae}\hbar}{2me}\boldsymbol{\sigma}\cdot\boldsymbol{\nabla} a = -2\frac{e\hbar}{2m_e}\boldsymbol{\sigma}\cdot\left(\frac{g_{ae}}{2e}\right)\boldsymbol{\nabla} a \equiv -2\mu_B\boldsymbol{\sigma}\cdot\boldsymbol{B}_a, \tag{2}$$

which has clearly the form of the interaction between the spin magnetic moment and an effective magnetic field, where $e$ is the electron charge, $\mu_B$ is the Bohr magneton, $\boldsymbol{\sigma}$ is the vector Pauli matrices, and $\boldsymbol{B}_a \equiv g_{ae}/(2e)\boldsymbol{\nabla} a$ is the effective magnetic field. For DFSZ axions, the coupling to electrons is $g_{ae} = m_e/(3F_a)\cos^2\beta \simeq 2.8 \times 10^{-15}(m_a/10^{-4}eV)$ assuming O(1) value for the free parameter $\cos^2\beta$. To calculate amplitude and frequency of the effective magnetic field due to the presence of the DM axion we use the standard model of galactic halo: a spherical distribution with a pseudo-isothermal density profile, local density $\rho_{DM} \sim 0.3GeV/cm^3$ corresponding to $n_a \sim 3 \times 10^{12}$ ($10^{-4}$ eV/$m_a$) axions per cubic centimeter, and local velocity distribution described by the Maxwell Boltzmann distribution with a dispersion $\sigma_v \approx 270$ km/sec. The Earth velocity with respect the galactic halo is $|\boldsymbol{v}_E| \simeq 220$ Km/sec. Therefore the equivalent oscillating rf field has an expected mean amplitude and central frequency

$$B_a = 2.0 \times 10^{-22}\left(\frac{m_a}{200\,\mu\text{eV}}\right)\ \text{T}, \quad \frac{\omega_a}{2\pi} = 48\left(\frac{m_a}{200\,\mu\text{eV}}\right)\ \text{GHz}, \tag{3}$$

with relative linewidth $\Delta\omega_a/\omega_a \simeq 5.2 \times 10^{-7}$ and direction $\boldsymbol{v}_E$. The explicit dependence on $\omega$ of the power spectrum of axion field has been calculated in Ref. 6.

Once the calculation is tailored for the gradient of the axion field, the coherence time and correlation length for the QUAX detector read

$$\tau_{\nabla a} \simeq 0.68\,\tau_a = 17\left(\frac{200\,\mu\text{eV}}{m_a}\right)\left(\frac{Q_a}{1.9\times 10^6}\right)\ \ \mu\text{s};$$
$$\lambda_{\nabla a} \simeq 0.74\,\lambda_a = 5.1\left(\frac{200\,\mu\text{eV}}{m_a}\right)\ \text{m}, \tag{4}$$

where the standard DM halo parameters were used[7].

### 2.1. *The QUAX proposal*

In the QUAX proposal we focused our analysis to frequencies in the $40 \div 50$ GHz range. To measure the power released by extremely small rf field $B_a$ we make use of the Electron Spin Resonance (ESR) in magnetic samples[7]. To enhance the interaction, the ferromagnetic resonance of the sample – i.e. the Larmor frequency $\omega_L = \gamma B_0$ of the electron spin precession in an external magnetic field $B_0$ – is tuned to the frequency $\omega_a$ associated with mass value of the searched for axion. Here $\gamma/2\pi = e/m_e = 28GHz/T$ is the electron gyromagnetic ratio. In the limit of weak rf field, the steady state solutions of Bloch Equations of the magnetization $M_a(t)$ relative to the ESR Kittel mode reads

$$M_a(t) = \gamma\mu_B B_a n_S \tau_{\min}\cos(\omega_a t), \tag{5}$$

where $n_S$ is the material spin density and $\tau_{\min} \equiv \min(\tau_{\nabla a}, \tau_2, \tau_r)$ is the shortest coherence time among the axion wind coherence $\tau_{\nabla a}$, magnetic material relaxation $\tau_2$ and radiation damping $\tau_r$, and it represent the coherence time of $M_a(t)$ oscillatiions. However, the radiation damping mechanism may result in an issue for the QUAX detector. In fact, in free space, the energy damping due to magnetic dipole emission $\tau_r = (c^3/\omega_L^3)/(\gamma\mu_0 M_0 V_s)$, and so high Larmor frequency, large magnetization $M_0$, and large volume $V_s$ of magnetized material imply $\tau_r << \tau_a$. However, the radiation damping mechanism can be inhibited by inserting the magnetized material inside a microwave resonant cavity in the strong coupling regime. In this case, the hybridization between Kittel magnetic mode of the sample and a suitable cavity mode occurs, and the limited phase space of the resonant cavity inhibits the radiation damping mechanism, thus providing a more favourable damping time equal to the cavity decay time. In the hybridization regime we have $\tau_{\min} = \min(\tau_{\nabla a}, \tau_2, \tau_c)$, where $\tau_c$ is the cavity decay time[7].

In the presence of the axion wind, the average amount of power absorbed by the magnetized sample in each cycle is

$$P_{\text{in}} = \mu_0 \mathbf{H}\cdot\frac{d\mathbf{M}}{dt} = B_a\frac{dM_a}{dt}V_s$$
$$= \gamma\mu_B n_S \omega_a B_a^2 \tau_{\min} V_s. \tag{6}$$

In a steady state condition, the power balance ensures that $P_{\text{in}}$ will be emitted as rf radiation, and so $P_{\text{in}}/2$ can be collected by using an antenna critically coupled to

the hybridized mode. The output power can be expressed in terms of the relevant experimental design parameters

$$P_{\rm out} = \frac{P_{\rm in}}{2} = 3.8 \times 10^{-26} \left(\frac{m_a}{200\,\mu{\rm eV}}\right)^3 \left(\frac{V_s}{100\ {\rm cm}^3}\right) \left(\frac{n_S}{2 \cdot 10^{28}/{\rm m}^3}\right) \left(\frac{\tau_{\rm min}}{2\,\mu{\rm s}}\right) {\rm W}, \tag{7}$$

where the chosen axion mass is determined by a magnetizing field $B_0 = 1.7$ T, and the value of the spin density is typical of paramagnets at low temperature or material as YIG (Yttrium Iron Garnet) even at room temperature. To measure such a low power is a very difficult experimental challenge. To reach the QUAX goal of detecting cosmological QCD axions, we need to improve the detector sensitivity along the following lines:

1) Study of materials: decrease linewidth of ferromagnetic resonance in the $10 \div 100$ GHz frequency range at low temperatures and increase spin density of magnetized materials (YIG, GaYIG, LiF or BDPA and other paramagnets); make use of ultrapure material (e.g. by trying to minimize rare earths contamination); highly accurate polishing and smoothing of surfaces.
2) Cavity design: design of a high-Q ($\sim 10^6$) cavity to be operated in few Tesla magnetic fields; cavity design should also maximize SNR and allow for housing the required amount of magnetized material.
3) Static magnetic field source: realization of a highly uniform magnetic field (up to 10 ppm for a few Tesla field to avoid inhomogeneous broadening).
4) Decrease of noise level: use a dilution refrigerator to lower thermal noise that also allow for the operation of a Josephson Parametric Amplifier (JPA); a crucial issue is the concurring development of a single photon counter in the microwave frequency range in order to overcome the Standard Quantum Limit of linear amplifiers.

It is worth noticing that only the component of the equivalent magnetic field $\boldsymbol{B_a}$ orthogonal to the magnetizing field $\boldsymbol{B_0}$ will drive the magnetization of the sample, therefore QUAX is a directional detector and it shows a daily modulation of the axion signal that can be exploited to get rid of spurious noise sources[7].

### 2.2. *The QUAX demonstrator*

We have addressed experimentally some issues that affect the sensitivity of a ferromagnetic haloscope, such as ferrimagnetic dissipation, cavity quality factor, magnetic field homogeneity[8]. Thus we have set up a demonstrator of the QUAX experiment which is made of 5 GaYIG (Gallium Yttrium Iron Garnet), 1 mm diameter spheres, placed in a cylindrical copper cavity (diameter $\sim$ 26 mm and length 50 mm), and immersed in a $\sim$ 0.5 T magnetic field. We use the TM110 mode with resonance frequency $f_c \simeq 13.98$ GHz and linewidth $k_c/2\pi \simeq 400$ kHz at liquid helium temperature. The degeneracy of this mode has been removed by digging

two symmetric grooves in the lateral surface of the cylinder. The TM110 mode is characterized by a uniform maximum magnetic rf field along the cavity axis, and therefore we can house more YIG spheres along it. Moreover, cavity volume can be increased by lengthening the cylinder without changing the TM110 mode resonance frequency. With cylindrical geometry we can also exploit the uniformity of magnetic field produced by a solenoid along the symmetry axis so as to avoid the inhomogeneous broadening of the resonances. In fact, the Larmor frequency $f_L$ of the GaYIG spheres is established by an highly uniform solenoidal magnetic field (1 part in $10^4$), and the hybridization condition $f_L \simeq f_c$ is met when $B_0 \simeq 0.5$ T. In the strong coupling regime, the hybrid mode frequencies are $f_+ = 14.061$ GHz and $f_- = 13.903$ GHz. The detection electronics (a cascade of a room temperature and a cryogenic amplifier) was calibrated with a Johnson noise source at different temperature. The output of the cavity is down-converted in its in-phase and quadrature components with respect to a local oscillator and sampled at 2 MHz. The power of hybridized modes was estimated with $\sim 2 \times 10^6$ FFTs of 8192 bins each (frequency resolution of 244 Hz), which were square averaged and rebinned into 7.8 kHz bandwidths (256 bins), close to the expected axion bandwidth. The standard deviation of the estimated power is $\sigma_P = (2.2 \pm 0.1) \times 10^{-22}$ W, compatible with the Dicke radiometer equation. No significant excess power consistent with DM axions was found. Therefore we can set the upper limit $\sigma'_P \sim 10^{-21}$ W within the 3 MHz band around 13.903 GHz at the 95% C.L.. This value translates to the upper limit $B_a \leq 1.6 \times 10^{-17}$ T of the equivalent axion field, corresponding to a axion electron coupling $g_{ae} \leq 5 \times 10^{-10}$ for axion masses $58.527 \leq m_a \leq 58.541$ $\mu$eV at 95% CL[8].

## 3. Conclusions

We have reported on the QUAX proposal, i.e. a ferromagnetic haloscope sensitive to DM axions through their interaction with electron spin. Our findings by means of the QUAX demonstrator indicate the possibility of performing ESR measurements of a sizable quantity of material inside a cavity cooled down to cryogenic temperatures. The sensitivity of the demonstrator reached the limit of the Dicke radiometer equation, the overall behavior of the apparatus is as expected, and we are confident that the QUAX detector can reach a cosmological relevant sensitivity.

# What could the value of the cosmological constant tell us about the future variation of the fine structure constant?

Antonio Enea Romano

[1] *YITP, Kyoto University, Kyoto 606-8502, Japan;*
[2] *Instituto de Fisica, Universidad de Antioquia, A.A.1226, Medellin, Colombia*

Motivated by reported claims of the measurements of a variation of the fine structure constant $\alpha$ we consider a theory where the electric charge, and consequently $\alpha$, is not a constant but depends on the Ricci scalar $R$. We then study the cosmological implications of this theory, considering in particular the effects of dark energy and of a cosmological constant on the evolution of $\alpha$. Some low-red shift expressions for the variation of $\alpha(z)$ are derived, showing the effects of the equation of state of dark energy on $\alpha$ and observing how future measurements of the variation of the fine structure constant could be used to determine indirectly the equation of state of dark energy and test this theory. In the case of a $\Lambda CDM$ Universe, according to the current estimations of the cosmological parameters, the present value of the Ricci scalar is $\approx 10\%$ smaller than its future asymptotic value determined by the value of the cosmological constant, setting also a bound on the future asymptotic value of $\alpha$.

## 1. Introduction

There have been different claims about the detection of the variation[1–5] of the fine structure constant. Different models have been proposed to account for such a phenomenon, in particular theories where the electric charge is treated as free field[6]. We consider the cosmological implications of a model in which the electric charge depends on the local value of the space-time curvature. This model can be considered a special case of the Bekenstein theory[6], where the electric charge depends on the Ricci scalar, and consequently it is not necessary to introduce an additional kinetic term in the Lagrangian to determine the dynamics of the field associated to the electric charge, as in the standard Bekenstein case. In this sense this model has the advantage of not introducing a new fully independent degree of freedom and can consequently give more definite predictions. At the same time the hypothesis that the electric charge depends only on the Ricci scalar is in agreement with the principle of general covariance and as such could be extended to the study of the variation of other natural constants without the need of introducing any new degree of freedom.

On the basis of general covariance it is natural to consider as an extension of the standard electromagnetism an action of the type

$$S = \int \sqrt{-g}(f(R)F_{\mu\nu}F^{\mu\nu} + e_0 u_\mu A^\mu)\,, \tag{1}$$

where $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the Faraday tensor and $A\mu$ is the vector potential, as defined in the standard covariant formulation of electromagnetism.

The main difference respect to the classical formulation of electromagnetism corresponds to the fact that such an action implies a space time variation of the

fine structure constant $\alpha$. This can be seen easily by varying the action respect to the vector potential $A^\mu$, and after neglecting derivative terms of quantities varying only on very large scales we get

$$\partial_\mu F^{\mu\nu} = f(R)^{-1} e_0 u^\nu \,, \tag{2}$$

which shows how the effective electric charge appearing on the r.h.s. is not constant. The variation of the action respect to the metric is not expected to modify the standard Einstein's equations because the term $F_{\mu\nu}F^{\mu\nu} \propto (E^2 - B^2)$ should give an average vanishing contribution in the case of a homogenous electromagnetic field. The above action can be considered a particular case of the Bekenstein theory:

$$S_B = \int \sqrt{-g}(\epsilon^{-2} F_{\mu\nu}F^{\mu\nu} + e(x_\mu)\, u_\mu \tilde{A}^\mu) = \int \sqrt{-g}(\epsilon^{-2} F_{\mu\nu}F^{\mu\nu} + e_0 u_\mu A^\mu)\,, \tag{3}$$

$$A_\mu = \epsilon \tilde{A}_\mu \,, \tag{4}$$

$$F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu \,, \tag{5}$$

where the electric charge appearing in the Lagrangian is treated as a free field

$$e(x_\mu) = e_0 \epsilon(x^\mu) \,, \tag{6}$$

and the action (1) corresponds to the case in which

$$\epsilon(x^\mu) = f(R)^{-1/2} \,, \tag{7}$$

$$\alpha(z) = \alpha_0 f(R)^{-1} \,. \tag{8}$$

In the Bekenstein theory an additional kinetic term is introduced in the Lagrangian in order to determine the dynamics of $\epsilon$, while for the action S (1) this is not necessary since $f(R)$ entirely determines the variation of the fine structure constant. From a physical point of view this corresponds to assuming that the fine structure constant value depends only on the Ricci scalar, preserving the invariance under general coordinate transformations.

The Ricci scalar can be related to the trace of the energy momentum tensor by taking the trace of the Einstein tensor:

$$R = -T^\mu_\mu \,, \tag{9}$$

For a set of perfect fluids with equation of state

$$P_i = w_i \rho_i \,, \tag{10}$$

we get

$$R = \sum_i (3w_i - 1)\rho_i \,, \tag{11}$$

where the index i stands for the i-th component of the total energy density of the Universe. It is interesting to note that, according to the above equation, radiation does not contribute to the Ricci scalar at any time, since it vanishes for $w_i = 1/3$.

We can now derive a low red-shift expansion of the variation of the fine structure constant. Even if this would not be valid at higher re-shift, it can still give some useful insight about the features of the theory we are studying. In order to get the leading corrections to the value of $\alpha$ we expand the equation of state of dark energy $w(z)$ and the function $f(R)$ according to:

$$\Delta\alpha = \frac{\alpha(z) - \alpha_0}{\alpha_0} = \Delta\alpha_1 z + \Delta\alpha_2 z^2 + \cdots , \tag{12}$$

$$w(z) = w_0 + w_1 z + w_2 z^2 + \cdots , \tag{13}$$

$$f(R) = 1 + f_1 \left( \frac{R - R_0}{R_0} \right) + f_2 \left( \frac{R - R_0}{R_0} \right)^2 + \cdots , \tag{14}$$

where

$$R_0 = R(z = 0) . \tag{15}$$

is the present time value of the Ricci scalar, The above expansion for $f(R)$ is clearly dimensionally consistent and satisfy the normalization condition

$$\alpha(z = 0) = \alpha_0 . \tag{16}$$

It should also be noted that such a local expansion is only valid at relatively recent times otherwise, at early times, when $(R - R_0)/R_0 \to \infty$, $\alpha$ would diverge. Nevertheless it is a good approximation to estimate the future variation of $\alpha$ because $(R_\infty - R_0)/R_0 \approx -0.1$, as it will be shown later.

Assuming a flat Universe, after substituting in Eq. (11) the contributions from matter and dark energy

$$\rho_X(z) = 3H_0^2 \Omega_X \exp\left[ \int_0^z \frac{3[1 + w(x)]}{1 + x}\, dx \right] , \tag{17}$$

$$\rho_M(z) = 3H_0^2 (1 + z)^3 , \tag{18}$$

we get the following expression for the Ricci scalar as a function of the red-shift

$$R(z) = -3(1 + z)^3 H_0^2 \Omega_M + 3H_0^2 \Omega_X \exp\left[ \int_0^z \frac{3[1 + w(x)]}{1 + x}\, dx \right] [3w(z) - 1] . \tag{19}$$

The above expression is also valid at early times when the Universe was radiation dominated since, as noted previously, radiation does not contribute at any time to the Ricci scalar.

We can then compute the leading corrections to the value of the fine structure constant as a function of the red-shift:

$$\Delta\alpha_1 = \frac{3f_1(-1+2w_0\Omega_X+3w_0^2\Omega_X+w_1\Omega_X)}{3w_0\Omega_X-1}\,, \tag{20}$$

$$\Delta\alpha_2 = \frac{1}{2(1-3w_0\Omega_X)^2}\Bigg[3\Big((6f_1^2-3f_2)(-1+2w_0\Omega_X+3w_0^2\Omega_X+w_1\Omega_X)^2+\,, \tag{21}$$

$$-f_1(1-3w_0\Omega_X)(2-(-2+24w_0^2+18w_0^3+4w_1+2w_0(1+6w_1)+w_2)\Omega_X)\Big)\Bigg],$$

where we have used the relation

$$\Omega_\Lambda+\Omega_X=1\,, \tag{22}$$

following from the Friedman equation evaluated at present time. As it can be seen the linear contribution to the variation of the fine structure constant value is affected by the central value and first order derivative of the equation of state of dark energy and by the first derivative of function $f(R)$. Conversely the above expression shows how measurements of the variation of the fine structure constant could be used to determine indirectly the equation of state of dark energy.

Another important case to consider is that of a $\Lambda CDM$ Universe, for which the Ricci scalar ass a function of the red-shift is given by

$$R(z) = -\rho_M^0(1+z)^3-4\rho_\Lambda = -3H_0^2(\Omega_M^0(1+z)^3+4\Omega_\Lambda)\,, \tag{23}$$

which implies that at late times $R(z)$ tends to a constant value determined by the cosmological constant, while at earlier times it decreases.

We can then obtain a local expansion for $\alpha(z)$ as in the dark energy case:

$$\Delta\alpha_1 = \frac{3f_1(-1+\Omega_\Lambda)}{1+3\Omega_\Lambda}\,, \tag{24}$$

$$\Delta\alpha_2 = \frac{3(-1+\Omega_\Lambda)(6f_1^2(-1+\Omega_\Lambda)-3f_2(-1+\Omega_\Lambda)+f_1(2+6\Omega_\Lambda))}{2(1+3\Omega_\Lambda)^2}\,. \tag{25}$$

It can be easily checked that these last formulae are in agreement with the dark energy case when $\{w_n=0, w_0=-1\}$. In this case the variation of $\alpha$ is completely determined by the coefficients $\{f_1, f_2\}$ and the value of the cosmological constant.

Given the current estimation of cosmological parameters[7–9] the Ricci scalar is tending to an asymptotic value determined by the cosmological constant

$$\frac{R_\infty}{R_0} = \frac{4\Omega_\Lambda}{1+3\Omega_\Lambda} \approx 0.9\,, \tag{26}$$

and the present value is quite closed to the asymptotic one as it can be seen in Fig. 1. This shows how the Ricci scalar is not expected to vary largely in the future history of the Universe, and if the theory we are studying is correct, also the fine

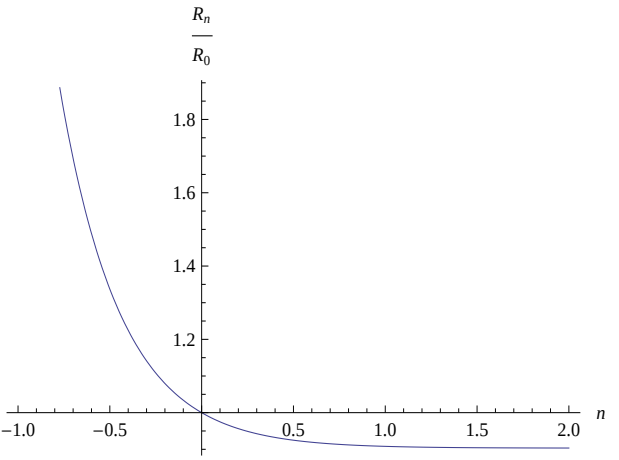

Fig. 1. The ratio $R_n/R_0$ is plotted as a function of the number $n$ of e-folds from today, where $R_n = -3H_0^2(\Omega_M^0(\frac{a_0}{a})^3 + 4\Omega_\Lambda)$, $a = a_0 e^n$ and $R_0$ is the value of the Ricci scalar today, when $n = 0$. As it can be seen the present value $R_0$ is quite closed to the asymptotic future value of R.

structure constant will reach a corresponding asymptotic value given by

$$\alpha_\infty \approx \alpha_0 f(R_\infty)^{-1} \approx \alpha_0[1 + f_1(-0.1) + f_2(-0.1)^2]^{-1} \approx \alpha_0[1 + f_1(0.1) - f_2(0.1)^2]\,. \tag{27}$$

According to this prediction the so called coincidence problem, i.e. the fact that we happen to live just around the time of transition between a matter dominated and a cosmological constant dominated stage of the evolution of the Universe, would also have implications on the future variation of the fine structure constant, which would be expected to tend to an asymptotic value not too different from the present one. After the coefficients $f_1, f_2$ have been determined by fitting available observational data of $\Delta\alpha(z)$ we could get a good estimation of $\alpha_\infty$, but we would have to wait a time interval of the order of the Hubble time $H_0^{-1}$ before the matter contribution to the Ricci scalar will be dominated by that of the cosmological constant and we could test such a prediction.

# Quintessence evolution of fundamental constants and cosmological parameters using the beta function formalism

Rodger I. Thompson

*Steward Observatory and Department of Astronomy, University of Arizona, Tucson, Arizona 85721, USA*
**E-mail: rit@email.arizona.edu*

A key lesson from the multi-messenger observations of colliding neutron stars is the importance of having accurate templates to compare with observations. This manuscript demonstrates the production of such templates for the evolution of cosmological parameters and fundamental constants using the beta function formalism. The beta function in this formalism is the derivative of the scalar field with respect to the natural log of the scale factor. This demonstration utilizes the quintessence cosmology with an inverse power law dark energy potential as an example but the formalism is expandable to other dark energy potentials and cosmologies. The advantage of the beta function formalism is that it produces analytic solutions of the evolutions as a function of the scale factor which is a fundamental observable quantity.

*Keywords*: Cosmology, Fundamental Constants.

## 1. Introduction

This article presents beta function formalism calculations of the evolution of fundamental constants and cosmological parameters in a quintessence cosmology for comparison with observational constraints. Quintessence is a well studied example of a dynamical cosmology where the dark energy equation of state is changing with time. The predicted evolution provides tests to determine whether dark energy is static or dynamically evolving. Interestingly the static ΛCDM cosmology is a special case of the dynamical quintessence cosmology, partially demonstrating the "Universality" of the beta function methodology. The epochs of interest are redshifts between 0 and 9 which correspond to scale factors $a$ between 1.0 and 0.1. These epochs are well covered by the upcoming JWST and Euclid space missions as well as the DESI and LSST ground based surveys.

## 2. The Potential and Related Parameters

For specificity a dark energy potential of the common form

$$V(\phi) = M^{4+p}\phi^{-p} \tag{1}$$

is considered here where $M$ has the units of the reduced Planck mass $M_p$. The potential $V(\phi)$ has units of $M_p^4$ and by the continuity equation

$$V(\phi) = 3\Omega_\phi \left(\frac{H(\phi)}{\kappa}\right)^2 \tag{2}$$

where $H(\phi)$ is the Hubble parameter, $\Omega\phi$ is the ratio of the dark energy density to the critical density and $\kappa = \frac{1}{M_p}$. This relation indicates that the value of $V_0$ is set by $H_0$ and $\Omega_{\phi_0}$ where the 0 subscript indicates the current value.

## 3. The Beta Function Formalism

The beta function formalism was recently developed to explore the universality of dynamical cosmologies thought previously to be independent of each other. The beta function formalism has its roots in a perceived correspondence between cosmological inflation and the Quantum Field Theory renormalization group flow equation (1), (2) and( 3). In that context it is valid as the solution for the slow evolution of a system approaching or leaving a critical (fixed) point (1). Both (1) and (2) have considered the formalism for the late time dark energy inflation where the critical point is in the infinite future. The descriptions here follow these references with particular dependence on (2) who have incorporated matter as well as dark energy in order to describe a real universe.

The beta function is defined as the derivative of the scalar field $\phi$ with respect to the natural logarithm of the scale factor of the universe $\ln(a)$.

$$\beta(\phi) \equiv \frac{\kappa d\phi}{d\ln(a)} = \kappa\phi' \tag{3}$$

where the prime in the right hand side denotes the derivative with respect to $\ln(a)$, Since $\phi$ has units of mass the product $\kappa\phi$ is dimensionless and $\phi$ is specified in units of reduced Planck masses. The reduced Planck mass is generally used in the cosmological literature since the factor of $8\pi$ simplifies several equations. Proper units are an important aspect of this article therefore $\kappa$ is retained throughout the article rather than being set to one as is common practice. Natural units are used where $G$, $c$ and $\hbar$ are set to one.

Specifying $\beta(\phi)$ provides a method to express the evolution of cosmological parameters and fundamental constants in terms of the observable scale factor $a$ rather than the unobservable scalar field $\phi$. References (4) and (5) give concrete examples of this process for quintessence. Where as the main purpose of (1), (2) and (3) was to demonstrate the universality of cosmologies associated with a given beta function the purpose of (4), (5) and this article is to calculate cosmological parameters for quintessence for a given dark energy potential $V(\phi)$. Here the beta function is determined by $V(\phi)$ rather than being prespecified.

Rather than being an arbitrary function of the scalar $\phi$, the beta function is determined by the potential, (1) and (2), such that

$$V_m(\phi) = V_0 \exp\left\{-\kappa \int \beta(\phi) d\phi\right\} \tag{4}$$

where $V_m(\phi)$ is the model potential given by Eq. (1). Equation (4) shows that $\beta(\phi)$ is the negative of the logarithmic derivative of the model potential.

The potential in Eq. (1) is an inverse power law, IPL, potential. The beta formalism for IPL potentials was considered in (4) which showed that the beta function for this type of potential is given by the simple form.

$$\beta(\phi) = \frac{p}{\kappa\phi} = \frac{\kappa d\phi}{d\ln(a)} \tag{5}$$

Integrating Eq. (5) yields

$$\kappa\phi = \sqrt{2p\ln(a) + (\kappa_0)^2} \tag{6}$$

where $\phi_0$ is the current value of the scalar which depends on the current values of cosmological parameters and the cosmology as shown in section 4.

## 4. Quintessence

The action for quintessence is given by

$$S = \int d^4x\sqrt{-g}\left[\frac{R}{2} - \frac{1}{2}g^{\mu\nu}\partial_\mu\partial_\nu\phi - V(\kappa\phi)\right] + S_m \tag{7}$$

where $R$ is the Ricci scalar, $g$ is the determinant of the metric $g^{\mu\nu}$, $V(\phi)$ is the dark energy potential, and, $S_m$ is the action of the matter fluid. The dark energy potential determines the form of quintessence being studied. The standard quintessence dark energy density, $\rho_\phi$, and pressure, $P_\phi$ equations are

$$\rho_\phi \equiv \frac{\dot{\phi}^2}{2} + V(\phi), \qquad P_\phi \equiv \frac{\dot{\phi}^2}{2} - V(\phi) \tag{8}$$

and the dark energy equation of state $w(\phi)$ is

$$w(\phi) = \frac{P_\phi}{\rho_\phi} = \frac{\frac{\dot{\phi}^2}{2} - V(\phi)}{\frac{\dot{\phi}^2}{2} + V(\phi)}. \tag{9}$$

Combining Eq. (8) gives

$$P_\phi + \rho_\phi = \dot{\phi}^2 \tag{10}$$

It follows that

$$\frac{P_\phi + \rho_\phi}{\rho_\phi} = w + 1 = \frac{\dot{\phi}^2}{\rho_\phi}. \tag{11}$$

From the definition of $H = \frac{\dot{a}}{a}$

$$\dot{\phi} = \frac{d\phi}{da}a\frac{da}{dt}\frac{1}{a} = \frac{d\phi}{d\ln(a)}H = \phi' H. \tag{12}$$

Using the following relations

$$\rho_\phi = \frac{3\Omega_\phi H^2}{\kappa^2}, \qquad \frac{\dot{\phi}^2}{\rho_\phi} = \frac{(\phi' H)^2}{\rho_\phi}, \tag{13}$$

a new relationship for $(w+1)$ is established.

$$\frac{\dot{\phi}^2}{\rho_\phi} = \frac{(\phi'\kappa)^2 H^2}{3\Omega_\phi H^2} = \frac{(\kappa\phi')^2}{3\Omega_\phi} = (w+1) \tag{14}$$

From Eq. (14)

$$\kappa\phi' = \sqrt{3\Omega_\phi(w+1)}. \tag{15}$$

From Eq. (3) $\beta(\phi) = \kappa\phi'$ coupled with Eq. (5) yields

$$\frac{p}{\kappa\phi} = \sqrt{3\Omega_\phi(w+1)}, \qquad \kappa\phi = \frac{p}{\sqrt{3\Omega_\phi(w+1)}} \tag{16}$$

Equation (16) establishes an important boundary condition on the scalar in terms of the current value of $\omega_\phi$ and $(w+1)$ for Quintessence IPL dark energy potentials.

$$\kappa\phi_0 = \frac{p}{\sqrt{3\Omega_{\phi_0}(w_0+1)}} \tag{17}$$

Equation (17) and Eq. (6) give the evolution of $\phi$ as a function of the scale factor $a$.

## 5. Parameter Relationships

A proper exploration of the parameter space of a cosmololgy such as quintessence requires an understanding of the relationships between the parameters. This section establishes the relations between the scalar $\phi$, the Hubble parameter $H$, the dark energy equation of state $w$ and the value of $M$ in Eq. (1). Combining Eq. (1) and Eq. (2) gives

$$M^{4+p}\phi^{-p} = 3\Omega_\phi \left(\frac{H}{\kappa}\right)^2. \tag{18}$$

Setting the current values of $H$, $\Omega$ and $w$ provides the boundary conditions for the remaining parameters. For a given value of the power $p$ in Eq. (1) Eq. (17) determines the value of $M$ as

$$M = \left[3\Omega_{\phi_0}\left(\frac{H_0}{\kappa}\right)^2 \phi_0^p\right]^{\frac{1}{4+p}}. \tag{19}$$

Equation (19) indicates that once $p$, $H_0$, $\Omega_{\phi_0}$ and $w_0$ are chosen the value of $M$ is set.

## 6. The Dark Energy Potentials

The beta function formalism utilizes a superpotential defined (2) simply as

$$W(\phi) = -2H(\phi) = -2\frac{\dot{a}}{a}. \tag{20}$$

It is obvious that calculation of the superpotential $W(\phi)$ is equivalent to the calculation of the Hubble parameter $H(\phi)$. In the absence of matter both the dark energy superpotential and the potential are defined by the beta function (2).

$$W(\kappa\phi) = W_0 \exp\left\{-\frac{1}{2}\int_{\kappa\phi_0}^{\kappa\phi} \beta(x)dx\right\} \tag{21}$$

and

$$V(\kappa\phi) = \frac{3}{4}W_0^2 \exp\left\{-\int_{\kappa\phi_0}^{\kappa\phi} \beta(x)dx\right\}\left(1 - \frac{\beta^2(\kappa\phi)}{6}\right) \tag{22}$$

where $W_0$ is the current value of $W$ equal to $-2H_0$. Equation (22) is the beta formalism equivalent of Eq. (4) and is called the beta potential $V_\beta(\phi)$ of the model potential $V_m(\phi)$. The beta potential is the model potential multiplied by $(1-\frac{\beta^2(\kappa\phi)}{6})$. If $\frac{\beta^2(\kappa\phi)}{6} << 1$ then the beta potential is an accurate but not exact representation of the model potential. In general the calculated evolution of the cosmological parameters and fundamental constants has the same accuracy as the beta potential representation of the model potential. Figure 1 shows the fractional deviation of the beta potential from the model potential for a sample case with a quartic potential, $p = 4$, $H_0 = 70$ for a flat Universe with $\Omega_\phi = 0.7$. It is clear that the error is less

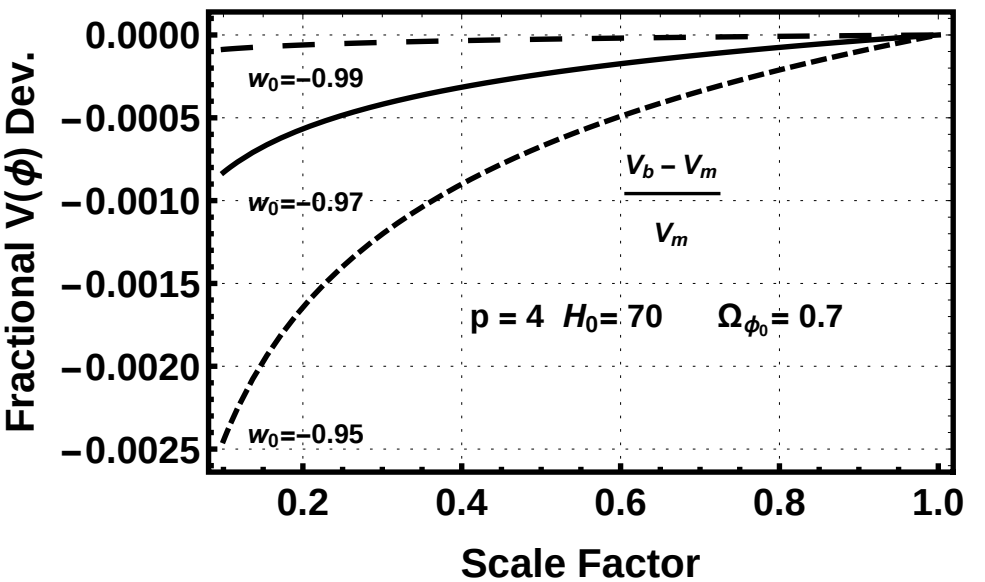

Fig. 1. The fractional error of the beta potential representation of the model potential for a quartic inverse power law model potential with $w_0 = -0.99$, $-0.97$ and $-0.95$.

than 0.25% for all cases and is less than 0.1% for the two $w_0$ values closest to minus one. This is a significantly higher accuracy than current observational cosmological parameter constraints.

## 7. A Universe with Matter

Since the goal of this article is the calculation of parameters for comparison with observations the dark and baryonic matter of the universe must be accounted for. In the beta function formalism the matter density $\rho_m(\kappa\phi)$ is given by

$$\rho_m(\kappa\phi) = \rho_{m0} \exp\left(-3 \int_{\kappa\phi_0}^{\kappa\phi} \frac{d\kappa\phi}{\beta(\kappa\phi)}\right) \tag{23}$$

where $\rho_{m0}$ is the current matter density. Using the definition of $\beta$ Eq. (23) can be written as

$$\rho_m(a) = \rho_{m0} \exp\left(-3\int_1^a dln(a)\right) = \rho_{m0} a^{-3} \tag{24}$$

as expected, independent of $\beta$.

### 7.1. *Introducing the superpotential to mass*

The presence of mass has a profound effect on the superpotential. Instead of the simple forms in section 6 there is a differential equation (2) for the superpotential $W$ that has the form

$$\frac{WW_{,\phi}}{\kappa^3} + \frac{\beta W^2}{2\kappa^2} = -2\frac{\rho_m}{\beta} \tag{25}$$

where $W_{,\phi}$ is the derivative of $W$ with respect to $\phi$. The solutions for $W$ are found through the use of integrating factors. Section 8 describes how the integrating factors can be found in general. The power and inverse power law integrating factors are $(\kappa\phi)^{-p}$ and $(\kappa\phi)^p$ respectively. Using the inverse power law integrating factor (4) shows that the the solution for $W(a)$ is

$$\begin{aligned} W_i(a) = -\Bigg\{ & -\frac{4\rho_{m_0}}{3}\left(\frac{2p}{3}\right)^{-\frac{p}{2}} \exp\left(\frac{3\phi_0^2}{2p}\right)(\phi(a))^{-p} \\ & \times\left[\Gamma\left(1+\frac{p}{2}, 3\ln(a)+\frac{3\phi_0^2}{2p}\right) - \Gamma\left(1+\frac{p}{2}, \frac{3\phi_0^2}{2p}\right)\right] \\ & + W_0^2\left(\frac{\phi_0}{\phi(a)}\right)^p\Bigg\}^{1/2} \end{aligned} \tag{26}$$

where $\Gamma$ is the incomplete Gamma function. The Hubble parameter is of course just $-\frac{1}{2}W$. Figure 2 shows the evolution of the Hubble parameter with $p = 4$.

### 7.2. *Onset of the acceleration of the expansion of the Universe*

An important check on the validity of the Hubble parameter is whether it initiates the late time acceleration of the universe at the correct epoch. Figure 3 shows the evolution of the speed of the expansion of the universe, $\dot{a}$, as a function of the scale factor $a$. The acceleration initiates at a scale factor of 0.6 consistent with the observations.

## 8. The Dark Energy Density

In a flat universe the dark energy density is just the total density minus the matter density therefore the ratio of the dark energy density to the critical density is

$$\Omega_\phi = \frac{3(H/\kappa)^2 - \rho_{m_0} a^{-3}}{3(H/\kappa)^2} \tag{27}$$

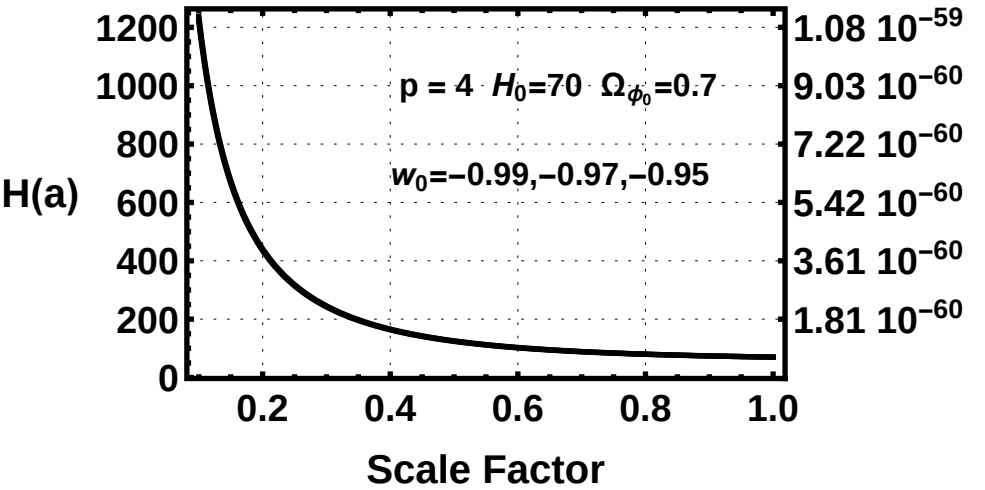

Fig. 2. The evolution of the Hubble parameter $H(a)$ with $p = 4$ and $w_0 = -0.97$. The left ordinate is labeled in $(km/sec)/Mpc$ and the right ordinate in reduced Planck mass $M_p$.

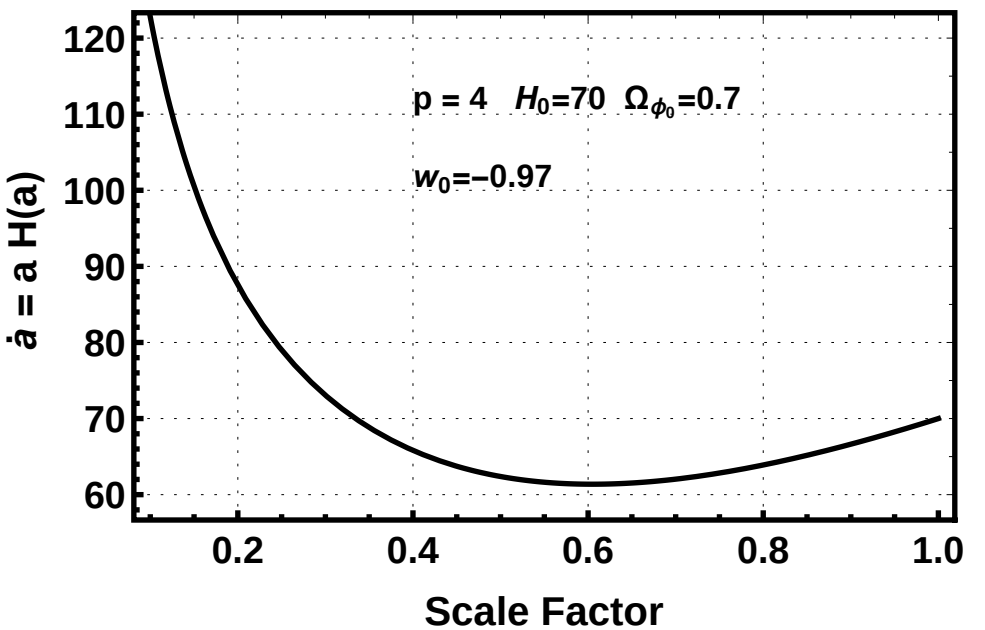

Fig. 3. The evolution of the speed of expansion of the universe $\dot{a}$ with $p = 4$ and $w_0 = -0.97$. The acceleration initiates at a scale factor of 0.6, consistent with observations.

Figure 4 shows the evolution of $\Omega_\phi(a)$ for $p = 4$ and the three values of $w_0$. The figure show that $\Omega_\phi$ is not a strong function of $w_)$ but some separation of the three plots is apparent near $a = 0.1$. $\Omega_\phi$ approaches zero at that point which is relevant in considering the evolution of $w$.

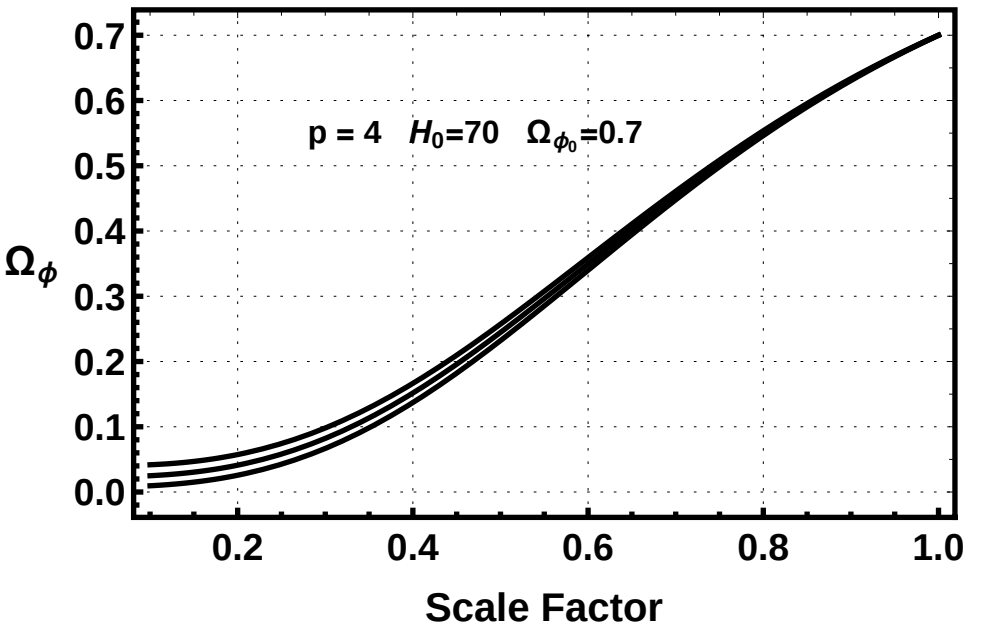

Fig. 4. The evolution of $\Omega_\phi$, the ratio of the dark energy density to the critical density, with $p = 4$ and $w_0 = -0.97$.

### 9. The Dark Energy Equation of State

The dark energy equation of state, DEoS, is an important cosmological parameter whose value discriminates between static and dynamic cosmologies. From (4) the equations for the equation of state with matter included are

$$1 + w(\phi) = \frac{\beta^2}{3} \frac{1}{(1 - \frac{4\rho_{m_0} a^{-3}}{3(W/\kappa)^2})} = \frac{\beta^2}{3} \frac{1}{(1 - \Omega_m)} = \frac{\beta^2(\phi)}{3\Omega_\phi} \tag{28}$$

This differs slightly from (4) because $\kappa$ is included in the equations rather than being set to one. Since, as shown in section 8, $\Omega_\phi$ approaches very close to zero at scale factors near $a = 0.1$ the more accurate first term to the right in Eq. (28) is used rather than the later terms. Figure 5 shows the evolution of $w(a)$ for $p = 4$ and the three $w_0$ values. Note that although the evolution of $w(a)$ is relatively well fit by the linear CPL model for scale factors larger than 0.5, the early evolution of $w(a)$ is very non-linear.

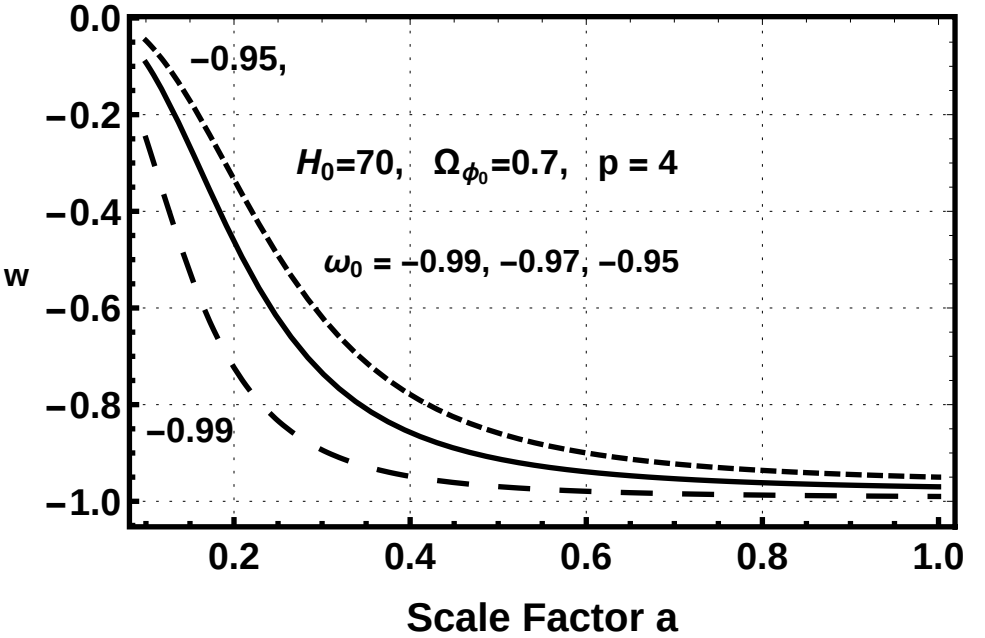

Fig. 5. The evolution of $w(a)$ with $p = 4$ and $w_0 = -0.99, -0.97$ and $-0.95$.

## 10. The Evolution of the Fundamental Constants $\alpha$ and $\mu$

Up until now we have concentrated on the evolution of cosmological parameters as a result of the rolling scalar field. Now attention is centered on two of the dimensionless fundamental constants, the fine structure constant $\alpha$ and the proton to electron mass ratio $\mu$. The same scalar field that interacts with the gravitational sector is also assumed to interact with the other sectors. It is difficult without fine tuning to limit the interaction of a scalar field to only the gravitational sector (6). The relationship between the variation of $\mu$ or $\alpha$ and $\phi$ is given simply by

$$\frac{\Delta x}{x} = \zeta_x \kappa(\phi - \phi_0) = \zeta_\mu \int_1^a \beta(a') d\ln(a') \tag{29}$$

where $x$ is either $\mu$ or $\alpha$ and $\zeta_x$ is the dimensionless coupling constant for the interaction. This can be taken as the first term in a Taylor series expansion of a more complicated coupling. $\beta(a)$ is equal to $\beta(\phi(a))$. From now on we consider the proton to electron mass ratio $\mu$ as it has the strongest limit on its variation $\Delta\mu/\mu \leq 10^{-7}$ at $z = 0.89$( 7) and (8) a look back time greater than half the age of the universe. Figure 6 shows the evolution of $\Delta\mu/\mu$ with a coupling constant $\zeta_\mu$ set to $10^{-6}$, a relatively large value set to highlight the nature or the evolution. All of the tracks in Fig. 6 except for $w_0 = -0.99$ violate the limit on $\Delta\mu/\mu$ at $z = 0.89$.

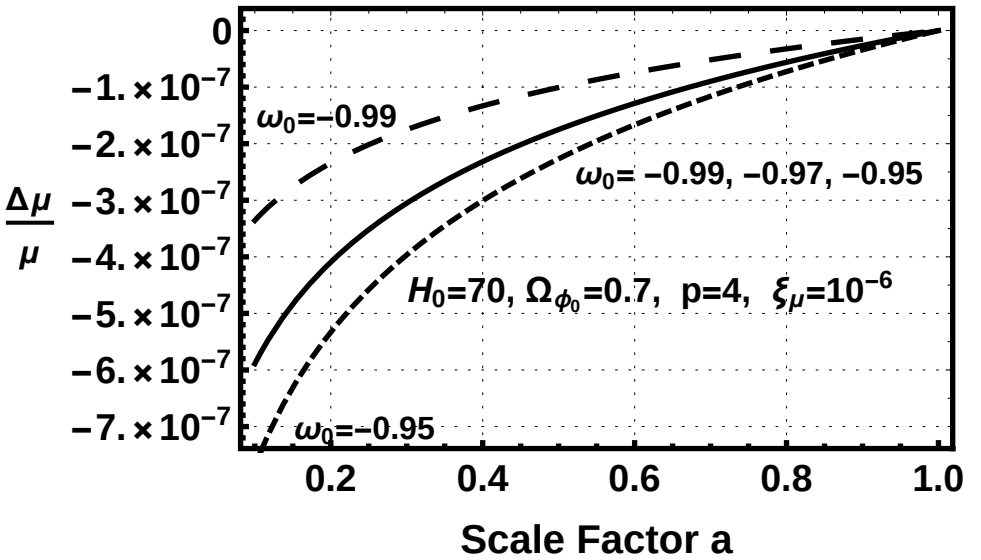

Fig. 6. The evolution of $\Delta\mu/\mu$ with $p = 4$ and $w_0 = -0.99, -0.97$ and $-0.95$.

## 11. Limiting the Parameter Space with Fundamental Constants

Equations (29) and (28) established a two dimensional parameter space in terms of $\zeta_\mu$ and $(w_0 + 1)$. The limits on $\Delta\mu/\mu$ or $\Delta\alpha/\alpha$ can be satisfied either by lowering the coupling constant or by moving $w_0$ closer to minus one. The explicit relation between $w_0$, $\Delta\mu/\mu$ and $\zeta_\mu$ is (5)

$$\zeta_\mu = \frac{\Delta\mu/\mu}{\kappa(\phi(a_{ob}) - \phi_0)}. \tag{30}$$

where $a_{ob}$ is the scale factor of the observation of the limiting constraint. Figure 7 shows the allowed and forbidden regions in the parameter space established by the limit on $\Delta\mu/\mu$ at $z = 0.89$. Future improvements on the variational limits of the fundamental constants can further reduce the allowable space. Only a verified observation of a change in $\mu$ or $\alpha$ can eliminate the ΛCDM and Standard Model point at $(0, 0)$.

## 12. Summary

This work is a demonstration of the beta function formalism using the quintessence cosmology with an inverse power law dark energy potential as an example. The beta function is defined as the derivative of the scalar field $\phi$ with respect to the natural log of the scale factor $a$, $\beta = d\phi/d\ln(a)$. The beta function is the negative of the logarithmic derivative of the dark energy potential and has potential the accurately but not exactly reproduces the true dark energy potential. When the criterion of $\beta^2/6 \ll 1$ is satisfied the beta potential to an accuracy of $(1 - \beta^2/6)$.

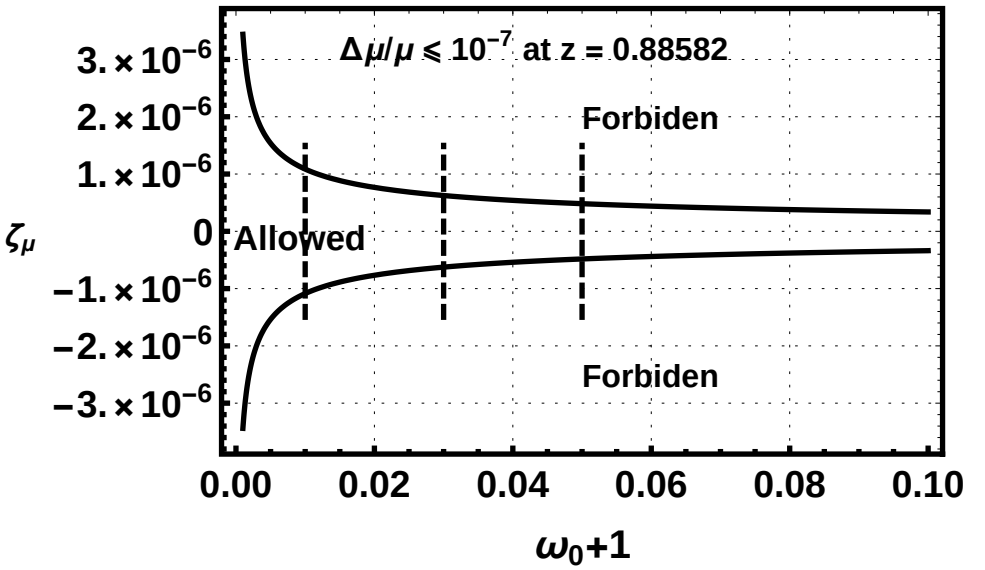

Fig. 7. The allowed and fforbidden areas in the $\zeta_\mu - (w_0 + 1)$ parameter space established by the observational limits on $\Delta\mu/\mu$. The vertical dashed lines indicate the three values of $w_0$ considered here.

An important feature of the beta function is that it provides a mechanism of determining $\phi(a)$ to produce analytic functions of the cosmological parameters and the evolution of fundamental constants as a function of the scale factor. These functions provided templates for comparison with observations that can discriminate between dynamical and static cosmologies along with the parameter space allowed for the cosmologies. The analysis reveals that ΛCDM is included in the quintessence cosmology power law potential as the zero power case.

Deployment of quantum technology in space provides opportunities for new types of precision tests of gravity. On the other hand, the operational demands of such technology can make previously unimportant effects practically relevant. We describe a novel optical interferometric red-shift measurement and a measurement scheme designed to witness the possible spin-gravity coupling effects.

*Keywords*: Equivalence principle; satellite-based experiments; optics; spin.

## 1. Introduction

Amazing progress in quantum sensing and quantum, together with satellite deployment of quantum technologies have ushered in a new era of experimental physics in outer space. The success of the first space based quantum key distribution experiments performed with the Micius satellite[1], is expected to be soon followed by European and North American missions. Current missions, such as LAGEOS-2, BEACON-C and LCT on Alphasat I-XL, are adapted for quantum optics experiments[2,3]. While the primary goal of the space-based platforms is to provide links for global quantum key distribution, the missions also envisage substantial scientific programs. These experiments have the exciting potential to enable novel searches for signatures of quantum gravity and/or physics beyond the standard model[4].

Here we describe the interplay of these technologies with the Einstein Equivalence Principle (EEP). The principle comprises three statements[5,6]. The first — *Weak Equivalence Principle* (WEP) — states that the trajectory of a freely falling test body is independent of its internal composition. Closely related to the WEP

is the Einstein elevator: if all bodies fall with the same acceleration in an external gravitational field, then to an observer in a small freely falling lab in the same gravitational field, they appear unaccelerated[6]. The remaining two statements deal with outcomes of non-gravitational experiments performed in freely falling laboratories where self-gravitational effects are negligible. The second statement — *Local Lorentz Invariance* — asserts that such experiments are independent of the velocity of the laboratory where the experiment takes place. The third statement — *Local Position Invariance* (LPI) — asserts that "the outcome of any local non-gravitational experiment is independent of where and when in the universe it is performed"[5].

We consider a novel all-optical test of LPI and the inertial and aspects of the spin-gravity coupling, commenting on implications for the validity of the WEP.

## 2. Optical test of position invariance

Tests of the "when" part of the LPI bound the variability of the non-gravitational constants over cosmological time scales[7]. The "where" part was expressed in Einstein's analysis of what in modern terms is a comparison of two identical frequency standards in two different locations in a static gravitational field. The so-called *red-shift* implied by the LPI affects the locally measured frequencies of a spectral line that is emitted at location 1 with $\omega_{11}$ and then detected at location 2 with $\omega_{12}$. The red-shift can be parametrized at the leading post-Newtonian order as

$$\Delta\omega/\omega_{11} = (1+\alpha)(U_2 - U_1) + \mathcal{O}(c^{-3}), \tag{1}$$

where $\Delta\omega := \omega_{12} - \omega_{11}$, $U_i := -\phi_i/c^2$ has the opposite sign of the Newtonian gravitational potential $\phi_i$ at the emission (1) and detection (2), while $\alpha \neq 0$ accounts for possible violations of LPI. In principle, $\alpha$ may depend on the nature of the clock that is used to measure the red-shift[5]. The standard model extension includes variously constrained parameters that predict LPI violation[8,9]. Alternative theories of gravity not ruled out by current data also predict $\alpha \neq 0$[5,10].

A typical red-shift experiment involves a pair of clocks, naturally occurring[11] or specially-designed[12–14], whose readings are communicated by electromagnetic (EM) radiation. The resulting estimates of $\alpha$ are based on comparison of fermion-based standards. Hence, different types of experiments, which employ a single EM-source and compare optical phase differences between beams of light traversing different paths in a gravitational field, provide a complementary test of LPI.

Such an all-optical experiment was proposed as a possible component of the QEYSSAT mission[4]. A photon time-bin superposition is sent from a ground station on Earth to a spacecraft, both equipped with an interferometer of imbalance $l$, in order to temporally recombine the two time-bins and obtain an interference pattern depending on the gravitational phase-shift:

$$\varphi_{\rm gr} = \frac{\Delta\omega}{\omega}\frac{2\pi}{\lambda}l \approx (1+\alpha)\frac{2\pi}{\lambda}\frac{ghl}{c^2}\ , \tag{2}$$

where $g$ is the Earth's gravity, $h$ the satellite altitude and $\lambda = 2\pi c/\omega$ the sent wavelength. For $\alpha = 0$, the order of magnitude of the gravitational red-shift is about 1 rad supposing $\lambda = 1550$ nm, l=1.2 km and an altitude $h = 1500$ km (which corresponds to $\Delta U \approx -1.3 \times 10^{-10}$).

However, a careful analysis of this optical COW-like experiment[15] revealed that first-order Doppler effects are roughly $10^5$ times stronger than the desired signal $\varphi_{\rm gr}$ from which $\alpha$ would be estimated. This first-order Doppler effect is an unavoidable part of the interferometric phase[16] was recently measured by exploiting large-distance precision interferometry along space channels[17], which constitute a resource for performing fundamental tests of quantum mechanics in space and space-based quantum cryptography.

We propose[18] a new gravitational red-shift experiment, which uses a single EM-source and a double large-distance interferometric measurement performed at two different gravitational potentials. By comparing the phase-shifts obtained at a satellite and on Earth, it is possible to cancle the first-order Doppler effect. Thus, this experimental proposal allows for a bound on $\alpha$ quantifying the violation of LPI in the EM-sector with a precision on the order of $10^{-5}$.

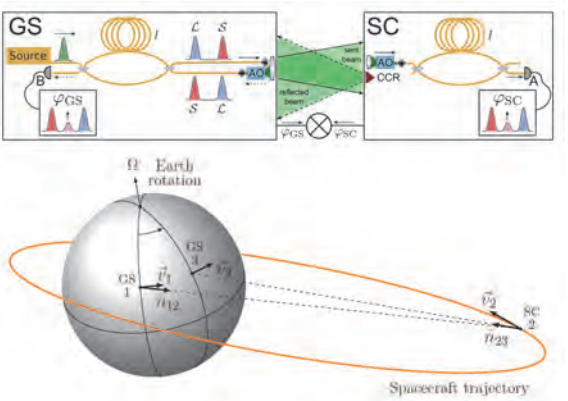

Fig. 1. Top: A schematic diagram of the proposed experiment. Both the ground station (GS) and spacecraft (SC) are equipped with a MZI of equal delay line $l$ and an adaptive optics system for fibre injection. Bottom: The geometry of the GS and SC used in the experiment, where $\vec{v}_1$ is the velocity of the GS at the emission location and potential $U_1$; $\vec{v}_2$ is the velocity of the SC at the detection location on the satellite and potential $U_2$; $\vec{v}_3$ is the velocity of the ground station at the detection of the beam retro-reflected by the SC, which occurs at a potential $U_3 = U_1$.

This proposal[17] is comprised of an interferometric measurement obtained by sending a light pulse through a cascade of two fiber-based Mach-Zehnder interferometers (MZI) of equal temporal imbalance $\tau_l$. After the first MZI, the pulse is split into two temporal modes, called *short* ($\mathcal{S}$) and *long* ($\mathcal{L}$) depending on the path taken in the first MZI. The equal imbalance of the two MZIs guarantees that the two pulses are recombined at the output of the second MZI, where they are detected. Such a satellite interferometry experiment setup is sketched in Fig. 1.

The combination of the possible paths the pulses may take leads to a characteristic detection pattern comprised of three possible arrival times for each pulse, as depicted in the insets of the upper picture in Fig. 1. The first (third) peak corresponds to the pulses that took the $\mathcal{S}$ ($\mathcal{L}$) path in both the MZIs, while the mid peak is due to the pulse that took the $\mathcal{S}$ path in the first interferometer and the $\mathcal{L}$ path in the second interferometer, or vice versa. Hence, interference is expected only in the central peak due to the indistinguishability of these latter two possibilities. A successful realization of the experiment depends on a number of important technical aspects that are described in detail in Ref. 18.

A bound on $\alpha$ is retrieved from the difference of the two phase-shifts, $\varphi_{\rm SC}$ and $\varphi_{\rm GS}$, that are obtained from interferometric measurements on the spacecraft and ground station, respectively. As just described, the interfering beams take different paths in the passage through the two MZIs. At the satellite, the beam that took the $\mathcal{L}$ path on Earth and the $\mathcal{S}$ path on the spacecraft interferes with the beam that passed took the $\mathcal{S}$ path on Earth and then took the $\mathcal{L}$ one on the spacecraft. This interference is a result of the phase difference $\varphi_{\rm SC}$. Analogously, at the ground station (GS) the beams that were delayed on the Earth before and after their round trip to the spacecraft (SC) will also interfere because of the phase difference $\varphi_{\rm GS}$.

The first-order Doppler terms are eliminated by manipulating the corresponding data sets from the GS and SC in a manner similar to the time-delay interferometry techniques[19] and those used in the Gravity Probe A experiment[13]. The basis for the derivation is the observation[16,18] that the phase difference at each detector is proportional to the proper time difference at the emission, that is related to the different travel times over $\mathcal{S}$ and $\mathcal{L}$. The key feature allowing for this elimination is that the ratio of the terms stemming from the first-order Doppler effect the two signals, $\varphi_{\rm SC}$ and $\varphi_{\rm GS}$ is exactly two[18]. Hence the target signal is $S = \varphi_{\rm SC} - \frac{1}{2}\varphi_{\rm GS}$, leading to

$$\frac{S}{\omega_0 \tau_l} = (1+\alpha)(U_2 - U_1) + \tfrac{1}{2}(\beta_2^2 - \beta_1^2) - \vec{\beta}_1 \cdot (\vec{\beta}_1 - \vec{\beta}_2) - (\mathfrak{d}_2^2 - \mathfrak{d}_1^2) - T(\hat{n}_{12} \cdot \vec{a}_1) - \left( (\vec{\beta}_2 - \vec{\beta}_1)^2 - (\mathfrak{d}_2 - \mathfrak{d}_1)^2 \right) \frac{\tau_l}{4T}, \qquad (3)$$

where $\alpha$ parameterizes the violation of LPI, $\vec{\beta}_i := \vec{v}_i/c$, $\mathfrak{d}_i := \hat{n}_{12} \cdot \vec{\beta}_i$, $T$ is the zeroth order time-of-flight between the GS and the SC, $\vec{a}_1$ is the centripetal acceleration of the GS at 1.

## 3. Weak equivalence principle and orbiting clocks

Matter of the Standard Model is characterized by two parameters of the irreducible representations of the Poincaré group: mass and spin (or helicity). General relativity is a universal interaction theory about masses[20], as the Newtonian gravity is, with polarization effects implicitly omitted from the WEP.

Regardless of their origins, spin-gravity coupling terms provide effective corrections to the Hamiltonian in the limit of weak gravity and non-relativistic motion.

The leading terms of the Hamiltonian of a free spin-$\frac{1}{2}$ particle that take into account the effects of rotation of the reference frame with angular velocity $\vec{\omega}$ and acceleration $\vec{a}$ (or a uniform gravitational field) can be represented as

$$H = H_{\rm cl} + H_{\rm rel} + H_\sigma + H_{\rm ext}. \tag{4}$$

The first three terms on the right hand side are obtained by performing the standard Foldy-Wouthuysen transformation and taking the non-relativistic limit [21]. The term $H_{\rm cl}$ represents the standard Hamiltonian of a free non-relativisitc particle in a non-inertial frame, $H_{\rm rel}$ describes the higher-order relativistic corrections that do not involve spin, and

$$H_\sigma = -\tfrac{1}{2}\hbar\vec{\omega}\cdot\vec{\sigma} + \frac{\hbar}{4mc^2}\vec{\sigma}\cdot(\vec{a}\times\vec{p}). \tag{5}$$

Finally, the term

$$H_{\rm ext} = \frac{\hbar k}{2c}\vec{a}\cdot\vec{\sigma} \tag{6}$$

represents the spin-accelerating (or spin-gravity) coupling. It is a limiting form of the simplest phenomenological addition to the Dirac equation that breaks the WEP [22]. For the value $k = 1$ it results from a particular version of the Foldy-Wouthuysen transformation [23]. While commonly considered a mathematical artefact of this transformation, the term naturally arises in gravitationally inspired Standard Model extensions. Only model-dependent bounds on $k$ in $H_{\rm ext}$ were obtained by a variety of techniques [24], including the optical magnetometery [25].

The spin dependent terms are small under normal conditions. On the Earth's surface $\hbar g/c = 2.15\times10^{-23}$ eV, which is equivalent to an effective magnetic field of $3.7\times10^{-19}$ Tl, still several orders of magnitude below the peak sensitivity of optical magnetometery. The spin-rotation term is significantly larger, since already on the ground $\omega c/g = 2.22\times10^{3}$. It will be about an order of magnitude stronger for low-orbit satellites that are planned to carry entangled optical clocks aiming to establish the precision of $10^{-18}-10^{-20}$, making it a factor to consider in the clock design.

A potentially promising way of detecting these effects is via so-called weak amplification [26]. Weak value amplification involves two systems (typically referred to as "system" and "meter") that can interact via an interaction Hamiltonian of the form $q\delta(t-t_0)\hat{A}\otimes\hat{p}$. The bipartite system-meter is prepared in an initial state $|s_i\rangle\otimes|m_i\rangle$, following which the two are allowed to interact for a small time that includes $t_0$. Following this, the system is measured and measurements corresponding to a post-selected system state $|s_f\rangle$ are considered. This pre- and post-selection induces a "kick" in the meter state, given by the evolution $e^{-iq\mathcal{A}_w\hat{p}}|m_i\rangle$, where $\mathcal{A}_w \equiv \langle S_f|A_s|S_i\rangle/\langle S_f|S_i\rangle$.

The key insight here is that since $\langle S_f|S_i\rangle$ can be a small number, the measurement of $q$ is influenced by a large multiplicative factor $\mathcal{A}_w$. A subsequent measurement of the meter reveals the desired parameter $q$. Trapped atoms are potentially promising system to implement this scheme [26].

The simplest model of such a set-up consists of a species of spin interacting with a harmonic mode, subject to an interaction of the form

$$H \approx \hbar\omega_t(a^\dagger a + 1/2) + \frac{\hbar\omega_g}{2}\sigma_z + \hbar\lambda[(1 - i\delta)\sigma_+ a + (1 + i\delta)\sigma_- a^\dagger], \tag{7}$$

$\omega_g$ being the gravitational term and constants $\delta, \lambda$ are related to the interaction with the harmonic mode[26]. Analysis of the unitary evolution that is followed by post-selection indicates that for realistic parameter values the inertial and gravitational effects are within the sensitivity range of the optical magnetometery.

GINGER (Gyroscopes IN GEneral Relativity) is a project based on an array of large dimension ring laser gyroscopes, which is aiming at measuring in a ground laboratory the gravito-electric and gravito-magnetic effects (also known as De Sitter and Lense-Thirrings effect), foreseen by General Relativity, and proposed at the underground Gran Sasso laboratory (LNGS). The geometry control to keep constant the scale factor and the optimal orientation of the array have been studied. GINGERINO, a square ring-laser prototype built inside LNGS, has shown the advantages of an underground location for GINGER. At present, it is the only high sensitivity laser gyro running unattended in a seismically active area. It recorded the large signals of the sequence of the central Italy 2016 earthquakes and microseismic signals of the Mediterranean area five orders of magnitude smaller. The analysis of 90 days of continuous operation shows that its duty cycle is higher than 95%, with noise limit of the order of $10^{-10}$ (rad/s)/$\sqrt{Hz}$.

## 1. Introduction

The Sagnac effect has been discovered by Georges Sagnac more than 100 years ago, and states that the difference of time of flight of two light beams counter-propagating inside a closed path, is proportional to the angular rotation rate of the frame.[1–3] Usually the closed path is an optical fiber coil or a ring Fabry-Perot cavity composed by $3-4$ mirrors. The device can be passive or active: passive is when the resonant cavity is interrogated injecting light from the outside; active when it contains an active medium, and the device is itself a laser emitting along two counter propagating modes, in this case it is called Ring Laser Gyro (RLG).[4] RLGs based on large frame ring cavities, with perimeters of several meters, are at

present the most sensitive angular rotation sensors based on Earth. They have been built for geodesy, geophysics and for General Relativity (GR) tests[1] (for geophysics see *https : //www.geophysik.uni − muenchen.de/ROMY/*). Since 2011 we are studying the feasibility of the Lense Thirring test at the level of 1%, with an array of large frame RLGs,[5–7] studying in details the orientation of the RLGs in order to define the specifications of such apparatus. At the same time several tests have been pursued in order to define and test in details the geometry control and the data analysis. It is necessary to push the relative sensitivity of the Earth rotation rate measurement in the range from 3 parts in $10^9$ (present record[8]) up to 1 part in $10^{12}$, this is equivalent to reach the sensitivity level of $10^{-16}$rad/s. It is necessary to point out that this measurement is even more demanding since it requires very high accuracy. At present, the accuracy limit is certainly at least 10 times worst than the sensitivity limit. RLG consists of a laser with a cavity comprising of three or four mirrors, depending if the cavity is triangular or square, rigidly attached to a frame; the two counter-propagating cavity modes have slightly different frequency, and the beat note $f_s$ of the two beams is proportional to the angular rotation rate $\Omega$ felt by the ring cavity.

$$f_s = S\Omega\cos\theta \qquad (1)$$
$$S = 4\frac{A}{\lambda L}$$

where $A$ is the area of the ring cavity, $L$ is its perimeter, $\lambda$ the wavelength of the light, and $\theta$ the angle between the area versor of the ring and the rotation axis. Considering RLG attached to the Earth crust, horizontally aligned (*i.e.* area versor vertical) $\theta$ is the colatitude angle, while for RLGs aligned at the maximum Sagnac signal (*i.e.* area versor along the Earth rotation axes) $\theta = 0$. Eq. (1) connects $\Omega$ with the scale factor $S$, which depends on the geometry, and the wavelength $\lambda$. RLGs have large interest in fundamental physics to study the property of the gravito-magnetic field, and they have been proposed in the past for axion search and Lorenz invariance violation.[9] GINGER would provide *the first measurement* of a *GR* dynamic effect of the gravitational field on the Earth surface (not considering the gravitational redshift). Though not in free fall condition, it would be a direct local measurement, independent from the global distribution of the gravitational field and not an average value, as in the case of space experiments. It is important to point out that this kind of measurement depends on the angular momentum of the Earth, so it provides a way to check whether dark matter is nearby rotating. There are space based project to further develop the gravito-magnetic measurements in space to test the presence of dark matter.[10] The measurement is based on properties of the velocity of light and on the measurement of the frequency, ensuring fast response, large bandwidth, and a huge dynamical range. For example GINGERINO, our RLG prototype at LNGS, has recorded microseismic events in the range of fraction of nrad/s and high magnitude nearby earthquakes[11] 5 orders of magnitude higher. Fig. 1 shows the typical lay-out of a square cavity RLG. The

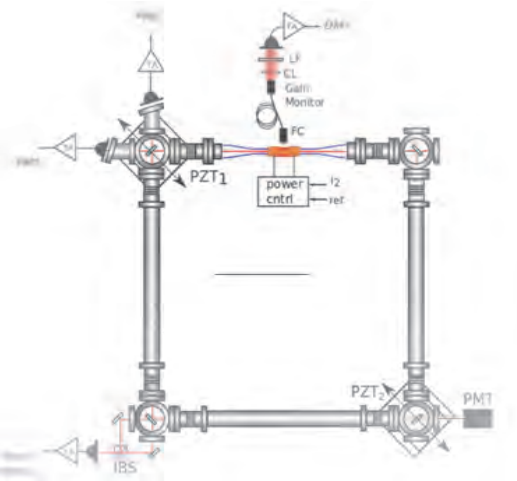

Fig. 1. Typical scheme of RLG with a square ring cavity.

four mirrors are placed at the corners of the square ring, each contained inside small vacuum chambers connected by steel pipes. The whole setup is vacuum tight and filled with Helium and an isotopic 50/50 mixture of $^{20}$Ne and $^{22}$Ne. The r.f. discharge, located in one of the side, generates the laser plasma. In most of the cases, piezoelectric actuators are utilised to translate the mirrors, allowing a control of the RLG perimeter length. The Sagnac beat note signal is observed at one corner (bottom-left) by superimposing the two output beams on a photodiode. At the top left corner two amplified photodiodes monitor the clock-wise (cw) and the counter clock-wise (ccw) output beams optical power (mono-beam photodiodes). Another photodiode monitors the fluorescence from the discharge, filtered around 633nm by an interference filter, providing a rough indication of the density of excited atoms in the laser upper state. In normal operation, plasma discharge is electronically controlled in order to keep as much as possible constant the optical power of one of the two mono-beams. All these signals are acquired by an ADC card at a frequency rate of a 5 kHz, suitable to allow their reliable reconstruction from DC up to the Sagnac frequency.

## 2. GINGER

The effects of the gravito-magnetic (Lense-Thirring, LT) and gravito-electric (de Sitter, dS) fields are observable by the gyro as angular velocity $\mathbf{\Omega_{LT}}$ and $\mathbf{\Omega_{dS}}$, that combine with $\mathbf{\Omega}_\oplus$, the Earth angular velocity, seen in the Cosmic inertial frame. *GR* is extremely predictive, allowing to compute the orientation and the amplitude of $\Omega_{LT}$ and $\Omega_{dS}$, in function of the latitude of the observer. Note also that several alternative theories of gravitation predict different dependence on latitude; so that a direct observation would, perhaps, discriminate between different theories.[12] Fig. 2

shows the mutual orientation of the various vectors for $\simeq 45^o$ of latitude (as e.g. at the GranSasso laboratories, LNGS).

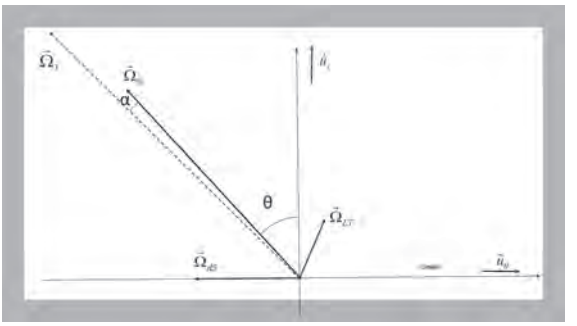

Fig. 2. The three axial vectors $\vec{\Omega}_\oplus$, $\vec{\Omega}_{LT}$, and $\vec{\Omega}_{dS}$ are shown, with the relative orientation at the latitude of the underground laboratory of GranSasso (LNGS), following General Relativity. The angle $\alpha$ and $\Omega_T$ (dashed line) are shown in the picture. The graph is not to scale, it gives just a pictorial view of the relative orientations of the different components. In reality, the modulus of $\vec{\Omega}_\oplus$ is 9 orders on magnitude bigger than the $GR$ terms, and the angle $\alpha$ is of the order of $\sim 3.5{\cdot}10^{-10}$ rad at the latitude of $45^o$.

The idea is to measure the total angular velocity seen by the gyros array and to evaluate the GR terms comparing the results with the measurement done by the international system IERS (International Earth Rotation and reference System), which independently measures the kinematic term $\Omega_\oplus$. The problem of the Lense-Thirring test is a very general one, similar to any effect induced by geophysical phenomena; it is particularly challenging since it is a DC effect, and not only sensitivity is required, but also accuracy. The main points of the GINGER apparatus are the following:

- reconstruct with very high precision a vector in the space using the information of the projectors, Eq. 2 shows that the geometry of the apparatus must be controlled, in particular the ratio $\frac{A}{P}$, the wavelength $\lambda$ and the variation of the absolute inclination $\delta\theta$;
- in general at least 3 independent gyros, 4 or more would be better for redundancy;
- it is necessary to study the noise related to any kind of variations of the apparatus, in particular all geophysical signals.

The main difficulty is the required accuracy, because it is necessary to distinguish a DC signal $9-10$ orders of magnitude smaller than the dominant signal $\Omega_\oplus$. It has been shown that in general the signal can be reconstructed combining the different RLG of the array,[6] but the relative angles between the different RLGs must be known with adequate accuracy. This means accuracy in the relative alignment of the RLGs of the order of nrad or better. One technique suitable to monitor with nanometer accuracy the distance between the mirrors has been tested.[13] Utilising

the natural symmetry of the problem it is possible to mitigate the requirement of the relative alignment. It has been shown that aligning one of the RLG at the maximum signal and the other horizontally or vertically it is possible to evaluate the angle between the two and solve the problem.[7] The RLG aligned at the maximum signal, so with area versor along the Earth rotational axis, has the interesting property that delivers the modulus of the total angular velocity and is at first order insensitive to local tilts. In principle it delivers the variations of the modulus of $\Omega_{\oplus}$, or equivalently the Length of Day (LoD). The details of the specification have been published.[6,7] Fig. 3 shows a picture of GINGER with 3 independent RLG, the location may be node B of LNGS, an area far apart from the main experiments. The exact dimension of the ring laser resonators has not been decided yet, but they will be squared structures with side length of $5 - 6$ meters.

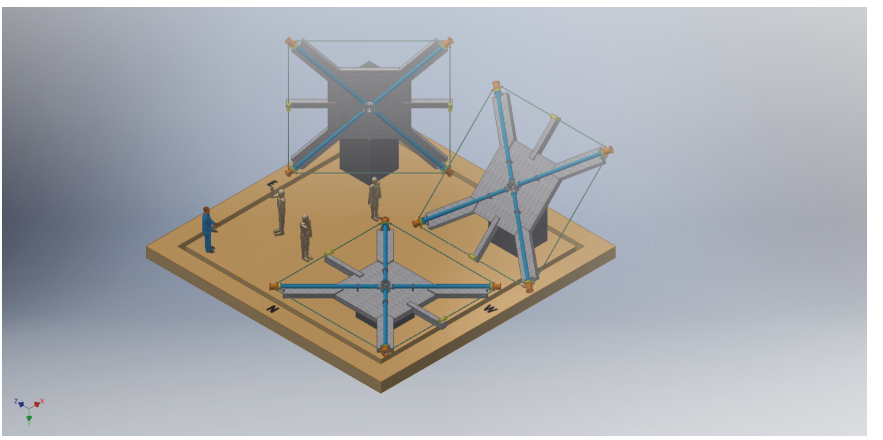

Fig. 3. Pictorial view of the GINGER project.

## 3. GINGERINO and work toward GINGER

Large effort has been pursued in Italy toward GINGER. Presently the most performing RLG is "G", situated at the Geodetic Observatory of Wettzell in Germany; it is composed of a monolithic structure, a rigid block of Zerodur with mirrors optically contacted in order to have a geometry fixed by construction. It is evident that such a structure cannot be extended to form a three axial array. Hetero-lithic mechanical structures have to be used instead, and in this case an electronic control is necessary in order to keep constant the geometry. A suitable control scheme to keep constant the scale factor has been studied and tested.[14–16] It is a well known fact that RLGs are affected by non linearity of the laser, and, in particular, optical back-scattered noise. In 2012-2014 Kalman filters have been successfully applied,[17,18] more recently we have developed a novel analytical technique to reconstruct the Sagnac frequency avoiding laser systematic.[19] Fig. 4 shows the time

behaviour of the data of GP2, analysed with the standard method and with the new one. GP2 is a square ring laser with side of 1.6m, aligned at the maximum Sagnac signal and presently working in Pisa for test purposes.[16] Gingerino is a test RLG

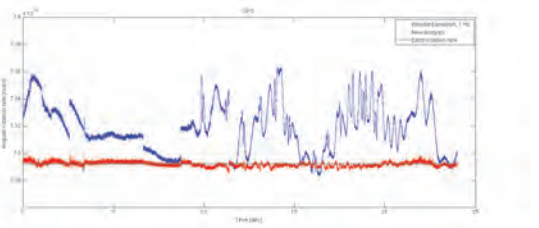

Fig. 4. One day of data of the prototype GP2 analysed with the standard method and the new one, the black line is the expected Earth angular rotation rate. GP2 is the RLG prototype with 6.4m perimeter, aligned at the maximum Sagnac signal.

3.6 m in side, installed at LNGS since 2014. In seismology, translation and strain are routinely observed by seismometer and strain meters. However, a full description of the ground movements requires also the acquisition of a third type of information, namely rotations. In particular, co-located translation and rotation sensors allow to estimate the local underground velocity structure, which is an information of high interest in geophysical survey. Rotational signals induced by seismic waves have a quite small amplitude. A strong seismic wave with a linear acceleration of 1 mm/$s^2$ produces a rotation velocity amplitude of some $10^{-7}$ rad/s, while micro-seismic rotational background noise (around 0.1 Hz) is smaller than $10^{-10}$ rad/s.[11,20] GINGERINO has shown the advantage of the underground location, since it is the first large frame hetero-lithic RLG, which operates continuously unattended with high sensitivity and with 95% duty cycle.[21] It has also shown that the local tilts on long time are below $\mu$rad,[7] this is an important parameter for the installation of a RLG at the maximum signal. GINGERINO is taking data for seismology, so at present inside LNGS there is one of the few seismic station allowing to record at the same time both the three translation components and the rotation angle.[11,20] Besides, GINGERINO is a very useful tool to develop new analysis technique, to investigate the very low frequency signals and to test all the equipment to remotely control and operate on the apparatus.

## 4. Conclusion

A large experimental work has been pursued toward GINGER, the array of RLGs designed to detect on ground the Lense-Thirring effect at 1% precision. Geometry control of each independent RLG, study of the optimal orientation of each RLG of the array, and reconstruction of the angular rotation rate taking into account the systematic of the laser. GINGERINO has been realized to validate LNGS for this experiment, and it has shown the advantage of an underground location

far from atmospheric perturbations and large thermal variation. In fact it is the first high sensitivity RLG based on a hetero-lithic mechanical structure operating with 95% duty cycle and with a sensitivity of the order of $10^{-10}$rad/s. It has detected microseismic signals of the order of $10^{-10}$ rad/s and large teleseismic events 5 orders of magnitude larger. It is the first and only RLG operative in one of the Mediterranean most important seismically active area.

With the technology development in the cold atomic clock etc. and the gyposcope etc., many relativistic geodetic project and the plan of Atomic Gravitational wave Interferometric Sensor (AGIS) was proposed. Here we introduce one plan of spacetime structure exploration in the earth-moon system by the above mentioned thecniques, which focus on surveying the gravitational potential and gravitational first order redshift in spacetime geometry of the earth-moon system. We also discussed that apply those satellites and instrumenmts to find Geometrodynamic field moment which include gravitomagnetic clock, the possible CPT violation (Lorentz Invariance Violation) from Gravitional second order Redshift.

*Keywords*: Gereral relativity experiments; the clock and gyposcope; gravity; spacetime; difference geometry.

## 1. The Introduction

With the technology development in the clock and the gyroscope, we propose our plan of relativistic geodetic project which based on spacetime geometry of the earth-moon system. In Sec. 2, we introduce the instrument onboard, then we explain the major scientific objectives in Sec. 3, and the other scientific objectives in Sec. 4.

## 2. A Spacetime structure exploration plan in the earth-moon system

### 2.1. *The technology development in the clock and the gyposcope*

Recently, Space cold atomic clock (SCAC) had been test in the orbit[1], and ACES (Atomic Clock Ensemble in Space) also been installed on the ISS (International Space Station). An atomic clock with $10^{-18}$ instability on the ground had been about ten years[2,3]. Optical clock also arrive to high-accuracy[4].

In another side, the gyroscope from continuous cold-atom inertial sensor had reach 1 nrad/sec rotation stability[5]. Ring laser gyroscope have can detect earth tide and tilt detection[6]. Those technology provide the chance to check the relativity theory.

### 2.2. *Our Spacetime structure exploration plan in the earth-moon system*

Our plan is that the spacetime structure exploration in the earth-moon system by the Full Tensor Gradiometry (FTG) from the above mentioned thecniques inlcude the clock and gyroscope (more than 5 units), which focus on surveying the gravitational potential and gravitational first order redshift in the spacetime geometry of the earth-moon system. The satellite (or the detector) will sent to the Earth-Moon Lagrangian points which difference with Italy project [7–9] after finished relativistic geodetic mission.

And we will study the Psedo-Newtonian potenial in Kerr Spacetime like Paczyski-Wiita potential [10,11] et al. Although all Psedo-Newtonian potenial can back to PPN (Parameterized Post-Newtonian formalism) in some order, we will check it in the experiment. we also will check the effectness of the diffecence local quasi-inertial frame defined of PPN in the experiment.

Gyroscope in Local and nonlocal measurements of the Riemann tensor had study [12]. We will try to study the relation between the precision of the clock and gyroscope array and the large scale structure of spacetime, and the later with local and nonlocal measurements. We will try to find time dilation symmetry violations in the Gravitational secondary Red-shift in the data of the clock and the gyroscope.

## 3. The major scientific objectives

### 3.1. *Gravitational potential and Gravitational first order redshift for Relativitic geodesic*

Now atomic clocks is enough to measure relativity [2], many relativistic experiments with atomic clocks has been proposed [13]. A precision measurement of the gravitational red-shift by the interference of matter waves has been done [14], even a clock can directly linking time to a particle's mass [15].

Based on the sample relation between the gravitational potential and gravitational first order redshift in general relativity, many relativitic geodesic plan has been proposed, for example, A spaceborne gravity gradiometer concept based on cold atom interferometers for measuring Earth's gravity field [16]. Atomic clocks and gravity field determination for geodesy by many researcher [17,18]. In USA, many theory work [19–21] was done with the plan of NASA [22]. In German, the plan of gravitational clock compass [23] based on the early direction study of the curvature [24] was done. Compared with them, our theoretical basis is gravitoelectromagnetism analogy based on tidal tensor and the Terrae proper reference frame, and the instrument is FTG.

### 3.2. *The symmetry violations of Gravitational second order redshift*

After measure the gravitational first order red-shift[25], Jaffe and Vessot want to study the Second-Order gravitational redshift in the earth[26,27]. Then the symmetry violations of gravitational redshift is exist that was pointed out in the frame of parametrized post-Newtonian[28]. The similar result also had from the frame of gravitoelectromagnetism[29]. If the precision of the instrument is enough, we will try to find it from the data with the orbital raw data.

## 4. The other scientific objectives

### 4.1. *Gravitomagnetic effect in the clock and gyroscope*

Now many plan had been done for explore relativistic phenomena like LenseThirring (LT) effect and gravitational redshift et al. In clock, many gravitational redshift detecting plan for geodesy was proposed[2,13]. In gyroscope, there are cold atomic gyroscope[5] and superfluid gyroscope[30] for LT precession like the project of Gravty Probe B[31]. A multi-ring-laser gyroscope also designed for measuring gravitomagnetic effects[32]. In especial, OPTIS (`http://www.exphy.uni-duesseldorf.de/OPTIS/optis.html`) design the plan include the core technologies for OPTIS are optical cavities, highly stabilized lasers, capacitive gravitational reference sensors, dragfree control, ion clocks, frequency combs, and laser tracking systems for the experiments include Special Relativity, and General Relativity, and constancy of speed of light, and gravitational redshift, and LenseThirring effect et al.[33].

Recently, generalized gravitomagnetic clock effect was calculated for the GPS near the earth[34] after Mashoon give the gravitomagnetic clock effect for the circular orbits[35]. And some result shown it is in the order of $10^{-6}$ [36]. consider our instrument is FTG which difference with GNSS, and the orbit is in the large ellipse, we will try to find it from the data with the orbital raw data.

### 4.2. *Gravitational moment and wave detecting by the clock and atomic interferometer*

With the technology development in the clock which include cold atomic interferometric and optical frequency comb et al., and in the gyroscope which include laser gyroscopes and fiber optic gyroscopes based on the Sagnac effect and the matter wave gyroscopes et al., the plan of Atomic Gravitational wave Interferometric Sensor (AGIS) was proposed. A comparison between matter wave and light wave interferometers for the detection of gravitational waves had been done[37]. If our FTG instrument is well in the stability at long term, we will try to find the singal of gravitational wave from the data with the orbital raw data.

## 5. The Summary

Our plan is that using high-precision FTG based the atomic clock or (and) gyroscope to finishing relativistic geodetic mission and exploring spacetime geometry. About full tensor gravitational gradiometer (array) in measurement of gravitational theory and cosmology, we are applying the patent in China and in PCT (Patent Cooperation Treaty)[38–40].

The dimensionality of the quantum spacetime is often understood in terms of the spectral dimension; a different notion of dimensionality, the thermal dimension, has recently been proposed by some of us in Ref. 1. We showed through the study of specific models of quantum gravity that, in those cases where the spectral dimension has puzzling physical properties, the thermal dimension gives a different and more meaningful picture. In Ref. 2, we applied the statistical mechanics developed to define the thermal dimension to the study of the production of primordial cosmological scalar perturbations, assuming a running Newton constant and Rainbow Gravity. Here, we briefly review the main arguments and results of these studies.

## 1. Thermal dimension of quantum spacetime

In the last decade it has been found that many different quantum gravity models share the common feature of "dynamical dimensional reduction" of spacetime: the familiar four-dimensional picture of spacetime in the IR is replaced by a quantum picture with an effective number of spacetime dimensions smaller than four in the UV.

This phenomenon has been studied mostly in terms of the spectral dimension, that provides a valuable characterization of classical Riemannian geometries[3], but its proposed applicability to a quantum spacetime involves some adaptations that are arguably responsible for some of its inadequacies.

When the IR Hausdorff dimension of spacetime is $D+1$, and the Euclidean d'Alembertian of the theory is represented on momentum space as $\mathcal{C}_p^{Euc}(E,p)$, the spectral dimension is computed via $d_S(s) = -2\frac{d\ln P(s)}{d\ln s}$ where $P(s)$ is given by $P(s) \propto \int dE\, dp\, p^{D-1}\, e^{-s\,\mathcal{C}_p^{Euc}(E,p)}$. Reasons to be concerned can be found in the use done of Euclidean d'Alembertian (it is in fact well known that the Euclidean version of a quantum-gravity model can be profoundly different from the original model in Lorentzian spacetime[4]), in the role played by off-shell modes and in the

invariance of $P(s)$ under active diffeomorphisms on momentum space (an active diffeomorphism on momentum space amounts to an irrelevant change of integration variable for $P(s)$). Since an active diffeomorphism can map a given physical theory into a very different one, this degeneracy of the spectral dimension is worrisome.

While these concerns are very serious, it must be acknowledged that several analyses centered on the spectral dimension give rather meaningful results. Therefore, the guiding idea is that it is necessary to replace the spectral dimension with some other fully physical notion of dimensionality of a quantum spacetime, with the requirement that in most cases the new notion should agree with the spectral dimension. Only when the unphysical content of the spectral dimension plays a particularly significant role should the new notion differ significantly from the spectral dimension.

The guidance adopted in searching for such a new notion is the observation, reported in recent studies[5–8], that in some instances the Stefan-Boltzmann law and the equation of state (EOS) parameter give indications on the dimensionality of spacetime that are consistent with the spectral dimension. One can view the Stefan-Boltzmann law and EOS parameter as indicators of spacetime dimensionality since for a gas of radiation in a classical spacetime with $D+1$ dimensions they take the form $U \propto T^{D+1}$ and $w \equiv \frac{p}{\rho} = \frac{1}{D}$. These observations inspire the proposal of assigning a "thermal dimension" to a quantum spacetime.

Consider a class of generalized Hořava-Lifshitz (HL) scenarios[9,10]. These are cases where the momentum-space representation of the deformed d'Alembertian takes the form $\mathcal{C}_{\gamma_t\gamma_x}(E,p) = E^2 - p^2 + \ell_t^{2\gamma_t} E^{2(1+\gamma_t)} - \ell_x^{2\gamma_x} p^{2(1+\gamma_x)}$, where $E$ is the energy, $p$ is the modulus of the spatial momentum, $\gamma_t$ and $\gamma_x$ are dimensionless parameters, and $\ell_t$ and $\ell_x$ are parameters with dimension of length (usually assumed to be of the order of the Planck length). For this model it is known[10] that the UV value of the spectral dimension, obtained from the Euclidean version of the above d'Alembertian ($E^2 + p^2 + \ell_t^{2\gamma_t} E^{2(1+\gamma_t)} + \ell_x^{2\gamma_x} p^{2(1+\gamma_x)}$), is $d_S(0) = \frac{1}{1+\gamma_t} + \frac{D}{1+\gamma_x}$.

In deriving the thermal dimension for this case one can start from the logarithm of the thermodynamical partition function, written as

$$\log Q_{\gamma_t\gamma_x} = -\frac{2V}{(2\pi)^3} \int dE\, d^3p \left[ \delta(\mathcal{C}_{\gamma_t\gamma_x})\, \Theta(E) \cdot \right. \\ \left. \cdot\, 2E \log\left(1 - e^{-\beta E}\right) \right]. \tag{1}$$

where $\beta = \frac{1}{k_B T}$, and the delta function $\delta(\mathcal{C}_{\gamma_t\gamma_x})$ enforces the on-shell relation $\mathcal{C}_{\gamma_t\gamma_x} = 0$. From (1) one obtains the energy and pressure densities respectively as $\rho_{\gamma_t\gamma_x} \equiv -\frac{1}{V}\frac{\partial}{\partial\beta} \log Q_{\gamma_t\gamma_x}$ and $p_{\gamma_t\gamma_x} \equiv \frac{1}{\beta}\frac{\partial}{\partial V} \log Q_{\gamma_t\gamma_x}$. For the UV/high-temperature values of $\rho_{\gamma_t\gamma_x}$ and $w_{\gamma_t\gamma_x}$ one can easily establish the following behaviours at high temperature,

$$\rho_{\gamma_t\gamma_x} \propto T^{1+3\frac{1+\gamma_t}{1+\gamma_x}}\,, \quad w_{\gamma_t\gamma_x} = \frac{1+\gamma_x}{3(1+\gamma_t)}\,. \tag{2}$$

One sees that both of these results give a consistent prediction for the "thermal dimension" at high temperature, which is

$$d_T = 1 + 3\frac{1+\gamma_t}{1+\gamma_x}\,. \tag{3}$$

In the context of generalized HL scenarios it is simple to show (see Ref. 1 for more details) that while the spectral dimension is insensitive to the difference between active and passive diffeomorphisms on momentum space, the thermal dimension takes generally different values for different theories connected by an active diffeomorphism. Since physics is not invariant under such diffeomorphisms, this difference of sensitivity gives the thermal dimension a stronger discrimination power than the spectral dimension.

Another case which might deserve special interest from the quantum-gravity perspective, as stressed in Ref. 11, is that in which deformed d'Alembertian takes the form $\mathcal{C}_\gamma(E,p) = E^2 - p^2 - \ell^{2\gamma}\left(E^2-p^2\right)^{1+\gamma}$ . For this case one easily finds that the UV spectral dimension is $d_S(0) = \frac{4}{1+\gamma}$, but the fact that the UV dimensionality of spacetime depends on $\gamma$ is puzzling and points very clearly to the type of inadequacies of the spectral dimension previously mentioned. In fact, in the UV limit the parameter $\gamma$ has no implications for the on-shell/physical properties of the (massless) theory. In general, massless particles governed by $\mathcal{C}_\gamma$ will be on-shell only either when $E^2 = p^2$ or when $E^2 = p^2 + \frac{1}{\ell^2}$ , independently of the value of $\gamma$. Also, in the UV limit the two possibilities become indistinguishable, all particles are governed by $E \simeq p$ just like in any 4-dimensional spacetime. So without any need to resort to complicated analyses one knows that this theory in the UV limit must behave like a 4-dimensional theory, in contradiction with the mentioned result for the UV spectral dimension.

Indeed, exact computation confirms that the value of the thermal dimension is 4, as it is computed strictly on-shell. The disastrous failures of the spectral dimension in this case is to be attributed to a combination of its sensitivity to off-shell properties and its reliance on the Euclidean d'Alembertian. It is noteworthy that for the Euclidean d'Alembertian $\mathcal{C}_\gamma^{Euc} = E^2 + p^2 + \ell^{2\gamma}(E^2+p^2)^{1+\gamma}$ , in the UV limit one can neglect $E^2 + p^2$ with respect to $\ell^{2\gamma}(E^2+p^2)^{1+\gamma}$. Instead for on-shell modes of the original Lorentzian $\mathcal{C}_\gamma$ one can never neglect $E^2 - p^2$ with respect to $\ell^{2\gamma}(E^2-p^2)^{1+\gamma}$.

In summary, it should be evidently seen as advantageous for the thermal dimension the fact that it assigns different UV dimension to very different theories (connected by an active diffeomorphism) and not being dominated by off-shell modes.

## 2. Primordial perturbations in a rainbow universe with running Newton constant

It is interesting to investigate the implications that the proposed modified themrodynamics could have in certain models of primordial Universe. In fact, recent

results suggest that the properties of primordial cosmological fluctuations might be a consequence of quantum-gravitational effects, which are relevant in the early universe[12,13], with no need for inflation. In particular it has been shown[12,14–18] that a scale invariant power spectrum can be obtained in those theories for which the dimension of spacetime runs to 2. These results rely on rigid assumptions[a] that are can be relaxed in order to find a mechanism that would produce the observed small departure from exact scale invariance[2].

We assume that gravity is described by an energy-dependent metric as proposed in Ref. 19, an energy-dependent Newton constant[b] and we consider both perturbations of quantum origin for a vacuum state and perturbations that are originated in a thermal state[24–28]. In the latter case it is assumed that the universe is filled with radiation and that both the background and the fluctuations are thermalized, so that they share the same (modified) thermodynamical properties[29].

For a deformed dispersion relation $E^2 = p^2(1 + (\ell p)^\gamma)$ the associated rainbow metric is $ds^2 = dt^2 - \frac{a^2(t)}{1+(\ell p)^\gamma}\delta_{ij}dx^i dx^j$. After lengthy but straightforward computations[2] one finds the evolution equation for perturbations modes $v$

$$v'' - \left(\left(\ell\frac{k}{a}\right)^{2\gamma} k^2 + \frac{a''}{a}\right) v = 0\,. \tag{4}$$

where $\frac{d}{d\eta} \equiv a\frac{d}{dt}$ and $k = ap$ is the comoving momentum. If the Newton constant has a power-law dependence on energy in the UV regime, $G(E) = \ell^2(\ell E)^\alpha \sim \ell^2\left(\frac{\ell k}{a}\right)^{(1+\gamma)\alpha}$, then $\alpha$ must satisfy

$$-\frac{2+\gamma}{1+\gamma} < \alpha < \frac{\gamma-2}{1+\gamma} \tag{5}$$

in order to solve the horizon paradox and having cosmological expansion (with positive conformal time $\eta$). The spectral index of vacuum perturbations is

$$n_s^V - 1 = \frac{(\gamma+4)(2-\gamma)}{2-\gamma+\alpha(1+\gamma)}\,. \tag{6}$$

Clearly $\gamma = 2$ gives a scale invariant power spectrum for any value of $\alpha$ allowed by the constraint[c] (5). One can require $n_s^V$ to match the present observational constraint from Planck[30] $n_s^V = 0.968 \pm 0.006$, obtaining the allowed range of values shown in Fig. 1 of Ref. 2. The values of $\alpha$ that are selected by observational constraints are all negative, suggesting a vanishing Newton constant in the deep UV regime. On the other hand, from the modified Hubble equation[2] one can see that observational constraints allow for both an accelerated or decelerated expansion.

[a]Such as that the second order action for perturbations is the one of Einstein gravity and that the perturbations are produced in a quantum vacuum state.

[b]This is motivated by results in Hořava-Lifshitz gravity and in Asymptotic Safety[20–23], where the Newton constant tends to zero at super-Planckian energies.

[c]The fact that scale invariance is achieved independently of how the Newton constant scales with energy is due to the time perturbations being already scale-invariant and proportional to the scale factor $a$ inside the horizon.

Including the thermal contribution, the spectral index of perturbations becomes

$$n_s^T = n_s^V - 1 - \gamma. \tag{7}$$

Using the value of the vacuum spectral index found in the previous section, Eq. (6), the thermal spectral index can be written as

$$n_s^T = \frac{4(2-\gamma) - \alpha\gamma\,(1+\gamma)}{2-\gamma+\alpha(1+\gamma)}\,. \tag{8}$$

For $\alpha \neq 0$, asking that the perturbations are scale invariant leads to a constraint linking $\alpha$ and $\gamma$. Asking in addition that the horizon problem is solved, Eq. (5), introduces an inferior bound $\gamma > 2$ on the allowed values of $\gamma$. Then the values of $\alpha$ that are compatible with scale invariance and which allow to solve the horizon problem fall in the range $-1/4 < \alpha < 0$. It is also possible to match the spectral index to the Planck observed value giving the constraints shown in Fig. 2 of Ref. 2. According to he modified Hubble equation[2], these observational constraint on $\alpha$ and $\gamma$ only allow for a decelerating expansion of the universe.

## 3. Concluding remarks

The exciting realization that the UV dimension of spacetime might be different from its IR dimension adds significance to the old challenge of describing the dimension of a quantum spacetime and it is argued that it is crucial to link this issue to observable properties. The notion of thermal dimension reviewed here is free from the shortcomings of the spectral dimension, since it relies on the analysis of observable thermodynamical properties of radiation in the quantum spacetime. We showed how it is not only physical but also particularly useful, at least for studies of the early universe, which is anyway the context where the UV dimension of spacetime should find its most significant applications[12,17].

We saw how a rainbow universe with running Newton constant can accommodate primordial perturbations whose spectral index matches current constraints, without relying on inflation to solve the horizon problem. Crucially, it has been assumed a power-law dependence of the Newton constant on energy and that the background satisfies the thermodynamical relations peculiar to radiation subject to deformed dispersion relations. For both kinds of initial conditions for the perturbations (vacuum and thermal) the running of the Newton constant is essential in achieving a viable picture. In particular, the Newton constant is constrained to be decreasing with energy in the ultraviolet regime. This is consistent with intuition from quantum gravity theories, such as Hořava-Lifshitz gravity and Asymptotic safety. It also resonates with the conjecture put forward in Ref. 17.

# Counting initial conditions and degrees of freedom in nonlocal gravity

Gianluca Calcagni

*Instituto de Estructura de la Materia, CSIC, Serrano 121, 28006 Madrid, Spain*
*E-mail: g.calcagni@csic.es*

Nonlocal quantum gravity is a class of fundamental theories whose classical and quantum dynamics is specified by "form factors", operators with infinitely many derivatives. After briefly reviewing this paradigm and its role in the resolution of big-bang and black-hole singularities, we count the number of nonpertubative field degrees of freedom as well as the number of initial conditions to be specified to solve the Cauchy problem. In particular, in four dimensions and for the string-related form factor, there are 8 degrees of freedom (2 graviton polarization modes, which propagate, and 6 nonpropagating rank-2 tensor modes) and 4 initial conditions. The method to obtain this result is illustrated for the case of a nonlocal scalar field.

## 1. Introduction

"Nonlocal quantum gravity" is an umbrella name including at least two different settings. The first group, which includes general relativity, consists in classically local gravitational theories which receive quantum corrections such that the effective one-loop action is nonlocal (i.e., it is made of operators with infinitely many derivatives). In this brief review of recent results, we will confine ourselves to the second meaning of the term, where nonlocality is fundamentally present already at the classical level and, thanks to the suppression of the graviton propagator in the ultraviolet (UV), the theory is renormalizable or finite. Nowadays, nonlocal quantum gravity has achieved a high degree of independence both from these antecedents and from other proposals, to the point where it can be considered as one of the most promising and accessible candidates for a theory where the gravitational force consistently obeys the laws of quantum mechanics. In particular, there exist several renormalization results, both at finite order and to all orders in a perturbative Feynman-diagram expansion, which showed that the good UV properties guessed at the level of power-counting indeed hold rigorously (e.g., Ref. 1).

Despite the investment of much effort in taming fundamental nonlocality, several questions remain open to date: (i) Is the Cauchy problem well-defined? (ii) If so, how many initial conditions must one specify for a solution? (iii) How many degrees of freedom are there? (iv) How to construct nontrivial solutions? (iv) Is causality violated? (v) Are singularities resolved at the classical or quantum level?

Here we will give the following answers to some of these issues: (i) Yes, for the form factors appearing in fundamental theories (not for all conceivable form factors). (ii) Two or higher for a scalar field theory and four or higher for gravity (depending on the form factor), but finite. (iii) Eight (in $D = 4$ dimensions), but only the graviton modes propagate. (iv) Via the diffusion method. Let us now examine where these cryptic responses come from. The main results can be found in Refs. 2, 3.

## 2. Action and form factors

The classical fundamental (not effective) action of the theory is

$$S = \frac{1}{2\kappa^2}\int d^D x\sqrt{-g}\,[R + G_{\mu\nu}\gamma(\Box)R^{\mu\nu}]\ , \tag{1}$$

where $G_{\mu\nu}$ is the Einstein tensor and $\gamma(\Box)$ is a weakly or quasi-polynomial nonlocal form factor. Formally, $\gamma$ is an analytic function that can be expressed as an infinite series with infinite convergence radius, $\gamma(\Box) = \sum_n c_n\Box^n$, although this expansion does not actually span the whole space of solutions in general.[4] As long as we require good properties at the quantum level (in particular, locality of the counterterms), the coefficients $c_n$ can be selected in a subclass of entire functions having special asymptotic properties.[1,5–9] There are several form factors that preserve perturbative unitarity in (1) (see Table 1). In general, we can parametrized $\gamma$ as

$$\gamma(\Box) = \frac{e^{H(\Box)} - 1}{\Box}\,, \qquad H(\Box) := \alpha\int_0^{P(\Box)} d\omega\,\frac{1 - f(\omega)}{\omega}\,, \tag{2}$$

where $H(\Box)$ depends on the dimensionless combination $l^2\Box$ and $l$ is a fixed length scale. The profile $H(\Box)$ can be defined through an integral where $\alpha > 0$ is real and $P(\Box)$ is a generic function of $l^2\Box$. The parameter $\alpha$ will not play any important role in what follows, but we included it to reproduce some form factors in the literature.

Table 1. Form factors in nonlocal gravity.

| $H(\Box)$ | $P(\Box)$ | $f(\omega)$ | Form factor name |
|---|---|---|---|
| $H^{\rm pol}(\Box) := \alpha\{\ln P(\Box) + \Gamma[0, P(\Box)] + \gamma_{\rm E}\}$ | $-l^2\Box$<br>$O(\Box^n)$ | $e^{-\omega}$ | Kuz'min[6]<br>Tomboulis[5,8] |
| $H^{\rm exp}(\Box) := \alpha P(\Box)$ | $-l^2\Box$<br>$l^4\Box^2$ | $1 - \omega$ | string-related[10]<br>Krasnikov[11] |

All these form factors share the common property of blowing up in the UV in momentum space. In general, this implies asymptotic freedom, i.e., interactions are subdominant at short scales.

## 3. The wild beast of nonlocality

Consider the scalar field theory on Minkowski spacetime

$$S_\phi = \int d^D x\,\left[\frac{1}{2}\phi\Box\gamma(\Box)\phi - V(\phi)\right]\ , \tag{3}$$

where $V$ is an interaction potential. How could one explore its classical dynamics?

As a first attempt, one can try to truncate the nonlocal operator up to some finite order, $\gamma(\Box) \simeq \sum_{n=0}^{N} c_n\Box^n = c_0 + c_1\Box + \cdots + c_N\Box^N$. However, the resulting

finite-order dynamics is physically inequivalent to the original one and there is no smooth transition between them. The free ($V = 0$) case illustrates the point well:

$$\begin{aligned} \gamma(\Box) = e^{-l^2\Box} &\Rightarrow \text{dispersion relation:} \quad -k^2 e^{l^2 k^2}\phi_k = 0 \\ &\Rightarrow \text{propagator:} \quad -\frac{e^{-l^2k^2}}{k^2} \quad \Rightarrow \quad 1 \text{ DOF}\,, \qquad (4) \\ g(\Box) \simeq 1 - l^2\Box &\Rightarrow \text{dispersion relation:} \quad -k^2(1+l^2k^2)\phi_k = 0 \\ &\Rightarrow \text{propagator:} \quad -\frac{1}{k^2} + \frac{1}{l^{-2}+k^2} \quad \Rightarrow \quad 2 \text{ DOF, } 1 \text{ ghost}\,. \qquad (5) \end{aligned}$$

This example provides a good occasion to comment also on how to determine the number of field degrees of freedom (DOF). In the free case, there is only one double pole, corresponding to 1 DOF. This can also be seen by making a nonlocal field redefinition $\tilde{\phi} := \sqrt{\gamma(\Box)}\phi$, so that the free Lagrangian reads $\tilde{\mathcal{L}}_\phi = (1/2)\tilde{\phi}\Box\tilde{\phi}$. This operation is safe if $\gamma$ is an entire function; if $\gamma$ is not entire (for instance, $\gamma = \Box^{-n}$), then the field redefinition may result in the elimination of physical modes or the introduction of spurious ones. The Lagrangian $\tilde{\mathcal{L}}_\phi$ is second-order in spacetime derivatives and features one local field $\tilde{\phi}$, hence there is only 1 DOF and solutions are specified by two initial conditions. However, when $V$ is nonlinear of cubic or higher order the field redefinition does not absorb nonlocality completely and one is left with a possibly intractable problem, with extra nonperturbative degrees of freedom[12] and an infinite tower of Ostrogradsky modes.

In fact, the Cauchy problem can be naïvely stated as the assignment of an infinite number of values at some initial time $t_{\rm i}$,

$$\phi(t_{\rm i}),\ \dot{\phi}(t_{\rm i}),\ \ddot{\phi}(t_{\rm i}),\ \dddot{\phi}(t_{\rm i}),\ \ldots\,. \qquad (6)$$

Thus, paradoxically, we can solve the dynamics only if we already know the solution:[13]

$$\phi(t) = \sum_{n=0}^{+\infty} \frac{\phi^{(n)}(t_{\rm i})}{n!}(t-t_{\rm i})^n\,. \qquad (7)$$

If we do not specify all the initial conditions, the solution may be non-unique.

Finally, a word on how to rewrite nonlocalities as a convolution. It is well known that infinitely many derivatives can be traded for integrated kernel functions:

$$\gamma(\Box)\,\phi(x) = \int d^D y\, F(y-x)\,\phi(y)\,. \qquad (8)$$

However, by itself this operator bears no practical advantage. Hiding infinitely many derivatives into integrals does not help in solving the Cauchy problem, *unless* the kernel $F$ could be found by solving some auxiliary, finite-order differential equations. This is precisely the leverage point we will focus on.

## 4. Diffusion method

The diffusion method was proposed some years ago[4,12,14,15] to solve nonlocal scalar field theories with exponential form factor (4), a very specific nonlocal operator that arises in string theory. By trading nonlocal operators with shifts in a fictitious extra direction $r$, the method allows one to count the number of DOF and of initial conditions (which are finite) and to find nonperturbative solutions. All these features can be easily illustrated by the scalar field theory

$$S_\phi = \int d^D x \, \left[ \frac{1}{2} \phi(x) \Box e^{-l^2 \Box} \phi(x) - V(\phi) \right] , \tag{9}$$

where $l^2$ is a constant. The equation of motion is

$$\Box e^{-l^2 \Box} \phi - V'(\phi) = 0 \, . \tag{10}$$

Define now a *localized system*, *a priori* independent of (9), living in $D+1$ dimensions and featuring two scalars $\Phi(r,x)$ and $\chi(r,x)$:

$$\mathcal{S}[\Phi,\chi] = \int d^D x \, dr \, (\mathcal{L}_\Phi + \mathcal{L}_\chi) \, , \tag{11}$$

$$\mathcal{L}_\Phi = \frac{1}{2} \Phi(r,x) \Box \Phi(r - l^2, x) - V[\Phi(r,x)] \, , \tag{12}$$

$$\mathcal{L}_\chi = \frac{1}{2} \int_0^{l^2} dq \, \chi(r-q,x)(\partial_{r'} - \Box) \Phi(r',x), \qquad r' = r + q - l^2. \tag{13}$$

The equations of motion are

$$0 = (\partial_r - \Box)\Phi(r,x), \qquad 0 = (\partial_r - \Box)\chi(r,x), \tag{14}$$

$$0 = \frac{1}{2}[\Box\Phi(r-l^2,x) + \chi(r-l^2,x)] + \frac{1}{2}[\Box\Phi(r+l^2) - \chi(r+l^2)] - V'[\Phi(r,x)]. \tag{15}$$

The first line is telling us that the fields are diffusing along the extra direction. At this point, one assumes that there exists a constant $\beta$ such that the equation of motion (15) coincides with the one of the nonlocal system (9), Equation (10), on the slice $r = \beta l^2$ (the *physical slice*). This is achieved provided the following conditions hold:

$$\Phi(\beta l^2, x) = \phi(x), \qquad \chi(\beta l^2, x) = \Box \Phi(\beta l^2, x) \, . \tag{16}$$

The conclusion is that the localized system has 4 initial conditions $\Phi(r, t_\mathrm{i}, \mathbf{x})$, $\dot{\Phi}(r, t_\mathrm{i}, \mathbf{x})$, $\chi(r, t_\mathrm{i}, \mathbf{x})$, $\dot{\chi}(r, t_\mathrm{i}, \mathbf{x})$ and 2 field DOF $\Phi$ and $\chi$. On the physical slice, because of (16) the number of DOF reduces to 1 and the initial conditions are on the field $\phi$ and its first two derivatives (the initial conditions of $\chi$ are not independent):

$$\phi(t_\mathrm{i}, \mathbf{x}), \quad \dot{\phi}(t_\mathrm{i}, \mathbf{x}) \, . \tag{17}$$

With traditional methods, only *perturbative* solutions of the linearized EOM or what we call "static" (in the extra direction $r$) solutions are available to inspection. By this name, we mean solutions where nonlocality is, in one way or

another, trivialized, such as when $\Box\phi = \lambda\phi$. In contrast, the diffusion method gets access to nonperturbative solutions valid in the presence of nonlinear interactions and nontrivial nonlocality. These solutions are, in general, only approximate, and are found by searching for the value of $\beta$ minimizing the equations of motion[4,15,16]. Examples are: $\phi(t) = \text{Kummer}(t)$ on a Friedmann–Robertson–Walker (FRW) background; rolling tachyon $\phi(t) = \sum_n a_n e^{nt}$ in string field theory, $V = \phi^3$; kink $\phi(x) = \text{erf}(x)$, $V = \phi^3$; $\phi(t) = \gamma(\alpha, t)$ (incomplete gamma function), $V = \phi^n$ on FRW background; instanton $\phi(x) = \text{erf}(x)$, $V = \phi^4$ (brane tension recovered at 99.8% level); kink $\phi(x) = \text{erf}(x)$, $V = (e^{\Box}\phi^2)^2$; various profiles $\phi(t)$ in bouncing and singular cosmologies.

The main reason why diffusion works is that nonlocal operators are represented as a shift in an extra direction rather than as an infinite sum of derivatives. The latter representation does not span the whole space of solutions, as one can see by a toy example.[4] Consider a $D = 4$ FRW background with Hubble expansion $H = \dot{a}/a = H_0/t$, the Laplace–Beltrami operator $\Box = -\partial_t^2 - 3H\partial_t$, and the homogeneous power-law profile $\phi(t) = t^p$. If we try to calculate the object $e^{r\Box}\phi$ as a series, the result diverges: $e^{r\Box}\phi = \sum_{n=0}^{\infty}(r\Box)^n\phi/n! = \infty$. On the other hand, with the diffusion method one interprets $\phi(t) = \Phi(t, 0)$ as the initial condition in the diffusion scale $r$ and the profile $e^{r\Box}\Phi(t, 0) = \text{Kummer}(t, r)$ is a linear superposition of well-defined Kummer functions.

## 5. Initial conditions and degrees of freedom

The diffusion method has been extended to the case of gravity in Ref. 2 for the string-related and Krasnikov exponential form factors and in Ref. 3 for the asymptotically polynomial (Kuz'min and Tomboulis–Modesto) form factors. The reader can consult those papers for technical details; here we only quote the bottom line, which is that, for the string-related form factor, the localized system associated with (1) has 6 initial conditions $g_{\mu\nu}(t_\text{i}, \mathbf{x})$, $\dot{g}_{\mu\nu}(t_\text{i}, \mathbf{x})$, $\Phi_{\mu\nu}(r, t_\text{i}, \mathbf{x})$, $\dot{\Phi}_{\mu\nu}(r, t_\text{i}, \mathbf{x})$, $\chi_{\mu\nu}(r, t_\text{i}, \mathbf{x})$, $\dot{\chi}_{\mu\nu}(r, t_\text{i}, \mathbf{x})$, two for each rank-2 symmetric tensor field (the metric $g_{\mu\nu}$ and the tensors $\Phi_{\mu\nu}$ and $\chi_{\mu\nu}$). Since, on the physical slice, $\Phi_{\mu\nu}(\beta l^2, x) = G_{\mu\nu}$ and $\chi_{\mu\nu}(\beta l^2, x) = R_{\mu\nu}$, the initial conditions on these fields are not independent. However, while $\chi_{\mu\nu}$ is an auxiliary field of the localized system and depends on the dynamical degrees of freedom of the nonlocal system, $\Phi_{\mu\nu}$ is an auxiliary field already at the level of nonlocal dynamics and it encodes the two derivatives hidden in the Ricci tensor and scalar. Therefore, the solutions of the nonlocal system (1) are characterized by 4 initial conditions:

$$g_{\mu\nu}(t_\text{i}, \mathbf{x}), \quad \dot{g}_{\mu\nu}(t_\text{i}, \mathbf{x}), \quad \ddot{g}_{\mu\nu}(t_\text{i}, \mathbf{x}), \quad \dddot{g}_{\mu\nu}(t_\text{i}, \mathbf{x})\,. \tag{18}$$

Regarding the degrees of freedom, the counting for the exponential form factor is the following. (i) Graviton $g_{\mu\nu}$: symmetric $D \times D$ matrix with $D(D+1)/2$ independent entries, to which one subtracts $D$ Bianchi identities $\nabla^\mu G_{\mu\nu} = 0$ and $D$ diffeomorphisms (the theory is fully diffeomorphism invariant). Total: $D(D-3)/2$.

In $D = 4$, there are 2 degrees of freedom. (ii) Tensor $\phi_{\mu\nu}$: symmetric $D \times D$ matrix with $D(D+1)/2$ independent entries, to which one subtracts $D$ transverse conditions $\nabla^\mu \phi_{\mu\nu} = 0$. Total: $D(D-1)/2$. In $D = 4$, there are 6 degrees of freedom. Similar results hold for the asymptotically polynomial Kuz'min form factor, although in that case the diffusion method requires more elaboration.[3]

The grand total is $D(D-2)$. In $D = 4$, there are 8 DOF. Two of them (the graviton) are visible already at the perturbative level, while the other 6 are of nonperturbative origin. Their role in phenomenology[3] has been determined only recently.[17] It was shown that the extra $D(D-1)/2$ tensor degrees of freedom do not propagate on Ricci-flat backgrounds, at any perturbative order.

## 6. Conclusions

The number of degrees of freedom and of initial conditions of fundamentally nonlocal gravitational theories with "well-behaved" form factors is finite. In the diffusion method, infinitely many initial conditions are traded for boundary conditions in an extra direction. Solving the diffusion equation and algebraic relations is way simpler than solving nonlocal equations. By making sense of the Cauchy problem in this class of theories, the doors of classical top-down phenomenology may open up.

# Emerging Hawking-like radiation in gravitational scattering beyond the Planck scale

Dimitri Colferai

*Department of Physics and Astronomy, University of Florence, Sesto Fiorentino, 50019, Italy*
**E-mail: colferai@fi.infn.it*

We generalize the semiclassical treatment of graviton radiation to gravitational scattering at very large energies $E \gg M_P$ and finite scattering angles $\theta_s$, so as to approach the collapse regime. Our basic tool is the extension of the recently proposed, unified form of radiation to the Amati-Ciafaloni-Veneziano reduced-action model. By resumming eikonal scattering diagrams, we are able to derive the corresponding (unitary) coherent-state operator. The resulting graviton spectrum, tuned on the gravitational radius $R$, fully agrees with previous calculations for small angles $\theta_s \ll 1$ but, for sizeable angles $\theta_s \sim 1$ acquires an exponential cutoff of the large frequency region ($\omega > 1/R$), due to energy conservation, so as to emit a finite fraction of the total energy. In the approach-to-collapse regime we find a radiation enhancement due to large tidal forces, so that the whole energy is radiated off, with a large multiplicity $\langle N \rangle \sim Gs \gg 1$ and a well-defined frequency cutoff of order $1/R$. The latter corresponds to the Hawking temperature for a black hole of mass somewhat smaller than $E$.

*Keywords*: Gravitational scattering; Gravitational radiation; Quantum gravity.

## 1. Introduction

One of the main unsolved problems in physics is to reconcile quantum mechanics (QM) with general relativity (GR). Its resolution is a formidable task, but important informations can be obtained by investigating some processes lying at the interface between QM and GR with the theories and tools at our disposal.

This work aims at studying gravitational scattering of particles at very high energies $E \gg M_p$ beyond the Planck scale, in order to investigate graviton bremmsstrahlung and possibly macroscopic black-hole (BH) formation and evaporation at (semiclassical) quantum level, and therefore to shed light on the so-called "information paradox". What we would like to understand is whether a semiclassical picture of collapse emerges from the quantum theory, or if something different happens.

In this talk I present a model that describes gravitational processes in trans-planckian particle collisions. I shall show you that a quantum description of particle scattering at extreme energies gives rise to graviton radiation

- whose properties are similar to Hawking radiation, thus suggesting a sort of gravitational collapse.
- but can still be described by a unitary S-matrix, thus pointing towards a resolution of the information paradox.

## 2. The Eikonal Model

Following the pioneering works of Amati-Ciafaloni-Veneziano (ACV)[1] and others, we consider two massless particles (which could be strings) colliding at center of mass energy much larger than the Planck scale $2E = \sqrt{s} \gg M_P$ with some impact parameter $b$. Such a simple initial state allows us to use the formalism of QM, while the condition on the energy should imply the formation of a macroscopic BH of radius $R = 4GE$, according to GR.

In this high-energy regime the adimensional parameter $\alpha_G \equiv Gs/\hbar \gg 1$ is very large and plays the role of effective gravitational coupling. It also measures the typical action of such processes, in units of $\hbar$.

Actually, we are interested in the semiclassical regime where both $R, b \gg \lambda_P, \lambda_s$ (the latter being the Planck and string lengths, respectively).

### 2.1. *Elastic scattering*

When $b \gg R$, scattering is essentially elastic. Let us consider the expansion of the elastic amplitude in terms of string diagrams. In the high-energy limit $s \gg |t|$ and in the semiclassical regime $R, b \gg l_s$, the $N$-loop amplitude is factorized in the convolution of $N$ single-graviton-exchange amplitudes between the colliding particles, represented by ladder-like effective diagrams (Fig. 1(a)).

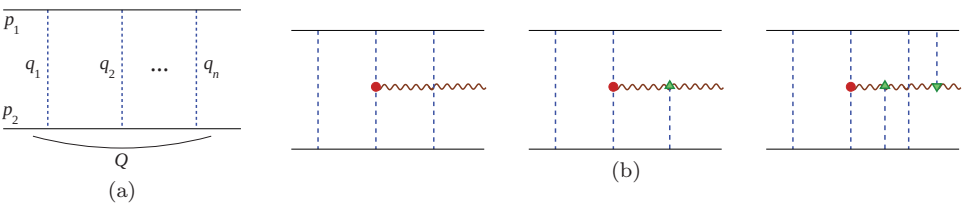

Fig. 1. Leading eikonal diagrams: (a) elastic scattering; (b) graviton emission and rescattering. The red disk represents the Lipatov vertex.

Such convolution in transverse momentum can be diagonalized by a Fourier transform in impact parameter space, and the ladder diagrams can be resummed in exponential series, yielding the elastic $S$-matrix in eikonal form, $S = \mathrm{e}^{\mathrm{i}2\delta(b,s)}$. The quantity $\delta(b,s) \equiv Gs\Delta(b) = Gs\log(L/b)$ can be interpreted as the (very large) phase shift in potential scattering. Here $L$ is an IR cutoff needed to regularize the Coulomb-like infinite phase shift which occurs in long-range interactions like gravity.

Note that the phase shift is real in this eikonal approximation, therefore the $S$-matrix is unitary. From the phase shift one can compute various observables, like the deflection angle, proportional to the gradient of the phase shift. One finds perfect agreement with the Einstein deflection angle $\theta_s = 2R/b$.

### 2.2. *Graviton emission*

Graviton emission at high-energy (Regge kinematics) is described by the so-called effective Lipatov vertex[2] (Fig. 1(b)), which is accurate in the region where the graviton emission angle $\theta$ is much larger than the deflection angle $\theta_s$ of the incoming particles. However such vertex is inaccurate when $\theta \sim \theta_s$. In this case, the emission amplitude for soft gravitons whose energy $\omega \ll E$ is well described by the soft-graviton emission theorem in terms of the Weinberg current[3]. It turns out that, for spin-2 particles, a very simple and elegant unifying amplitude can be derived which interpolates both angular regimes for all the relevant graviton energies, even $\omega \gg M_P$, provided $\omega \ll E$.

In addition we have to take into account the so-called rescattering diagrams[1], which describe the gravitational interaction of the radiated gravitons with the original sources, as shown in the last two diagrams of Fig. 1(b).

By neglecting correlations such as emissions from the same rung, we were able to resum all diagrams of Fig. 1(b) and we obtained a remarkably simple result[4]:

$$\mathcal{M}_{2\to 2+N} = \mathrm{e}^{2\mathrm{i}\delta(\boldsymbol{b},s)} \prod_{j=1}^{N} \mathfrak{M}_{\lambda_j}(\boldsymbol{b},\omega_j,\boldsymbol{q}_j) \times \left[1 + \mathcal{O}\left(\omega_j^2/E^2\right)\right] \tag{1}$$

$$\mathfrak{M}_\lambda(\boldsymbol{b},\omega,\boldsymbol{q}) = \sqrt{Gs}\frac{R}{\pi}\mathrm{e}^{\mathrm{i}\lambda\phi_{\boldsymbol{q}}} \int \frac{\mathrm{d}^2\boldsymbol{x}}{2\pi|\boldsymbol{x}|^2\mathrm{e}^{\mathrm{i}\lambda\phi_{\boldsymbol{x}}}}\, \mathrm{e}^{\mathrm{i}\boldsymbol{q}\cdot\boldsymbol{x}} \frac{\mathrm{e}^{2\mathrm{i}\omega R\Phi_B(\boldsymbol{x})} - \mathrm{e}^{2\mathrm{i}\omega R\Phi_A(\boldsymbol{x})}}{2\mathrm{i}\omega R} \tag{2}$$

$$\Phi_A(\boldsymbol{x}) \equiv \frac{E}{\omega}\left[\Delta(\boldsymbol{b} - \tfrac{\omega}{E}\boldsymbol{x}) - \Delta(\boldsymbol{b})\right], \qquad \Phi_B(\boldsymbol{x}) \equiv \left[\Delta(\boldsymbol{b}-\boldsymbol{x}) - \Delta(\boldsymbol{b})\right] \tag{3}$$

In words, the total emission amplitude is given by the elastic amplitude times an emission factor $\mathfrak{M}$ for each emitted gravition. $\mathfrak{M}$ represents the basic object for the description of graviton radiation.

Soft infrared divergencies coming from phase-space integrations of emitted soft gluons are cancelled by virtual correction, that we incorporate by means of the Weinberg method[3], which amounts to write the final state of graviton in Fock space as a coherent state operator $S$ acting on the vacuum with creation (real emission) and destruction (virtual corrections) operators:

$$S = \mathrm{e}^{2\mathrm{i}\delta} \exp\left\{\int \frac{\mathrm{d}^3q}{\sqrt{2\omega}}\, 2\mathrm{i} \sum_\lambda \left[\mathfrak{M}_\lambda a_\lambda^\dagger(q) + \mathfrak{M}_\lambda^* a_\lambda(q)\right]\right\} \tag{4}$$

We are therefore able to construct an explicitly unitary $S$ matrix for particle scattering and associated bremmsstrahlung. From Eq. (4) we can compute the energy spectrum of graviton radiation $\mathrm{d}E^{\mathrm{GW}}/\mathrm{d}\omega$ which is given by $2\omega|\mathfrak{M}|^2$, integrated over all angular directions. The result is depicted in fig. Fig. 2(a). We notice that the spectrum at low frequencies tends to a constant, in agreement with the zero-frequency-limit[5].

It then shows a $\log(1/\omega)$ behaviour in the intermediate range $1/b < \omega < 1/R$, while for $\omega > 1/R$ the spectrum decreases as $1/\omega$, almost independently of the impact parameter $b$, i.e., of the deflection angle $\theta_s$ of the hard particles. Note

that $R$ increases with energy $E$. This means that if we increase the energy of the process, the typical frequencies of the radiation decrease, in a way reminiscent of how Hawking radiation depends upon the BH mass.

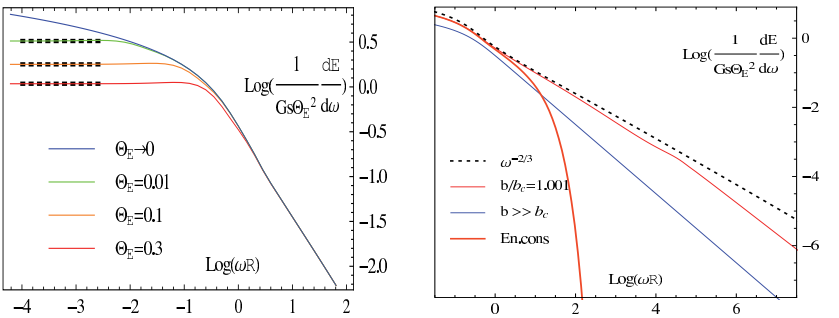

Fig. 2. Rescaled frequency spectrum of graviton radiation. (a) Spectrum in the leading eikonal approximation ($b \gg R$) for various values of $\theta_s$; the black dashes on the left represent the zero-frequency limit. (b) Resummed spectrum with subleading contribution at $b \sim b_c \sim R$, showing the intermediate enhanced region and the exponential fall-off when including energy conservation.

Remarkably, this result agrees with the classical limit ($\hbar\omega/E \to 0$) frequency spectrum of Ref. 6. Of course, in our framework we can compute also the quantum corrections.

## 3. Strong Gravity Regime

By decreasing the impact parameter $b$ towards the gravitational radius $R$, we enter the strong gravity regime, the one we are really interested in. In this regime we have to consider subleading corrections.

### 3.1. *Elastic scattering*

ACV were able to identify and resum also the class of subleading diagrams, the so-called H diagrams[7]. These are diagrams with a trilinear interaction (the Lipatov vertex) which is responsible for graviton emissions from exchanged gravitons.

As a consequence, a very interesting feature appears: the phase shift $\delta(b, s)$ acquires an imaginary part for impact parameters $b < b_c \simeq 1.6R$ so that the elastic $S$-matrix is suppressed. The question then arises: is this unitarity deficit in the elastic channel compensated by inelastic graviton production? Or is this critical value a signal of gravitational collapse? Let us note that the unitarity deficit has a fractional critical exponent $= 3/2$, resembling a sort of phase transition.

### 3.2. *Graviton emission*

By including graviton production from the multi-H diagrams we argue that the resummed emission amplitude maintains the form of Eq. (1) by replacing the leading phase shift $\delta(b,s)$ with the resummed one. For $b \to b_c^+$ the non-analytic behaviour of $\delta(b)$ severely affects the energy spectrum. In particular, for $\omega > 1/R$ there is an intermediate region where the frequency spectrum decreases less rapidly than $1/\omega$, actually $\omega^{-2/3}$ (Fig. 2(b)), implying a much higher radiation due to strong tidal forces[8].

### 3.3. *Energy Conservation*

Because of the logarithmic behaviour of $\mathrm{d}E^{GW} \sim Gs\theta_s^2 \mathrm{d}\omega/\omega$, and also because of the enhanced emission of radiation at large angles, it is mandatory to take into account energy conservation, i.e., to require that the energy carried by emitted gravitions be less than the total CM energy.

Following the proposal of Ref. 9, we impose energy conservation event by event, by requiring $\sum_j \omega_j < E$ in each hemisphere, and extending this bound to virtual corrections on the basis of AGK cutting rules[10]. Without entering here into technical details, such procedure amounts to multiply each amplitude by $\Theta(E - \sum_j \omega_j)$ and maintaining phase coherence them. By a saddle point evaluation of the usual integral representation of the $\Theta$-function one can compute the radiated energy distribution[8]. We observe that, while $b$ approaches the critical value $b_c = 1.6\,R$, the energy distribution shows an intermediate regime where it is enhanced by tidal forces and decreases only as $\sim \omega^{-2/3}$, before the eventual exponential decrease $\sim \mathrm{e}^{-\omega/T}$ at large $\omega$'s. Such exponential behaviour is typical of a thermal radiation. But here the radiation is coherent since the $S$ matrix is unitary. The "quasi-temperature" parameter $T$ is of order of the Hawking temperature $T_H = 1/(4\pi R)$ for $b \to b_c$: $T \simeq 0.8/R$. In particular it decreases with increasing energy of the collision.

## 4. Conclusions

To summarize, we claim we have a reliable model of gravity which allows us to compute graviton interactions and radiation in transplanckian collisions.

Within this model, we now see the role of the gravitational radius as the inverse of the characteristic frequency for all values of CM energies and impact parameters.

When the impact parameter $b$ is smaller than the gravitational radius $R$, tidal forces cause a dramatic enhancement of graviton radiation and all energy is radiated off. By taking into account energy-conservation constraints, we obtain a coherent radiation pattern with an exponentially decreasing spectrum, resembling a thermal radiation with a temperature of the order of Hawking's one $T \sim T_H$ of a BH somewhat lighter than $\sqrt{s}$.

All in all, these results suggest a possible mechanism of solving the information paradox.

# Observables from modified dispersion relations on curved spacetimes: Circular orbits, redshift and lateshift

Christian Pfeifer

*Laboratory of Theoretical Physics, Institute of Physics, University of Tartu, W. Ostwaldi 1 50411 Tartu, Estonia*
*E-mail: christian.pfeifer@ut.ee*

The Hamiltonian formulation of modified dispersion relations (MDRs) allows for their implementation on generic curved spacetimes. In turn it is possible to derive phenomenological effects. I will present how to construct the kappa-Poincare dispersion relation on curved spacetimes, its spherically symmetric realizations, among them the kappa deformation of Schwarzschild spacetime, and its implementation on Friedmann-Lemaître-Robertson-Walker spacetimes with arbitrary scale factor. In addition we will construct the general first order modifications of the general relativistic dispersion relation. Afterwards we will use the perturbative MDRs to calculate specific observables such as the redshift, lateshift and photon circular orbits.

*Keywords*: Quantum gravity phenomenology, modified dispersion relations, observables, lateshift, redshift, photon orbits.

## 1. Traces of quantum gravity in point particle motion

A large source of information about the gravitational interaction come from the observation of trajectories of freely falling particles, such as for example neutrinos or photons, through spacetime. Traces of the expected quantum nature of gravity and its influence on the particles' paths therefore should manifest itself in the data collected by telescopes and observatories. One approach to derive effects, one can search for in the available data, is provided by quantum gravity phenomenology [1]. Due to a still missing fundamental theory of quantum gravity, we proceed along the following convincing pictorial idea to set up an effective model for the interaction between point particles and gravity on small distances or high energies: When test particles propagate through spacetime they probe spacetime on lengths scales inverse proportional to their energy. Thus particles with larger energy probe smaller length scales then lower energetic ones. The quantum nature of gravity is expected to become relevant at the Planck scale, i.e. at the Planck energy $E_{pl}$ respectively the Planck length $\ell_{pl}$. Hence particles with larger energies, closer to the Planck energy, probe length scales closer to the Planck length and should thus interact stronger with the quantum features of gravity.

This pictorial idea can be seen analogue to how a medium can be probed with photons of different energies, to obtain insights about its constituents. For very low energetic photons the medium may be invisible, while photons within a certain energy range may interact with the medium, get scattered and transport information about the medium to an observer. For the interaction between photons and the elementary constituents of the medium we know, that they are fundamentally explained by the standard model of particle physics. However effectively one can

describe several aspects of the system by an energy dependent propagation of the photons through the medium. The latter can be derived from an effective theory of electrodynamics, such premetric electrodynamics[2], and leads to a non local lorentz invariant (LLI) dispersion relation of the photons. Thus even though a fundamental interaction is LLI, observables may be described effectively by a non LLI theory.

Regarding the structure of spacetime and the quantum nature of gravity, we do not know the fundamental theory and of quantum gravity and its properties yet. In analogy to the effective description of the propagation of photons through media we will consider modifications of the general relativistic dispersion relation of point particles on spacetime. From such modifications we can calculate observables and look for their signatures in the available data. Any evidence or non-detection of such a signal then reveals properties, suitable semi-classical limits of quantum gravity must have.

Most famous effects searched for are an energy dependent redshift and time of arrival (lateshift) of photons[3]. Preliminary analyses of the ICECUBE and Fermi Gamma-Ray Space telescope observations for a lateshift effect have recently been performed[4–7] and shall be extended as soon as additional data is available.

We demonstrate how modified dispersion relations (MDRs) are realized on generically curved spacetimes we will derive observables such as the redshift, the lateshift and photon orbits.

## 2. Dispersion relations as Hamilton functions

The study of non LLI effects and MDRs as effective description of the interaction of point particles with the quantum nature of gravity has a long history in the literature, see for example[8–12] and references therein.

In Ref. 13 we demonstrated how to realize modified dispersion relations on curved spacetimes covariantly: *A dispersion relation of a point particle on curved spacetime is given by a level set of a Hamilton function $H(x,p)$ on the point particle phase space (cotangent bundle) of spacetime. The particle's motion is determined by the corresponding Hamilton equations of motion.* Moreover the Hamiltonian defines the geometry of phase space in a canonical way. In general spacetime and momentum space are curved and their curvatures depend on positions and momenta.

Using this covariant approach to dispersion relations we recall the Hamilton functions of general relativistic particles $H_{GR}$ and construct its first order perturbations $H_\ell$ as well as its $\kappa$-Poincaré deformations $H_\kappa$ [14,15] on general[16], static spherically symmetric[16] and homogeneous and isotropic spacetimes[16–18].

On a generically curved spacetime the Hamiltonians are build from a spacetime metric $g$, a perturbation function $h$ and unit timelike vector field of the metric $Z$

$$H_{GR}(x,p) = g^{ab}(x)p_a p_b\,, \tag{1}$$

$$H_\ell(x,p) = g^{ab}(x)p_a p_b + \ell h(x,p)\,, \tag{2}$$

$$H_\kappa(x,p) = -\tfrac{4}{\ell^2}\sinh\left(\tfrac{\ell}{2}Z^c(x)p_c\right)^2 + e^{\ell Z^c(x)p_c}\left(g^{ab}(x)p_a p_b + (Z^d(x)p_d)^2\right). \tag{3}$$

In static spherical symmetry the dependence of the Hamiltonians on the positions and momenta is restricted to $H(x,p) = H(r,p_t,p_r,v)$ with $v^2 = p_\theta^2 + \sin\theta^{-2} p_\phi^2$ [16],

$$H_{GR}(x,p) = -a(r)p_t^2 + b(r)p_r^2 + r^{-2}v^2\,, \tag{4}$$

$$H_\ell(x,p) = -a(r)p_t^2 + b(r)p_r^2 + r^{-2}v^2 + \ell h(r,p_t,p_r,v)\,, \tag{5}$$

$$\begin{aligned} H_\kappa(x,p) = &-\tfrac{4}{\ell^2}\sinh\left(\tfrac{\ell}{2}(c(r)p_t + d(r)p_r)\right)^2 + e^{\ell(c(r)p_t + d(r)p_r)} \\ &\times\left((-a(r)+c(r)^2)p_t^2 + 2c(r)d(r)p_tp_r + (b(r)+d(r)^2)p_r^2 + \tfrac{1}{r^2}v^2\right). \end{aligned} \tag{6}$$

Setting here $a(r)^{-1} = b(r) = 1 - \frac{r_s}{r}$ we obtain the $\kappa$-Poincaré deformations of Schwarzschild spacetime parametrized by two free function $c(r)$ and $d(r)$.
On homogeneous and isotropic spacetimes the form of the Hamiltonian is further restricted to $H(x,p) = H(t,p_t,w)$ with $w^2 = p_r^2(1-kr^2) + r^{-2}w^2$

$$H_{GR}(x,p) = -p_t^2 + A(t)^{-2}w^2\,, \tag{7}$$

$$H_\ell(x,p) = -p_t^2 + A(t)^{-2}w^2 + \ell h(t,p_t,w)\,, \tag{8}$$

$$H_\kappa(x,p) = -\tfrac{4}{\ell^2}\sinh\left(\tfrac{\ell}{2}p_t\right)^2 + e^{\ell p_t}A(t)^{-2}w^2\,. \tag{9}$$

## 3. Observables

A detection of traces of quantum gravity is most likely with high energetic photons and every MDR of interest can be expanded to first order around $H_{GR}$. Thus we focus on the derivation of observables for massless particles from $H_\ell(x,p)$.

### 3.1. *Redshift*

The redshift of photons involves a description of how observers measure the frequency of a photon. A classical observer, not subject to the MDR, on a worldline $\mathrm{x}(\tau)$ with tangent $\dot{\mathrm{x}}(\tau)$, momentum $p_\mathrm{x}(\tau)$ and mass $m_\mathrm{x}^2 = -H_{GR}(\mathrm{x},p_\mathrm{x})$, associates to a photon, subject to the MDR, on a worldline $\mathrm{y}(\tau)$ ,with momentum $p_\mathrm{y}(\tau)$ and satisfying $H_\ell(\mathrm{y},p_\mathrm{y}) = 0$, the frequency

$$\nu_\mathrm{x}(\mathrm{y}) = \dot{\mathrm{x}}^a p_{\mathrm{y}a} = \tfrac{1}{2m_\mathrm{x}}\partial_{p_a}H_{GR}(\mathrm{x},p_\mathrm{x})\; p_{\mathrm{y}a} = \tfrac{1}{m_\mathrm{x}}g^{ab}(\mathrm{x})\; p_{\mathrm{x}b}\; p_{\mathrm{y}a}\,. \tag{10}$$

The redshift of a photon between two observers $\mathrm{x}_i$ and $\mathrm{x}_f$ then is

$$z(t_i,r_i,t_f,r_f) \equiv z = \tfrac{\nu_{\mathrm{x}_i}(\mathrm{y})}{\nu_{\mathrm{x}_f}(\mathrm{y})} - 1. \tag{11}$$

Thus, two observers at rest at $\mathrm{x}_i = (t_i, r_i, \frac{\pi}{2}, 0)$ and $\mathrm{x}_f = (t_f, r_f, \frac{\pi}{2}, 0)$ find for a radially freely falling photon in spherical symmetry from (5) the redshift [16]

$$z = \sqrt{\tfrac{a(r_f)}{a(r_i)}} - 1 + \mathcal{O}(\ell^2)\,, \tag{12}$$

while for the homogeneous and isotropic case (8) they find that the redshift becomes dependent of the constant of motion $w$, which is related to the photons frequency [18]

$$\begin{aligned} z &= \left(\tfrac{A(t_f)}{A(t_i)} - 1\right) - \tfrac{\ell}{2w^2}\tfrac{A(t_f)}{A(t_i)}\left(A(t_f)^2 h(t_f, p_t^0(t_f,w), w) - A(t_i)^2 h(t_i, p_t^0(t_i,w), w)\right) \\ &\to \left(\tfrac{A(t_f)}{A(t_i)} - 1\right) - \ell w \tfrac{A(t_f) - A(t_i)}{2A(t_i)^2}\,. \end{aligned} \tag{13}$$

The first order momentum is $p_t^0(t,w) = -\frac{w}{A(t)}$ and the last line displays the result for a first order in $\ell$ expansion of the $\kappa$-Poincaré dispersion relation (9).

### 3.2. *Lateshift*

For the so called lateshift consider two massless particles with different frequency parameters $w_1$ and $w_2$ on radial trajectories $r_1(t,w_1)$ and $r_2(t,w_2)$ solving the Hamilton equations of motion of (8). They shall be emitted at the same coordinates $(t_i, R_i)$, i.e. $R_i = r_1(t_i,w_1) = r_2(t_i,w_2)$, and we ask when do they reach the same radial distance $R_f = r_1(t_1,w_1) = r_2(t_2,w_2)$. The difference in their time of arrival $\Delta t = t_2 - t_1$ is the so called lateshift. For the solutions of the radial Hamilton equation of motion of (8), derived in Ref. 18, we find,

$$\Delta t = \ell A(t_1) \int_{t_i}^{t_1} \mathrm{d}\tau \ \tfrac{f(\tau,p_t^0(\tau,w_2),w_2) - f(\tau,p_t^0(\tau,w_1),w_1)}{A(\tau)} \tag{14}$$

$$\to -\ell \tfrac{A(t_1)(w_1-w_2)}{2} \int_{t_i}^{t_1} d\tau \tfrac{1}{A(\tau)^2}\,. \tag{15}$$

where again $p_t^0(t,w) = -\frac{w}{A(t)}$, the last line is the first order in $\ell$ result of (9), and

$$f(t,p_t^0(t,w),w) = \tfrac{1}{2(p_t^0)^2}\big[h(t,p_t^0,w) - p_t^0 \partial_{p_t} h(t,p_t^0,w) - w\partial_w h(t,p_t^0,w)\big]\,. \tag{16}$$

### 3.3. *Innermost circular photon orbits*

To calculate the innermost circular photon orbits we solve the Hamilton equations of motion of (5) with the assumption that $\dot{r} = 0$. Due to the spherical symmetry we can without loss of generality consider orbits in the equatorial plane $\theta = \frac{\pi}{2}$. The Hamilton equations of motion $\partial_{p_r} H_\ell = \dot{r} = 0$ and $\partial_r H = -\dot{p}_r$ with $p_r = p_r^0 + \ell p_r^1$, together with the fact that $p_t$ and $v$ are constants of motion, then imply to first order in $\ell$

$$p_r^0 = 0, \quad p_r^1 = -\tfrac{\partial_{p_r} h(r,p_t,p_r^0,v)}{2b(r)} \quad \Rightarrow \quad \dot{p}_r^0 = 0 = \dot{p}_r^1\,. \tag{17}$$

Using $H_\ell(x,p) = 0$ to express $p_t$ as function of $r$ and $v$, and solving $\partial_r H = -\dot{p}_r = 0$ yields,

$$0 = \tfrac{a'(r_0)}{a(r_0)} + \tfrac{2}{r_0}, \quad r_1 = \frac{\partial_r h(r_0,p_t^0(r_0,v),0,v) - \frac{a'(r_0)}{a(r_0)} h(r_0,p_t^0(r_0,v),0,v)}{\left(\frac{a''(r_0)}{a(r_0)r_0^2} - \frac{a'(r_0)^2}{a(r_0)^2 r_0^2} - \frac{2a'(r_0)}{a(r_0)r_0^3} - \frac{6}{r_0^4}\right)v^2}\,, \tag{18}$$

which determine the allowed circular photon orbits $r = r_0 + \ell r_1$ to first order in $\ell$.

Considering MDRs on Schwarzschild spacetime by specifying the function $a(r)^{-1} = 1 - \frac{r_s}{r}$ the zeroth order becomes $r_0 = \frac{3}{2} r_s$, as it must be, and the equation which determines the first order correction becomes

$$r_1 = \frac{27 r_s^4 (\partial_r h(r_0,p_t^0(r_0,v),0,v) - \frac{a'(r_0)}{a(r_0)} h(r_0,p_t^0(r,v),0,v))}{32 v^2}\,. \tag{19}$$

Specifying to the first order in $\ell$ of the spherically symmetric $\kappa$-Poincaré dispersion relation (6) with $d(r) = 0$ and $c(r) = \frac{1}{\sqrt{1-\frac{r_s}{r}}}$ (19) yields $r_1 = \frac{v}{6}$ [16].

### 3.4. *Conclusion*

The implementation of modified dispersion relation on curved spacetimes allows for the prediction of traces of the quantum nature of gravity, which can be confirmed or constraint by observations. Particularly promising are time of arrival measurements of high energetic gamma-rays, which can be compared against equation (14) and the search for rainbow effects in lensing images, for example in the shadows of black holes, which would correspond to a non-trivial $v$ dependence in (18).

To bridge the the gap between fundamental approaches to quantum gravity and the phenomenological one presented here, it is necessary to derive the perturbation function $h(x, p)$ in (2) in some semi-classical limit from the fundamental approaches. This is one of the major tasks for future research.

I present recent results concerning the statistical description of the Black Hole entropy in terms of trapped gravitons. In particular, I present a theorem depicting a possible physical mechanism, from finite size effects induced by Planckian fluctuations, giving trapped gravitons with a linear equation of state. As a consequence, logarithmic corrections to the Black Hole entropy naturally arise. Finally, it is also shown that such a mechanism allows a statistical description of macroscopic configurations made of cosmological constant in terms of massless excitations within a spherical box.

*Keywords*: Black Hole Thermodynamics; Black Hole Entropy; Trapped Gravitons.

## 1. Corrections to the black hole entropy

As well known[1], black holes (BH) emit a thermal radiation with no information within and depending only from the mass (charge and angular momentum, no-hair theorem) and at the temperature $(r \to \infty)$ $T_h = \frac{c\hbar}{4\pi K_B R}$. The entropy is $S_H = \frac{K_B A}{4L_P^2}$. Many open questions are still unsolved:

- What is the physical origin of the degrees of freedom implying $S_h$?
- How can we obtain the log. corrections to the BH entropy?

The physical origin of the BH entropy degrees of freedom is still obscure. In Refs. 2, 3 we have proposed that the degree of freedom leading to the BH entropy are represented by trapped gravitons inside the event horizon. After imposing Dirichlet boundary conditions on the Zerilli or Regge-Wheeler functions (Gravitational waves in the vacuum) at $r = R$: $Z_{\ell m}^{(p,a)}(R, \omega) = 0$, we obtain the following expression for the allowed frequencies:

$$\omega_{\ell n} \simeq \frac{c}{2R}\left(2 + \ell + 2n\right)\pi, \;\; \ell \geq 2, \;\; n \in \mathbb{N}. \tag{1}$$

We assume, as usual, that the internal energy $U_i$ is provided by the ADM mass $M$, i.e. $U_i = Mc^2$. A statistical entropy can thus be derived from (1) in the usual way by means of the Shannon (von Newmann) entropy:

$$\begin{aligned} S = &-NK_B\left[\ln\left(1 - e^{-\frac{X}{2}}\right) + \ln\left(1 - e^{-X}\right)\right] \\ &+ \frac{c\pi\hbar N e^{-\frac{X}{2}}\left[1 + 3e^{-\frac{X}{2}}\right]}{2TR\left(1 - e^{-X}\right)}, \;\; X = \frac{c\pi\beta\hbar}{R}. \end{aligned} \tag{2}$$

The equation of state is the one of a radaition field $P_i V = \frac{U_i}{3}$. For the temperature we have $T_i = \alpha T_h = \frac{\alpha c \hbar}{4\pi K_B R}$, $\alpha \in (0, \infty)$. We find $S = K_B Y(\alpha) \frac{A_h}{4L_P^2}$, with $Y(\alpha) = 1$ with $\alpha \simeq 2.2 \sim 2$, where $\alpha = 2$ is the theretical value: our model it gives viable results within the approximation made for the (1). How can be obtained logarithmic corrections to the BH entropy? BH entropy is semi-classical, so we expect some quantum (Planckian) effect leading to the well known $\ln(A)$ corrections. First of all we expect modifications for the semi-classical formula $U(R)$. In a quantum spacetime[6–8], spacetime uncertainty relations are satured with $\Delta E \sim \frac{1}{R}$, and the following modification of $U_i$ emerges with $U_i(R) = \frac{c^4}{2G} R + \frac{C_1 c^4 L_P^2}{2GR}$, $\{C_1\} \in \mathbf{R}^+$. Unfortunately, the added term does not lead to logarithmic entropy corrections. To overcome this issue, in Ref. 4 and after in Ref. 5 for any massless excitation, we have proposed a physical mechanism, motivated by solid state physics, capable to depict a system with a gamma linear equation of state, i.e. quantum fluctuations change the equation of state $PV = \gamma U$, $\gamma \in \mathbf{R}$. The following theorem holds:

*Theorem:* Let $\omega_0 = \omega_{\ell n}$ denote the angular frequency of $N$ trapped gravitons with internal energy $U^{(0)}$ (radiation). The so trapped gravitons with angular frequency $\omega = \omega_0 + \frac{\phi(R)}{N}$ have a linear equation of state with $U = U^{(0)} + \hbar\, \phi(R)$ iff there exists a differentiable function $\phi(R)$, satisfying the following equation

$$\hbar \left[ R\, \phi_{,R}(R) + \phi(R) \right] = U(R)(1 - 3\gamma),$$

together with the condition

$$U - \hbar\, \phi(R) > 0.$$

To start with, consider the semi-classical BH case $U = \frac{c^4 R}{2G}$; for $\Phi(R)$ we have $\phi(R) = \frac{c}{4L_P^2} R(1 - 3\gamma)$. with limitation $\gamma > -\frac{1}{3}$ (independently on $R$), i.e. in the semi-classical case the active gravitational mass is positive and gravity is attractive, a reasonable result. Consider now $U = \frac{c^4}{2G} R + \frac{C_1 c^4 L_P^2}{2GR}$, we obtain

$$\phi(R) = \frac{cR}{4L_P^2}(1 - 3\gamma) + \frac{c\, C_1\, (1 - 3\gamma)}{2R} \ln\left( \frac{R}{s L_P} \right). \tag{3}$$

As a first important consequence of (2), since entropy, independently on the equation of state, is proportional to $N$, is that $N \sim R(U - \hbar\phi)$ and as a result logarithmic corrections emerge. We must discuss te existence condition $U - \hbar\, \phi(R) > 0$. After posing $W = \frac{R}{L_P}$, we get:

$$W + \frac{C_1}{W} - (1 - 3\gamma) \left[ \frac{W}{2} + \frac{C_1}{W} \ln\left( \frac{W}{s} \right) \right] > 0.$$

The results are:

- $\gamma = -1$, Cosmological constant: A maximum radius $R_M$ is present of the order (greater) of Planck length $L_P$. This implies that BH filled with gravitons with a cosmological constant equation of state are only possible with microscopic Planckian sizes.

- By supposing $C_1 < 0$ we obtain a minimum radius $R_m$ and a maximum one of the order of $\sim L_P$.
- For $\gamma \in [0, \frac{1}{3}]$ we have no restriction for $R$, while for $\gamma > \frac{1}{3}$ a minimum allowed value for $R$ is present. In the stiff case ($\gamma = 1$), we have $R_m \sim \frac{L_P}{2}$.
- For $\gamma < 0$ a maximum allowed radius does appear $R_M \sim L_P$. As an example, for $\gamma = -\frac{1}{3}$ ($s \sim 1$) we have $R_M = \sqrt{e} L_P$.

## 2. The dark energy

The treatment presented above can be extended to any massless excitation in a spherical box[5]. In this frame, the theorem proven is still valid. In particular, by considering the positive cosmological constant case $\rho = B, B \in \mathbf{R}^+, \gamma = -1$ with $U = BV + \frac{C}{R}$ (Planck effects again), macroscopic dark energy configurations can be obtained. It is worth to be noted that with $C = 0$ we obtain the constraint $\gamma > -1$. The case $\gamma = -1$ is only possible with the quantum correction term $\sim 1/R$ in $U(R)$. This fact, in my opinion, strongly suggests the quantum-gravity nature of the cosmological comstant as due to strong Planckian fluctuations. In fact, in a cosmological de Sitter spacetime, an effective cosmological constant $\overline{\Lambda}$ emerges after applying the technology depicted above:

$$\overline{\Lambda} = \Lambda + \frac{3\xi L_P^2}{L^4}, \tag{4}$$

where $L$ denotes the physical scale and $\xi$ is a positive constant expected to be less than unity and $\Lambda$ denotes the bare cosmological constant without Planckian fluctuations. It is important to stress that the (4) does not represent a quintessence dark energy, but rather the effective value of the cosmological constant depends on the scale at which the physics is considered that in turn depends on the volume $V = 4\pi L^3/3$. In my view the cosmological constant is averaged over bigger and bigger scales up to a scale $L_D$, decoherence scale, such that the quantum Planckian fluctuations are negligible and a de Sitter universe emerges thus representing the crossover to classicality. Exactly at $L = L_D$ we have an absolute minimum for $U(L)$ with zero specific heat: the cosmological constant is thus fixed (frozen) at this critical scale. This scale depends crucially on the phenomenological parameter $\xi$. As an example, for $\xi \sim 1$ at scales $L \sim 10^{-5} m \ \rightarrow \overline{\Lambda} \sim 10^{-52}/m^2$. This seems a rather huge value, but no arguments to reject this value are at our disposal, although a scale of decoherence near the Planck length could be more appropriate. In any case, the important fact is that a new view concerning the origin of the cosmological constant emerges in the context depicted above.

We study how one can avoid some ultraviolet problems in the description of a perturbative inhomogeneous Dirac field in inflationary hybrid Loop Quantum Cosmology (LQC). Within a canonical approach for the entire cosmology, we consider different separations between the canonical variables that describe the homogeneous geometry and the fermionic perturbations. Each of such choices leads to a different fermionic contribution to the total Hamiltonian. In the hybrid quantization scheme, a quantum version of that contribution contains a backreaction term on the homogeneous part of the wavefunction. We provide the conditions on the choice of fermionic variables that lead to a finite backreaction.

*Keywords*: Loop Quantum Cosmology, Fermionic Perturbations, Quantum Backreaction.

## 1. Introduction

In conventional Quantum Field Theory (QFT) in curved spacetimes, one is forced to employ, in one way or another, some type of regularization procedure to cure the infinities that generically arise in possible observables, such as the Hamiltonian, constructed out of products of the field operators[1]. It is commonly believed that the reasons behind these issues can be traced to the treatment of the spacetime as a classical, continuum background.

We investigate here whether these problems can be avoided in cosmology by treating the entire system, including the spacetime background, as a dynamical entity to be quantized. For that purpose, we adopt the so-called hybrid approach in LQC to the quantization of a homogeneous and isotropic cosmology minimally coupled to a Dirac field, that we treat as a perturbation[2]. The approach is based on a splitting of the phase space into a homogeneous sector, that is represented with LQC techniques[3], and an inhomogeneous one, which is treated with conventional QFT methods. In this context, we exploit the freedom in performing canonical transformations that assign different dynamical roles to the homogeneous sector and the inhomogeneities. We show that this freedom permits a fermionic contribution to the Hamiltonian constraint that, in particular, gives rise to a non-divergent backreaction on the homogeneous background in the quantum theory.

## 2. The Cosmological System

The starting point for the construction of the cosmology under study is a Friedmann-Lemaître-Robertson-Walker (FLRW) spacetime with flat and compact spatial

hypersurfaces (isomorphic to a three-torus, $T^3$). We employ spatial coordinates adapted to the homogeneity. The matter content is given by a homogenous scalar (inflaton) field subject to a potential, and a Dirac field, both of them minimally coupled. The Dirac field is treated entirely as a perturbation. We truncate our perturbed system so that its Einstein-Dirac action is at most quadratic in all the perturbations[4]. Our canonical formulation is obtained from the symplectic structure and from the Hamiltonian associated with this truncated action.

In view of the symmetries of the homogeneous FLRW background, it is convenient to expand each of the two chiral components of the Dirac field in a complete set of eigenspinors of the Dirac operator on $T^3$, after imposing the time gauge on the homogeneous tetrads[4]. The spectrum of that operator is discrete and characterized by eigenvalues $\pm\omega_k$ that grow asymptotically as $2\pi|\vec{k}|/l_0$, where $\vec{k} \in \mathbb{Z}^3$ and $l_0$ is the compactification length of the tori. In the expansion of the left-handed component of the Dirac field, we call $e^{-3\alpha/2}m_{\vec{k}}$ and $e^{-3\alpha/2}\bar{r}_{\vec{k}}$ the time-dependent coefficients of the eigenspinors of the Dirac operator on $T^3$ with respective eigenvalues $\omega_k$ and $-\omega_k$. Here, $\alpha$ is, up to an additive constant, the logarithm of the scale factor of the FLRW cosmology. Similarly, $e^{-3\alpha/2}\bar{s}_{\vec{k}}$ and $e^{-3\alpha/2}t_{\vec{k}}$ respectively denote the coefficients of the complex conjugates of the eigenspinors with eigenvalues $\omega_k$ and $-\omega_k$ in the expansion of the right-handed component of the Dirac field. All of these eigenspinor coefficients are taken as Grassmann variables. Besides, each of them forms a canonical pair with its complex conjugate, with a Dirac bracket equal to $-i$, and vanishing anticommutation relations with the rest of coefficients. Introducing these mode decompositions in the action, one obtains the fermionic contribution to the total Hamiltonian. This contribution is quadratic in the fermionic variables, and is given by a sum over all modes, which decouple from each other. It appears multiplied by the homogeneous lapse function $N_0$, so we call it $N_0 H_D$, hence it only affects the zero mode of the Hamiltonian constraint.

## 3. Fermionic Annihilation and Creationlike Variables

To describe the fermionic degrees of freedom, in this section we will consider a rather generic family of definitions of annihilation and creationlike variables for the Dirac field. For this purpose, we will exploit the freedom to perform linear canonical transformations of the fermionic variables that depend on the homogeneous background geometry described by $\alpha$ and its momentum $\pi_\alpha$. Specifically, we restrict to definitions that respect the symmetries of the fermionic Hamiltonian[5]:

$$\begin{aligned} a^{(x,y)}_{\vec{k}} &= f^k_1(\alpha,\pi_\alpha)\, x_{\vec{k}} + f^k_2(\alpha,\pi_\alpha)\, \bar{y}_{-\vec{k}-2\vec{\tau}}, \\ \bar{b}^{(x,y)}_{\vec{k}} &= g^k_1(\alpha,\pi_\alpha)\, x_{\vec{k}} + g^k_2(\alpha,\pi_\alpha)\, \bar{y}_{-\vec{k}-2\vec{\tau}}, \end{aligned} \tag{1}$$

where $(x_{\vec{k}}, y_{\vec{k}})$ is any of the ordered pairs $(m_{\vec{k}}, s_{\vec{k}})$ or $(t_{\vec{k}}, r_{\vec{k}})$, the constant tuple $2\vec{\tau}$ in $\mathbb{Z}^3$ fixes the spin structure[6] on $T^3$, and $a^{(x,y)}_{\vec{k}}$ and $\bar{b}^{(x,y)}_{\vec{k}}$ correspond to annihilation-like variables for particles and creationlike variables for antiparticles, respectively.

These variables only satisfy the standard canonical anticommutation relations if[5]:

$$g_1^k = e^{iJ_k}\bar{f}_2^k, \qquad g_2^k = -e^{iJ_k}\bar{f}_1^k, \tag{2}$$

$$f_2^k = e^{iF_2^k}\sqrt{1-\left|f_1^k\right|^2}, \tag{3}$$

with $J_k$ and $F_2^k$ being some (possibly background-dependent) phases.

One can restrict the selection of annihilation and creationlike variables to a privileged family by imposing some physically desirable properties. A satisfactory criterion is the imposition that, in the context of QFT in curved spacetimes, the dynamics of the annihilation and creationlike variables can be implemented as unitary nontrivial transformations in Fock space. This condition, together with the invariance of the vacuum under the symmetries of the fermionic Hamiltonian, and a standard convention for the notions of particles and antiparticles, leads to a family of unitarily equivalent Fock representations[7]. The family of fermionic variables (1)–(3) that satisfies the explained selection criterion is totally specified by the following asymtpotic behavior in the limit of large $\omega_k$:

$$f_1^k = \sqrt{\frac{\xi_k-\omega_k}{2\xi_k}} + \frac{\tilde{M}e^{\alpha}}{2\omega_k}\left[e^{iF_2^k}-1\right] + \theta_k \quad \text{with} \quad \sum_{\vec{k}\in\mathbb{Z}^3}|\theta_k|^2 < \infty, \tag{4}$$

where we have defined

$$\xi_k = \sqrt{\omega_k^2 + \tilde{M}^2 e^{2\alpha}}, \tag{5}$$

and $\tilde{M} = 2M\sqrt{\pi/(3l_0^3)}$ where $M$ is the mass of the Dirac field.

The family of annihilation and creationlike variables defined by (1)–(3), together with condition (4), is obtained by means of an $(\alpha,\pi_\alpha)$-dependent transformation that is canonical within the fermionic sector of the phase space. In order to be canonical in the entire truncated system, the geometric variables $(\alpha,\pi_\alpha)$ of the homogeneous sector must be replaced with a new, corrected, canonical pair $(\tilde{\alpha},\tilde{\pi}_\alpha)$. These new homogeneous variables differ from the old ones by some known corrections that are quadratic in the fermionic perturbations[5]. At the quadratic order of our perturbative truncation, the expression of the total Hamiltonian of the cosmological system in terms of these new variables can be obtained by directly substituting the new pair $(\tilde{\alpha},\tilde{\pi}_\alpha)$ in its functional dependence on $(\alpha,\pi_\alpha)$, and replacing the Dirac Hamiltonian $N_0H_D$ by $N_0\tilde{H}_D$, where $\tilde{H}_D$ is the sum over all $\vec{k}\in\mathbb{Z}^3$ of some functions $\tilde{H}_{\vec{k}}$ that, when $\omega_k\to\infty$, behave as[5,8]:

$$\begin{aligned}\tilde{H}_{\vec{k}} = \sum_{(x,y)}\Bigg[&\left(e^{-\tilde{\alpha}}\xi_k + 2h_D^k\right)\left(\bar{a}_{\vec{k}}^{(x,y)}a_{\vec{k}}^{(x,y)} + \bar{b}_{\vec{k}}^{(x,y)}b_{\vec{k}}^{(x,y)}\right) + 2h_J^k\left(\bar{b}_{\vec{k}}^{(x,y)}b_{\vec{k}}^{(x,y)}\right)\\ &+ e^{i(J_k-F_2^k)}e^{-\tilde{\alpha}}\left(2\omega_k\bar{\theta}_k + \bar{h}_I^k\right)a_{\vec{k}}^{(x,y)}b_{\vec{k}}^{(x,y)} + \text{H.c.}\Bigg],\end{aligned} \tag{6}$$

where $\xi_k$ is evaluated at $\tilde{\alpha}$, H.c. stands for Hermitian (complex) conjugate, and

$$h_D^k = \mathcal{O}(1), \quad h_J^k = \mathcal{O}(1), \quad h_I^k = i\tilde{\pi}_\alpha\frac{\tilde{M}e^{-\tilde{\alpha}}}{2\omega_k}e^{iF_2^k} + \mathcal{O}\left(\text{Max}[\theta_k,\omega_k^{-2}]\right). \tag{7}$$

Here, a contribution is $\mathcal{O}(.)$ when it is of the asymptotic order of the corresponding argument (or smaller), and the function Max[.,.] picks out the argument of dominant asymptotic order. To arrive at these asymptotic expressions, we have further restricted to functions $f_1^k, f_2^k, g_1^k$, and $g_2^k$ with asymptotic expansions (when $\omega_k \to \infty$) such that their partial derivatives with respect to $\alpha$ and $\pi_\alpha$ maintain the asymptotic order of each term of those expansions.

## 4. Backreaction and Unitarity in Hybrid LQC

The two sectors of the phase space to be quantized are the homogeneous FLRW background [with geometry described by $(\tilde{\alpha}, \tilde{\pi}_\alpha)$] and the fermionic degrees of freedom described above. For the former, we select a LQC-inspired representation[3,5] with kinematical Hilbert space that we denote by $\mathcal{H}_{\rm kin}^{\rm grav}$. On the other hand, for the inflaton field $\phi$ and its momentum we choose a standard Schrödinger representation, with Hilbert space given by $L^2(\mathbb{R}, d\phi)$. Finally, for the fermionic perturbations we consider the Fock representation associated with any choice of annihilation and creationlike variables within the family defined by (1)-(4). We call $\mathcal{F}_D$ the corresponding Fock space. Besides $\hat{a}_{\vec{k}}^{(x,y)}$ and $\hat{b}_{\vec{k}}^{(x,y)\dagger}$ respectively denote the annihilation operators of particle excitations and the creation operators of antiparticle excitations, with their adjoints acting reversely. Both of these sectors are jointly subject to the zero mode of the Hamiltonian constraint, formed by the sum of the constraint of the unperturbed inflationary model and the new fermionic contribution formed by $\tilde{H}_D$. In the hybrid approach, one attempts to represent this constraint on the resulting tensor product space, and then imposes that it annihilates the physical states of the system[5].

In order to find physical states of interest, we consider wave functions of the form $\Gamma(V,\phi)\psi_D(\mathcal{N}_D,\phi)$, where $V$ is the physical volume of the homogeneous sector of our cosmology, and $\mathcal{N}_D$ refers to the fermionic occupation numbers. Moreover, we restrict our considerations to normalized states $\Gamma$ in $\mathcal{H}_{\rm kin}^{\rm grav}$ with a unitary evolution in $\phi$, which furthermore is generated by certain positive operator[5]. The only restriction that we impose on this operator is to be such that the partial state $\Gamma$ differs from being an exact solution of the unperturbed FLRW cosmology at most in a quadratic contribution of the perturbations. With this ansatz for the states, we impose the Hamiltonian constraint. If in the partial state $\Gamma$ we can ignore any transition in the homogeneous geometry mediated by the action of our quantum Hamiltonian constraint, and the contribution of the perturbations to the momentum of the inflaton is negligible with respect to that of $\Gamma$, a sort of Born-Oppenheimer approximation can be applied. Then, one arrives at the following Schrödinger-like equation for the fermionic part of the wave function[5]:

$$i\partial_\phi \psi_D(\mathcal{N}_D,\phi) = \frac{l_0\langle \widehat{V^{2/3}e^{\tilde{\alpha}}\tilde{H}_D}\rangle_\Gamma - C_D^{(\Gamma)}(\phi)}{\langle \hat{\tilde{\mathcal{H}}}_0\rangle_\Gamma}\,\psi_D(\mathcal{N}_D,\phi). \tag{8}$$

Here, the hat over classical observables indicates their corresponding representation as operators. Besides, the brackets $\langle . \rangle_\Gamma$ stand for the expectation value in $\Gamma$, taken with respect to the inner product in $\mathcal{H}^{\rm grav}_{\rm kin}$. Since the momentum of $\phi$ does not appear in $\tilde{H}_D$, the right-hand side of (8) represents a $\phi$-dependent Hamiltonian operator acting on the fermionic sector. On the other hand, the function $C_D^{(\Gamma)}(\phi)$ is a backreaction term that provides, in mean value, how much $\Gamma$ departs from an exact solution of the unperturbed system[8].

The solutions of (8) can be studied by considering its associated Heisenberg equations for the annihilation and creation operators. Taking initial data $\hat{a}_{\vec{k}}^{(x,y)}$ and $\hat{b}_{\vec{k}}^{(x,y)\dagger}$ at $\phi = \phi_0$, these are generally solved by the linear combinations:

$$\begin{aligned}
\hat{a}_{\vec{k}}^{(x,y)}(\phi,\phi_0) &= \alpha_k(\phi,\phi_0)\hat{a}_{\vec{k}}^{(x,y)} + \beta_k(\phi,\phi_0)\hat{b}_{\vec{k}}^{(x,y)\dagger},\\
\hat{b}_{\vec{k}}^{(x,y)\dagger}(\phi,\phi_0) &= -e^{i\chi_k(\phi,\phi_0)}\bar{\beta}_k(\phi,\phi_0)\hat{a}_k^{(x,y)} + e^{i\chi_k(\phi,\phi_0)}\bar{\alpha}_k(\phi,\phi_0)\hat{b}_{\vec{k}}^{(x,y)\dagger},
\end{aligned} \tag{9}$$

where $|\alpha_k|^2 + |\beta_k|^2 = 1$ and, in the asymptotic limit $\omega_k \to \infty$[8],

$$\chi_k = \mathcal{O}(1), \quad \alpha_k = \mathcal{O}(1), \quad \beta_k = \mathcal{O}(G_k^{(\Gamma)}\omega_k^{-1}) = \mathcal{O}\left(\mathrm{Max}[\theta_k, \omega_k^{-2}]\right) \tag{10}$$

with:

$$G_k^{(\Gamma)} = \frac{2i\omega_k\langle \widehat{e^{i(F_2^k - J_k)}V}^{2/3}\theta_k\rangle_\Gamma + i\langle \widehat{e^{i(F_2^k - J_k)}V}^{2/3}h_I^k\rangle_\Gamma}{\langle \hat{V}^{2/3}\rangle_\Gamma}. \tag{11}$$

The Heisenberg evolution is thus described by a $\phi$-dependent family of Bogoliubov transformations, which are all unitarily implementable in $\mathcal{F}_D$ since the sequence of beta coefficients is clearly square summable[9] over all $\vec{k} \in \mathbb{Z}^3$. It is actually possible to explicitly construct the corresponding unitary operators, which are completely specified by the alpha and beta coefficients, up to an arbitrary phase. The state obtained from evolving the vacuum in $\mathcal{F}_D$ with these operators then indeed solves (8), with a backreaction term given by[8]:

$$C_D^{(\Gamma)} = l_0\langle \hat{V}^{2/3}\rangle_\Gamma \sum_{\vec{k},(x,y)} \Im(G_k^{(\Gamma)}\bar{\Delta}_k), \quad \Delta_k = \mathcal{O}(\beta_k), \tag{12}$$

up to a term coming from the $\phi$-derivative of the mentioned arbitrary phase in the evolution operator. Our aim is to obtain a backreaction contribution which needs not any regularization techniques by means of, e.g., a choice of the arbitrary phase that absorbs any possible divergences in (12), or an specific conditional summation rule that ensures the convergence of such equation. We therefore impose that the sum that specifies $C_D^{(\Gamma)}$ is absolutely convergent. Besides, we naturally require that this contribution to the backreaction converge independently of the choice of homogeneous state $\Gamma$, and for all $\phi$. This univocally leads to impose[8]:

$$\theta_k = -i\frac{\tilde{M}e^{-\alpha}}{4\omega_k^2}\pi_\alpha e^{iF_2^k} + \vartheta_k, \quad \sum_{\vec{k}\in\mathbb{Z}^3} \omega_k|\vartheta_k|^2 < \infty. \tag{13}$$

Finally, let us comment that one can restrict even further the choice of fermionic variables in order to guarantee that the Hamiltonian operator that appears in the Schrödinger equation (8) has, with normal ordering, a well-defined action on the Fock vacuum. This amounts to require that the coefficients of the $a_{\vec{k}}^{(x,y)} b_{\vec{k}}^{(x,y)}$ terms in $\tilde{H}_D$ form a square summable sequence over all $\vec{k} \in \mathbb{Z}^3$. This happens if and only if (13) is again satisfied, but now requiring the stronger condition: $\sum_{\vec{k}} \omega_k^2 |\vartheta_k|^2 < \infty$[8].

## 5. Conclusions

We have studied how to split the phase space of an inflationary cosmology minimally coupled to a perturbative Dirac field in such a way that, within the hybrid approach to LQC, one obtains a well-defined fermionic contribution to the quantum backreaction without the need of any regularization scheme. This criterion leads to a very specific choice of annihilation and creationlike variables for the fermionic degrees of freedom, something that amounts to a restriction on the dynamical characterization of their quantum excitations, as well as on the choice of their vacua.

# Detailed background dynamics and trans-planckian effects in loop quantum cosmology

Killian Martineau

*Laboratoire de Physique Subatomique et de Cosmologie, Université Grenoble-Alpes, Grenoble, 38000, France*
*E-mail: killian.martineau@lpsc.in2p3.fr*
*http://lpsc.in2p3.fr/index.php/en/*

Cosmology appears as the most promising way to test and constrain quantum gravity theories. Loop quantum gravity is among the most advanced attempts to perform a non-perturbative quantization of general relativity. Its cosmological counterpart, loop quantum cosmology, has clear predictions both for the cosmological background and for the perturbations. In particular, the initial Big Bang singularity is replaced by a bounce due to quantum geometry effects. In this proceeding I will focus on new results obtained in loop quantum cosmology: i) the prediction of the duration of inflation as a function of all the unknown parameters of the model and ii) new primordial power spectra obtained with modified dispersion relations accounting for trans-planckian effects.

*Keywords*: Loop quantum cosmology, inflation, trans-planckian problem, primordial power spectra.

## 1. Introduction

Loop quantum gravity [1, 2] (LQG) might be the most advanced non-perturbative and background-invariant quantization of general relativity. Loop quantum cosmology [3] (LQC) is a quantum theory inspired by the LQG quantization scheme that takes into account the cosmological symmetries. Its background dynamics, governed by the effective modified Friedmann equation

$$H^2 = \frac{\kappa}{3}\rho\left(1 - \frac{\rho}{\rho_c}\right), \tag{1}$$

leads to a bounce and is now well established. It has been confirmed by numerical simulations [4], but also by calculations in group field theory [5], underlining the robustness of the model. In this equation $H$ is the Hubble parameter, $\kappa = 8\pi$, $\rho$ stands for the energy density, and $\rho_c \sim \rho_{Pl}$ for its value at the bounce.

The situation is however less clear for perturbations. Not only because different settings are being considered (mainly the *deformed algebra* [6] and the *dressed metric* [7] approaches) but most importantly because trans-planckian effects are often neglected or not treated as a dominant process. It seems that too much emphasis has been put on *density* effects and not enough on *length* effects. Even if the former do trigger the bounce the latter cannot be ignored in a theory that modifies the space structure at the Planck length. In this proceeding I will therefore focus on two new results in LQC : i) the prediction of the duration of inflation as a function of all the unknown parameters of the model and ii) new primordial power spectra obtained with modified dispersion relations accounting for trans-planckian effects.

## 2. Exhaustive investigation of the inflation duration in the loop quantum cosmological framework

Remarkably, inflation is a strong attractor and appears naturally in the LQC model as long as the matter content of the universe is assumed to be a massive scalar field. One of the most interesting consequence of this cosmological framework is therefore that the inflation duration can, to some extent, be predicted.

However, even at the background level, three main uncertainties remain to be addressed systematically. The first one is related with the way to set initial conditions. There are mainly two schools of thought : the first one sets them in the remote past of the contracting branch whereas the other one sets them at the bounce. Since those initial conditions are in a one-to-one correspondence with each other the key point is to look for a variable to which a known probability distribution function (PDF) can be assigned. The second uncertainty is associated with the amount of anisotropic shear at the bounce, which is expected to play an important role in any bouncing model. Finally the third main uncertainty is the inflaton potential shape, as the matter content of the universe is not predicted by LQG (but can be partially experimentally determined).

Within this framework we have performed an exhaustive investigation of the duration of inflation by varying those three unknowns [8].

When dealing with the initial conditions issue, it is in our opinion more appealing to set them in the remote past of the classical contracting branch of the Universe. In this case, a flat PDF can easily be associated to the initial phase of the scalar field. If we do so, and if the inflaton potential is confining, the duration of inflation appears to be severely constrained and, most interestingly, the predicted number of e-folds is not much higher than the minimum value required by observations. This result is an important feature of the loop quantum cosmological model and underlines its strong predictive power for a massive scalar field. This predictive power is even increased when anisotropies are taken into account as the number of e-folds associated with the PDF mean value decreases. However the LQC predictive power is basically lost if initial conditions are set at the bounce as there is apparently no variable to which a known PDF can be assigned.

In summary, once the inflaton potential is determined and if initial conditions are set in the contracting branch, in agreement with the intuition of causality, there is an obviously interesting predictive power of LGC for the inflation duration. This predictive power is stronger when the potential is confining and weaker if it features a plateau-like shape. The initial amount of shear remains however unknown but this is not necessarily a problem if the inflaton potential is confining as the predicted $e$-folds number is then restricted to a small interval, bounded from below by observations and from above by the isotropic case.

## 3. A first step towards the inflationary trans-planckian problem treatment in loop quantum cosmology

The trans-planckian problem is a well-known cosmological issue [9] that cannot be ignored in the LQG framework. As soon as the number of e-folds of inflation is higher than 70, all modes of physical interest were highly trans-planckien at the bounce time.

As a first elementary step to account for trans-planckian effects, we have suggested the use of modified dispersion relations (MDRs) in the LQC framework [10]. This is obviously not the final word on this question and trans-planckian effects should ideally be considered in the full theory setting but we believe that MDRs are a meaningful first step.

Modified relations need to be applied to physical quantities and are therefore introduced in the Mukhanov-Sasaki equation by the replacement: $k_\varphi \to \mathcal{F}(k_\varphi)$. The $\mathcal{F}(k_\varphi)$ function depends on the considered dispersion relation, the standard case corresponding to $\mathcal{F}(k_\varphi) = k_\varphi$. The Mukhanov-Sasaki equation in the Deformed Algebra approach then becomes:

$$v_k''(\eta) + \left(\Omega(\eta)a^2(\eta)\mathcal{F}(k_\varphi)^2 - \frac{z_{T/S}''(\eta)}{z_{T/S}(\eta)}\right) v_k(\eta) = 0, \tag{2}$$

where $\Omega(\eta) = 1 - 2\rho(\eta)/\rho_c$. It is usually thought that the Deformed Algebra approach is excluded by data because of an exponential increase of the power spectra in the ultraviolet regime due to the $\Omega$ factor. One should however keep in mind that what is excluded is just a very specific scenario in which anisotropies, backreaction, and more importantly the trans-planckian problem, have been neglected. Namely we have shown that considering the MDR

$$\mathcal{F}(k_\varphi) = k_0 \tanh\left[\left(\frac{k_\varphi}{k_0}\right)^p\right]^{\frac{1}{p}} = k_0 \tanh\left[\left(\frac{k_c}{a(t)k_0}\right)^p\right]^{\frac{1}{p}}, \tag{3}$$

where $k_0$ is the transition scale in physical coordinates and $p$ determines the sharpness of the transition, cures the pathological behaviour of the deformed algebra, and leads to almost scale-invariant spectra in the observed regime both for tensor and scalar perturbations, as it can be seen in Figs. 1 and 2.

This is a significant result in the sense that the Deformed Algebra approach is now shown, when trans-planckian effects are taken into account, to be possibly in agreement with data. This also shows that the spectra are actually highly sensitive to quantum gravity effects and a better understanding of the trans-planckian behaviour from the full LQG theory is necessary to go ahead in this direction.

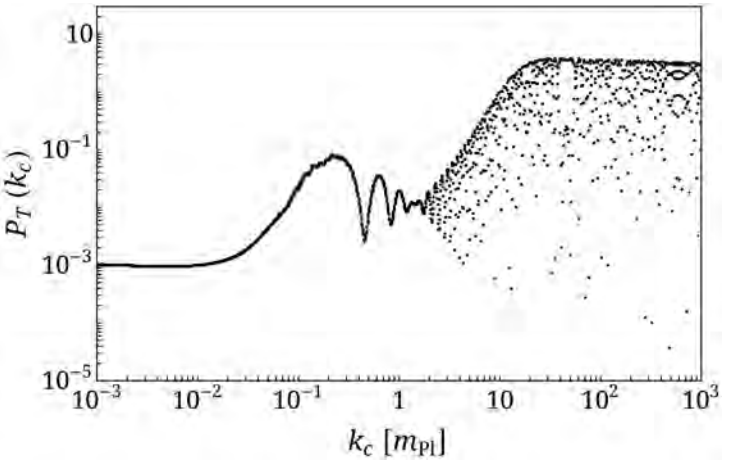

Fig. 1. Primordial tensor power spectrum in the deformed algebra approach with the Unruh-like MDR $\mathcal{F}(k_\varphi) = k_0 \tanh\left[(k_c/(a(t)k_0))^p\right]^{1/p}$, $k_0 = 10$ and $p = 1$.

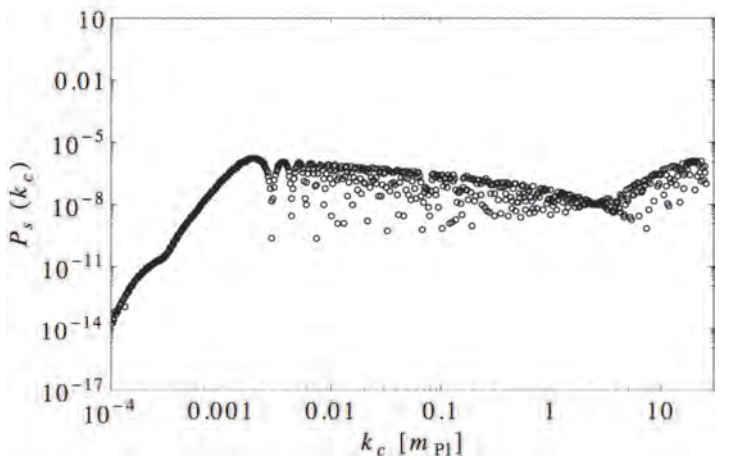

Fig. 2. Primordial scalar power spectrum in the deformed algebra approach with the Unruh-like MDR $\mathcal{F}(k_\varphi) = k_0 \tanh\left[(k_c/(a(t)k_0))^p\right]^{1/p}$, $k_0 = 10$ and $p = 1$.

Loop Quantum Cosmology has recently been applied to extend the analysis of primordial perturbations to the Planck era. Two approaches to Loop Quantum Cosmology leading to predictions that can be compatible with observations are the so-called hybrid and dressed metric approaches. In spite of their similarities, we show that the effective equations that they provide for the evolution of the perturbations are different. When backreaction is neglected, the discrepancy appears only in the time-dependent mass term of the corresponding field equations. We explain the origin of this difference.

*Keywords*: Loop Quantum Cosmology, Cosmological Perturbations.

## 1. Introduction

The present era of precision cosmology is opening potential windows to falsify alternative theories of gravity, including those that contain quantum effects. One of these theories is Loop Quantum Cosmology (LQC).[1] By applying the methods of Loop Quantum Gravity, LQC enables us to extend the study of cosmological perturbations beyond the onset of inflation. In particular, in LQC there exist physical states that are peaked on effective trajectories which avoid the Big Bang singularity by means of a quantum bounce, known as the Big Bounce.[1]

Two approaches to LQC that have a conventional ultraviolet behaviour and have led so far to predictions compatible with the observations are the so-called hybrid[2–5] and dressed metric[6] approaches. In both of them, quantum geometry effects around the bounce change not only the cosmological evolution, but also the propagation of the perturbations and their vacuum. Moreover, in both cases the primordial perturbations can be described by a collection of "harmonic" oscillators with a time-dependent mass. The aim of this work is to show that those masses are different, and therefore the evolution of the perturbations and the imprints left on them by quantum effects can differ. We use units with $c = \hbar = 1$.

## 2. Cosmological Perturbations in Loop Quantum Cosmology

We start with a homogeneous and isotropic cosmology with flat compact sections, with metric $ds^2 = -N_0^2(t)dt^2 + a^2(t)\ {}^0h_{ij}d\theta_i d\theta_j$. The angular coordinates $\theta_i$ have a period $l_0$, $a$ is the scale factor, ${}^0h_{ij}$ the Euclidean metric, and $N_0$ the lapse. We include a homogeneous scalar field, the inflaton, subject to a potential $V(\phi)$.

The phase space of this cosmology can be described with the canonical pairs $(a, \pi_a)$ and $(\phi, \pi_\phi)$. In LQC it is usual to replace $(a, \pi_a)$ with the pair[1] $(v, b/2)$,

where $v$ is the volume of the spatial sections, up to a constant, and $b$ is proportional to the Hubble parameter; $a^3 = 2\pi G\gamma\sqrt{\Delta_g}|v|/l_0^3$ and $a\pi_a = -3vb/2$. The sign of $v$ determines the orientation of the triad, $\gamma$ is the Immirzi parameter, and $\Delta_g$ is the area gap (the minimum positive area eigenvalue allowed by Loop Quantum Gravity).[1]

To consider small anisotropies and inhomogeneities, we next introduce perturbations in the geometry and the inflaton.[2] We expand them in scalar, vector, and tensor harmonics (of the spatial Laplacian) taking advantage of the background symmetries.[3] This perturbed cosmology is the system that we are going to analyze.

In the hybrid approach, one starts the analysis by truncating the action at quadratic order in perturbations. Zero modes are treated exactly at this order. After the truncation, the system can be shown to be symplectic and subject to constraints, inherited from General Relativity (GR).[3] Moreover, at our perturbation order, one can introduce canonical variables that include a gauge-invariant set for the perturbations [namely, the tensor modes and the Mukhanov-Sasaki (MS) scalar] and corrected zero modes, the rest of variables being perturbative constraints and gauge degrees of freedom.[3] The corrected zero modes differ from the original ones in quadratic perturbative contributions that can be understood as backreaction terms. In the following, we will adopt the same notation for the original and the corrected zero modes, to simplify the discussion and because we will assume that backreaction does not play an important role in our states.

Physical states depend only on zero modes and perturbative gauge invariants. In the hybrid approach, these states are still subject to a global constraint. It is the zero mode of the Hamiltonian constraint, obtained from that of the homogenous cosmology, $H_0$, by adding to it the Hamiltonians of the tensor and MS modes. To find solutions, it is common to adopt an ansatz with separation of variables in the different gauge invariants and the homogeneous geometry, with the inflaton viewed as an internal time (so that each partial state can vary with it). Moreover, as part of the ansatz, we consider states of the homogeneous geometry that are: 1) supported on the superselection sectors of homogenous LQC;[3] 2) solutions to homogeneous LQC (thus, we ignore the possible backreaction of the perturbations); and 3) peaked on trajectories of the so-called effective LQC dynamics.[1]

We recall that in LQC the connection variable $b$ does not admit a straightforward operator representation, and needs to be represented in terms of holonomies, which have elements of the form $e^{\pm ib/2}$. In practice, this has the effect of replacing the powers of $b$ in the Hamiltonian constraint by powers of sine functions. For the homogeneous cosmology, instead of $H_0$, the resulting effective Hamiltonian is $H_0^{eff} = [\pi_\phi^2 - 3\pi G v^2 \sin^2 b + 8\pi^2 G^2\gamma^2\Delta_g v^2 V(\phi)]/(4\pi G\gamma\sqrt{\Delta_g}v)$. The corresponding dynamics corrects the trajectories of GR.[1] In the rest of our discussion, we are going to consider precisely such effective trajectories.

If we define the density and pressure of the inflaton as in the homogenous case, i.e. $\rho = V(\phi) + \pi_\phi^2/(8\pi^2 G^2\gamma^2\Delta_g v^2)$ and $P = \rho - 2V(\phi)$, from the fact that the

volume has a minimum at the bounce one can check that the density reaches there a maximum,[1] known as the critical density: $\rho_{max} = 3/(8\pi G\gamma^2\Delta_g)$. Note also that, since the kinetic energy of the inflaton is positive, the potential contribution can never be larger than the density, and hence $V(\phi) \leq \rho_{max}$.

On effective trajectories of LQC, one gets in the hybrid approach a constraint for the perturbations that, in conformal time (with the corresponding derivative indicated with a prime), leads to the following mode equations:[4,5]

$$d''_{\vec{k},\epsilon} + \left[k^2 - \frac{4\pi G}{3}a^2(\rho - 3P)\right] d_{\vec{k},\epsilon} = 0, \quad v''_{\vec{k}} + \left[k^2 - \frac{4\pi G}{3}a^2(\rho - 3P) + \tilde{U}\right] v_{\vec{k}} = 0,$$

for the tensor modes $d_{\vec{k},\epsilon}$ and the modes $v_{\vec{k}}$ of the MS scalar, respectively. Here, $\vec{k}$ is the (constant) wave vector, $k$ is its norm, and $\epsilon$ indicates the two polarizations of the tensor perturbations. Besides, for the MS scalar, we have defined

$$\tilde{U} = a^2\left[V_{,\phi\phi} + \frac{8\pi G\gamma\sqrt{\Delta_g}}{l_0^3 a^3}\frac{\sin(2b)}{\sin^2 b}\pi_\phi V_{,\phi} + 48\pi G V(\phi) - \frac{128\pi^2 G^2\gamma^2\Delta_g}{\sin^2 b}V^2(\phi)\right].$$

We will refer to this function as the MS potential. The ratio of sine functions in $\tilde{U}$ appears because, in the hybrid quantization, one must adopt a prescription that respects the homogeneous superselection sectors, as we will further explain below.[5] The comma followed by $\phi$ denotes the derivative with respect to the inflaton.

We will call time-dependent mass the k-indepedent term that multiplies the perturbation mode in these equations of harmonic-oscillator type. In particular, for $d_{\vec{k},\epsilon}$ this mass can be rewritten as $4\pi G a^2(3P - \rho)/3 = -(\{a\{a, H_0\}, H_0\})_{eff}$, where the result of the double Poisson bracket with the generator of the homogenous dynamics, $H_0$, must be evaluated on effective trajectories after its computation.[8]

The dynamical equations for the gauge invariant perturbations in GR are actually very similar to those displayed above. In the case of GR, the MS potential is provided by the following slightly different function

$$U = a^2\left[V_{,\phi\phi} - 12\frac{\pi_\phi}{a\pi_a}V_{,\phi} + 48\pi G V(\phi) - \frac{72 l_0^6}{\pi_a^2}a^4 V^2(\phi)\right],$$

and the time-dependent mass of the tensor modes, though given by the same double Poisson bracket, is not evaluated on effective trajectories, but on Einsteinian ones.

Let us now discuss the dressed metric approach. In this case, one first imposes as a constraint the zero mode of the Hamiltonian in homogeneous LQC, $H_0$. Therefore, no backreaction is contemplated. Peaked solutions of this constraint determine a dressed metric, which incorporates quantum corrections. This homogeneous peak trajectory is then lifted to the truncated phase space, obtaining dynamical equations for the tensor and MS modes.[6] In the description of these gauge-invariant perturbations in the dressed metric approach, one often uses mode coefficients $T^{(\epsilon)}_{\vec{k}}$ and $Q_{\vec{k}}$ that are related by a scaling to the variables that satisfy equations of the harmonic-oscillator type: $T^{(\epsilon)}_{\vec{k}} = \sqrt{32\pi G l_0^3}\, d_{\vec{k},\epsilon}/a$ and $Q_{\vec{k}} = l_0^{3/2} v_{\vec{k}}/a$ (this scaling can be completed into a canonical transformation; for details see Ref. 5). After the

scaling one gets, in the corresponding conformal time, propagation equations that are similar to those of the hybrid approach, but with the time-dependent mass of the tensor modes and the MS potential replaced, respectively, with[8]

$$-\{a\{a,H_0^{eff}\},H_0^{eff}\} = 4\pi G a^2 P\left(1-2\frac{\rho}{\rho_{max}}\right) - \frac{4\pi G}{3}a^2\rho\left(1+2\frac{\rho}{\rho_{max}}\right),$$

$$W = a^2\left[V_{,\phi\phi} - 2\sqrt{f}V_{,\phi} + fV(\phi)\right], \quad f = \frac{48\pi G\pi_\phi^2}{\pi_\phi^2 + l_0^6 a^6 V(\phi)}.$$

We end with a caveat. Compatibility of the expression of $W$ with the value of the MS potential in GR requires that the sign of $\sqrt{f}$ coincides with the sign of $\pi_\phi/\pi_a$, which changes from collapsing to expanding branches in effective trajectories.[7,8]

## 3. Differences in The Time-Dependent Mass

We can now specify and explain the difference between the time-dependent masses of the hybrid and the dressed metric approaches. Let us start with the mass of the tensor perturbations. This mass is in fact minus the second derivative of the scale factor with respect to the conformal time, divided by the scale factor.[8] The difference arises because in the hybrid approach one obtains this second derivative in terms of canonical expressions, which are evaluated on the effective trajectory only at the very end of the calculation, whereas in the dressed metric approach the derivatives are computed with the generator of the effective dynamics. Thus, the difference comes from the fact that $(\{a\{a,H_0\},H_0\})_{eff} \neq \{a\{a,H_0^{eff}\},H_0^{eff}\}$.

Consider now the time-dependent mass of the MS scalar which, compared to the mass of the tensor modes, includes the MS potential as an additional contribution. Differences in this potential appear only in the term proportional to $V_{,\phi}$. On the one hand, as we have commented, its coefficient must have the sign of $-\pi_\phi/\pi_a$, something that is granted in the hybrid approach, but that in the dressed metric approach requires a cautious definition of the square root of $f$. On the other hand, this coefficient is not exactly the same in the two approaches. This is due to the different prescriptions adopted to represent the function $1/b$.[8] In fact, in GR the coefficient is $-12a\pi_\phi/\pi_a = 8a^2\pi_\phi/(vb)$. This becomes $8\pi G\gamma\sqrt{\Delta_g}\pi_\phi \sin(2b)/(l_0^3 a\sin^2 b)$ in the hybrid approach to respect the homogeneous superselection sectors (and assure a non-negative denominator).[8] In the dressed metric approach, however, it has the effective counterpart $16\pi G\gamma\sqrt{\Delta_g}\pi_\phi/(l_0^3 a\sin b)$, obtained with the direct promotion of $b$ to $\sin b$ without having to comply with any superselection issue.

It is worth noting that the differences that affect the MS potential are not relevant for kinetically dominated solutions, on which the inflaton potential has a small influence. This type of solutions are of the greatest interest in LQC, because they may lead to power spectra for the fluctuations that are compatible with the observations while retaining quantum features at large scales. These features were considered e.g. in Ref. 5 for the case of a quadratic potential, with a mass of $1.2\times10^{-6}$ Planck units. In the following, we will call $s^{(t)}$, $s^{(s)}$, $\breve{s}^{(t)}$, and $\breve{s}^{(s)}$ the time-dependent masses of the tensor (t) and scalar (s) modes in the hybrid and

the dressed metric approaches, respectively. With kinetic dominance, therefore, the tensor and scalar masses are almost identical. However, the masses of the hybrid and the dressed metric approaches are in general significantly different around the bounce, owing to the effects of the two distinct generators of the homogenous dynamics.[8]

On the other hand, in the effective trajectories of LQC the Big Bounce provides a distinguished spatial section that can be used to set initial conditions. The positivity of the time-dependent mass at the bounce becomes then a relevant issue, because the initial oscillatory or exponential behavior of the modes far from the ultraviolet sector depends just on it. Moreover, a negative mass can be an obstacle to impose initial conditions corresponding to adiabatic vacuum states, determined by a frequency $\Omega_k$ that is defined iteratively as a solution of a differential equation, starting with the value $\sqrt{k^2+s}$, where $s$ is the time-dependent mass.[4,5]

Since the density of the inflaton equals its critical value $\rho_{max}$ at the bounce, the pressure is determined there by the potential. Therefore, the tensor mass depends only on the potential at the bounce, $V_B$. We get[8] $s_B^{(t)}/(8\pi G a_B^2) = -V_B + \rho_{max}/3$ and $\breve{s}_B^{(t)}/(8\pi G a_B^2) = V_B - \rho_{max}$, where $a_B$ is the scale factor at the bounce. From this, we see that the mass is positive in the hybrid approach for $V_B \in [0, \rho_{max}/3]$, which includes the interesting sector of kinetic dominance. However, the mass of the dressed metric approach can never be positive at the bounce, since $V_B \leq \rho_{max}$.

We analyze now the scalar mass in the hybrid approach. The corresponding MS potential at the bounce has a quadratic expression in terms of $V_B$, namely $U_B = a_B^2[V^B_{,\phi\phi} + 48\pi G V_B - 128\pi^2 G^2\gamma^2\Delta_g V_B^2]$. Let us consider non-negative inflaton potentials, and treat the second derivative at the bounce $V^B_{,\phi\phi}$ as a non-negative parameter. Actually, in the case of a quadratic potential, this derivative is just the inflaton mass. The expression of $s^{(s)}$ is also a quadratic polynomial, with only one positive root, $x_+ = (5 + \sqrt{33 + 8\gamma^2\Delta_g V^B_{,\phi\phi}})\rho_{max}/12$. It is not difficult to check[8] that, with our assumptions, the mass is positive for $V_B \leq x_+$. This includes the region of kinetic dominance. Besides, since $x_+ \geq x_+(V^B_{,\phi\phi} = 0) \approx 0.895$, we can assure that the mass is always positive for $V_B \in [0, 0.895\,\rho_{max}]$.

For the case of the dressed metric approach, the MS potential at the bounce is $W_B = a_B^2[V^B_{,\phi\phi} \pm 16\pi G\gamma\sqrt{\Delta_g}(|\phi'_B|/a_B)V^B_{,\phi} + 48\pi G V_B - 128\pi^2 G^2\gamma^2\Delta_g V_B^2]$. Let us assume that $\left|V^B_{,\phi}\right| \leq C\sqrt{2V^B_{,\phi\phi}V_B}$, for a certain quantity $C \equiv C(V^B_{,\phi\phi})$ of the order of the unit. Actually, for a mass term, we have $C = 1$. Then we can bound the term of $V^B_{,\phi}$ and, defining the two polynomials of $V_B$ (with $V^B_{,\phi\phi}$ regarded as a parameter) $P_\pm = \breve{s}_B^{(t)} + a_B^2[V^B_{,\phi\phi} + 48\pi G V_B \pm 6C\sqrt{V^B_{,\phi\phi}}/(\gamma\sqrt{\Delta_g}) - 128\pi^2 G^2\gamma^2\Delta_g V_B^2]$, we conclude[8] that $P_- \leq \breve{s}_B^{(s)} \leq P_+$. Moreover, for small $\gamma^2\Delta_g V^B_{,\phi\phi}$, the roots of these polynomials satisfy $y_-(P_+) \leq y_-(P_-) \leq y_+(P_-) \leq y_+(P_+)$. Indeed, for a mass term as the inflaton potential, and values of the inflaton mass close to that considered in Ref. 5, one gets $\gamma^2\Delta_g V^B_{,\phi\phi} \approx 10^{-12}$, which is certainly very small. For such negligible values, the lowest root of the analyzed polynomials is $y_-(P_+) \approx \rho_{max}/6$.

As a consequence, the time-dependent mass of the scalar modes in the dressed metric approach is negative for $V_B \in [0, y_-(P_+)] \approx [0, \rho_{max}/6]$. In addition, for negligible $\gamma^2 \Delta_g V^B_{,\phi\phi}$, one can show that $\breve{s}^{(s)}_B$ is negative in the interval $[y_+(P_+), \rho_{max}]$ around the region of potential dominance.[8]

## 4. Conclusions

We have seen that the hybrid and the dressed metric approaches lead to different time-dependent masses for the cosmological perturbations, and therefore they predict different departures from GR in the early evolution of the primordial fluctuations. The most relevant difference is a consequence of the tension between the canonical methods and the effective dynamics when computing time derivatives in the expression of the tensor mass. There exist other differences arising from the distinct quantization prescriptions adopted for the term proportional to the derivative of the inflaton potential in the scalar mass, but this are not important in scenarios with kinetic dominance. Particularizing our study to the Big Bounce, we have seen that the time-dependent mass is positive in the hybrid approach in an ample sector of solutions that contains all kinetically dominated ones. Around those solutions, however, the mass is negative for the dressed metric approach. This negativity may be an obstruction for the definition of initial conditions for certain vacua.

Some recent results on black holes in effective loop quantum gravity are presented. Quantum gravity effects might allow the transition of a black hole into a white hole, when the Planck density is reached. I briefly review previous studies and focus on the random nature of the bouncing lifetime which was not previously taken into account. I show that, when we consider a stochastic lifetime, the signal emitted by bouncing black holes might explain fast radio bursts. Then, I present new results on the absorption cross sections calculated for a quasi Schwarzschild black hole including loop quantum gravity corrections. The black hole geometry deformation due to quantum effects has consequences for the cross sections and the Hawking spectrum.

*Keywords*: Black hole, quantum gravity, quantum field theory.

## 1. Bouncing black holes

This part is based on [1]. A bouncing black hole (BH) is described by a classical collapsing solution which is linked to the classical exploding one by a quantum tunneling. It was argued [2, 3] that a BH of mass M would have a lifetime in the order of $M^2$. Because of the quantum nature of the process, the lifetime of a bouncing BH should be considered as a random variable. The mean lifetime of a BH would be $\tau = kM^2$, with $k$ chosen to be around 0.05 [2]. The probability that a BH has not bounced yet after a time $t$ is given by $P(t) = \frac{1}{\tau}e^{-\frac{t}{\tau}}$. This is similar to the usual nuclear decay behavior. We focus on local effects and consider primordial black holes (PBHs) as we are interested in BH bouncing in the contemporary universe. The number of BHs bouncing after the Hubble time $t_H$ in a time interval $dt$ is

$$dN = \frac{N_0}{kM^2}e^{-\frac{t_H}{kM^2}}dt, \tag{1}$$

where $N_0$ is the initial abundance. The initial differential mass spectrum of the considered PBHs is given by $dN/dM$. Photons emitted have a characteristic wavelength in the order of the size of the BH. The shape of the signal emitted by a single BH is assumed to be given by a Gaussian function:

$$\frac{dN_\gamma^{BH}}{dE} = Ae^{-\frac{(E-E_0)^2}{2\sigma_E^2}}, \tag{2}$$

where $E_0 = 1/(2R_S) = 1/(4M)$, with $R_S$ the Schwarzschild radius. The width is fixed to be $\sigma_E = 0.1E_0$ but the results do not critically depend on this value.

The full signal due to a local distribution of bouncing BHs is given by

$$\frac{dN_\gamma}{dE} = \int_{M_{Pl}}^{\infty} Ae^{-\frac{(E-E_0)^2}{2\sigma_E^2}} \cdot \frac{dN}{dM}(M) \cdot \frac{1}{kM^2} e^{-\frac{t_H}{kM^2}}. \tag{3}$$

We considered two types of mass spectra for the PBHs. The first one is peaked around a value $M_0$ (4). It is justified if the PBHs are created during a phase transition [4], for exemple. The second one is quite wide (5). It could be explain if PBHs are produced by a scale-invariant density pertubations in a perfect fluid [5]. In that case the spectrum is proportional to $M^\alpha$. Here we considered $\alpha$ as an unknown parameter.

$$\frac{dN}{dM} \propto e^{-\frac{(M-M_0)^2}{2\sigma_M^2}}, \tag{4}$$

$$\frac{dN}{dM} \propto M^\alpha. \tag{5}$$

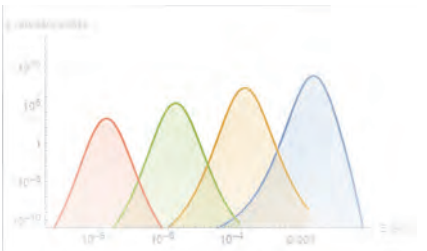

Fig. 1. Differential electromagnetic flux emitted by bouncing PBHs for a central mass $M_0$ equal (from right to left) to $M_{t_H}$, $10M_{t_H}$, $100M_{t_H}$, and $1000M_{t_H}$.

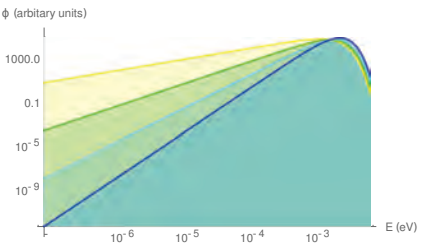

Fig. 2. Signal expected from a wide mass spectrum, with $\alpha = \{-3, -2, -1, 0\}$ from the lower curve to the upper curve at $10^{-6}$ eV.

In Fig. 1, the expected emitted flux is shown for different values of the central mass $M_0$. Actually the mean energy of the signal might not be the one naively expected: $E \sim 1/4M_{t_H}$ with $M_{t_H}$ the mass satisfying $t_H = kM_{t_H}^2$ (corresponding to BHs with a mean lifetime equal to the age of the universe). Because of the stochastic nature of the process, the mean energy of the emitted signal can be different from the one obtained in previous studies. The central mass $M_0$ can in principle be different than $M_{t_H}$. If the mass spectrum is peaked around masses higher than $M_{t_H}$, it is possible to have a signal in the energy range of the fast radio bursts (FRBs): the curve on the left in Fig. 1 is peaked around $10^{-6}$ eV. It was not the case when the lifetime was taken to be deterministic. Then, in Fig. 1, we observe that the mean signal highly depends on the value of the peak mass and at this stage, there is no obvious motivation for choosing a specific value. In Fig. 2, we present the expected signal for a wide spectrum. The shape of the mass spectrum does influence the shape of expected signal as the probabilistic nature of the lifetime is now taken into account: BHs with masses smaller or larger than $M_{t_H}$ do also contribute to the emitted radiation and changing their relative weights influences the result. Because of the probabilistic lifetime, we could observed a

signal in FRBs energy range. As a conclusion, one should expect a higher flux as the energy increases (up to the infrared band). The slope of the signal spectrum reflects that of the mass spectrum.

The key point of this study was to show that the randomness of the lifetime of BHs in quantum gravity can drastically change the spectral characteristic of the expected signal and can lead to predictions.

## 2. Emission cross section for loop black holes

The Hawking evaporation process [6] predicts that BHs emit a blackbody spectrum at temperature $T_H = 1/(8\pi M)$, with M the mass of the BH. However, the real spectrum is slightly more complicated because the emitted particles have to cross a potential barrier before escaping to infinity. This induces a modification, captured by the cross section $\sigma$, it encode information on the spacetime structure considered. The spectrum reads as:

$$\frac{dN}{dt} = \frac{1}{e^{\frac{\omega}{T_H}} \pm 1}\sigma(M, s, \omega)\frac{d^3k}{(2\pi)^3}, \tag{6}$$

with $s$ the particle spin and $\omega$ its energy. We have calculated this cross section for an effective loop BH [7]. The resulting metric (7) is obtained by considering a minisuperspace, based on polymerization procedure. It take into account that, in LQG, there is a minimal area.

$$ds^2 = -G(r)dt^2 + \frac{dr^2}{F(r)} + H(r)d\Omega^2, \tag{7}$$

$$G(r) = \frac{(r - r_+)(r - r_-)(r + r_*)^2}{r^4 + a_0^2}, \tag{8}$$

$$F(r) = \frac{(r - r_+)(r - r_-)r^4}{(r + r_*)^2(r^4 + a_0^2)}, \tag{9}$$

$$H(r) = r^2 + \frac{a_0^2}{r^2}, \tag{10}$$

with $a_0 = \frac{\sqrt{3}\gamma l_{Pl}^2}{2}$. There are two horizons $r_+ = 2M$ and $r_- = 2MP^2$, $r_* = \sqrt{r_+ r_-} = 2MP$ and $d\Omega^2 = d\theta^2 + sin^2\theta d\phi^2$. $\gamma$ is the Barbero-Immirzi parameter, $P = (\sqrt{1+\epsilon^2} - 1)$ is the polymeric function, $\epsilon = \gamma\delta$, with $\delta$ the polymeric parameter. With $a_0 = 0$, the metric (7) tends to the Schwarzschild one when $\delta$ tends to zero. According to the optical theorem [8], the cross section reads

$$\sigma(\omega) = \sum_{l=0}^{\infty} \frac{(2j+1)\pi}{\omega^2}|A_l|^2, \tag{11}$$

where $A_l$ is the transmission coefficient of the angular momentum mode $l$, and $j = l + s$ is the total angular momentum.

### 2.1. *Massless scalar field*

Considering the underlying symmetries, the scalar field can be written as $\Phi(r, \theta, \phi, t) = R(r)A(\theta)e^{i(\omega t + m\phi)}$, where $\omega$ is the frequency and $m$ is an integer.

The dynamics of a massless scalar field minimally coupled to a gravitational field is described by the generalized Klein-Gordon equation. With the metric (7) we obtain the radial equation (12):

$$\frac{\sqrt{GF}}{H}\partial_r\left(H\sqrt{GF}\partial_r R\right)+\left(\omega^2-\frac{G}{H}l(l+1)\right)R=0. \tag{12}$$

We define the tortoise coordinate $r^*$: $dr^*=dr/\sqrt{GF}$. At the horizon $r_+$, the radial part of the wave function $R^h$ will be a plane wave (13) with respect to $r^*$. At infinity, the radial wave function $R^\infty$ is a spherically wave (14):

$$R^h(r^*)=A^h_{in}e^{-i\omega r^*}+A^h_{out}e^{i\omega r^*}, \tag{13}$$

$$R^\infty(r)=\frac{A^\infty_{in}}{r}e^{-i\omega r}+\frac{A^\infty_{out}}{r}e^{i\omega r}, \tag{14}$$

with $A^h_{in}$ (respectively $A^h_{out}$) the probability amplitude for the incoming modes (resp. outgoing modes) at the horizon. Same definitions for $A^\infty$ at the infinity. For convenience, we choose the absorption point of view. With this convention, there are incoming and outgoing modes infinitively far from the BH and only incoming ones at the horizon. We therefore impose $A^h_{out}=0$. With the asymptotic solutions and by solving the differential equation (12), we obtained numerically the transmission amplitude from which the cross section can be obtained:

$$|A_l|^2=1-\left|\frac{A^\infty_{out}}{A^\infty_{in}}\right|^2. \tag{15}$$

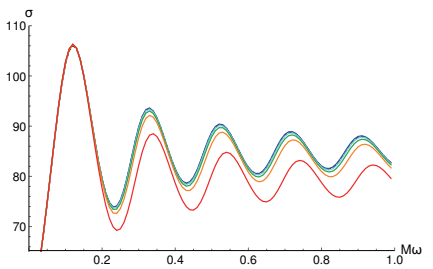

Fig. 3. Emission cross section for a scalar field with energy $\omega$ in the background spacetime of a loop BH of mass $M$ for different values of $\epsilon$ ($\epsilon=\gamma\delta$ measures the "quantumness" of spacetime). From bottom to top: $\epsilon=10^{\{-0.3,-0.6,-0.8,-1,-3\}}$. The blue line, corresponding to $\epsilon=10^{-3}$, is superposed with the cross section for a Schwarzschild BH.

In Fig. 3 we observe that the cross section does decrease when $\epsilon$ increases. When $\epsilon<10^{-0.8}$ it is hard to distinguish between the solutions. It therefore seems that taking into account the quantum correction does not influence the cross section of a scalar field for reasonable value of $\epsilon$, that is $\epsilon<<1$. However, the main trend is clear.

### 2.2. *Massless spin $\frac{1}{2}$ field*

For spin-$\frac{1}{2}$ fields, we have used the Newman-Penrose formalism [9]. We choose the following basis:

$$l^i = \frac{1}{\sqrt{2}}\left(\frac{1}{\sqrt{G}}, -\sqrt{F}, 0, 0\right), \quad n^i = \frac{1}{\sqrt{2}}\left(\frac{1}{\sqrt{G}}, \sqrt{F}, 0, 0\right),$$
$$m^i = \frac{1}{\sqrt{2}}\left(0, 0, \frac{1}{\sqrt{H}}, \frac{i}{\sqrt{H}sin\theta}\right), \quad \overline{m}^i = \frac{1}{\sqrt{2}}\left(0, 0, \frac{1}{\sqrt{H}}, \frac{-i}{\sqrt{H}sin\theta}\right)$$

Then we calculate the spin coefficients. The wavefunction is represented by a pair of spinors, $P^A$ and $\overline{Q}^{A'}$ with $A = 0, 1$ and $A' = 0, 1$. We use the ansatz

$$P^0 = \frac{e^{i(\omega t + m\phi)}}{\sqrt{H(r)}(G(r)F(r))^{\frac{1}{8}}} R_+(r)S_+(\theta), \quad P^1 = \frac{e^{i(\omega t + m\phi)}}{\sqrt{H(r)}(G(r)F(r))^{\frac{1}{8}}} R_-(r)S_-(\theta),$$
$$\overline{Q}^{0'} = -\frac{e^{i(\omega t + m\phi)}}{\sqrt{H(r)}(G(r)F(r))^{\frac{1}{8}}} R_+(r)S_-(\theta), \quad \overline{Q}^{1'} = \frac{e^{i(\omega t + m\phi)}}{\sqrt{H(r)}(G(r)F(r))^{\frac{1}{8}}} R_-(r)S_+(\theta).$$

Following the Chandrasekhar procedure [10], we obtain the radial equation

$$\sqrt{HF}\mathcal{D}\left(\sqrt{HF}\mathcal{D}^\dagger R_+\right) - \lambda^2 R_+ = 0, \quad \text{with} \quad \mathcal{D} = \partial_r + \left(\frac{G'}{8G} - \frac{F'}{8F}\right) + \frac{iw}{\sqrt{GF}}, \tag{16}$$

and $\lambda = l + 1$ a separation constant. At the horizon, the solution at the horizon reads as:

$$R_+(r^*) = A_1 e^{x_1 r^*}, \tag{17}$$

with $A_1$ a complex number and $x_1$ a complex number with a positive imaginary part. As before, we normalize such that $R_+(r_{ini}) = 1$, which leads to $\frac{dR_+(r_{ini})}{dr} = \frac{x_1}{\sqrt{G(r_{ini})F(r_{ini})}}$. At spacial infinity, the solution is a plane wave.

It has been shown in [11] that the transmission coefficient for spin 1/2 fields is given by:

$$|A_l|^2 = \left|\frac{A^h_{in}}{A^\infty_{in}}\right|^2. \tag{18}$$

By the same procedure described in the scalar field section, we obtain the cross section

In Fig. 4 we observe that the general trend is to decrease the cross section when the quantum correction increases. This should leave a footprint through a distortion of the instantaneous Hawking spectrum which will exhibit slight suppression of its UV tail because the relative effect is getting bigger with an increasing energy of the emitted particle. For scalar and fermionic fields, the trend is clear but the effects are

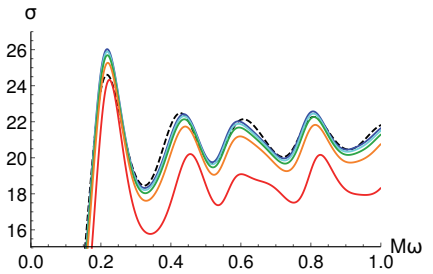

Fig. 4. Emission cross section for a fermionic field, with energy $\omega$, in the background spacetime of a LBH of mass $M$. From bottom to top: $\epsilon = 10^{\{-0.3,-0.6,-0.8,-1,-3\}}$. The dashed dark curve corresponds to the Schwarzschild cross section.

generically small. From the phenomenological point of view, if the polymerisation parameter is large we could probe a decreased cross section.

We summarize our investigations of the second-order perturbations in loop quantum cosmology (LQC). We shall discuss, primarily, two aspects. Firstly, whether the second-order contributions arising from the cosmic bounce, occurring at Planck scale, could be large enough to break the validity of perturbation theory. Secondly, the implications of the upper bounds on primordial non-Gaussianity, arrived at by the Planck collaboration, on the LQC phenomenology.

*Keywords*: Loop quantum cosmology; Primordial non-Gaussianity.

## 1. Introduction

Loop quantum cosmology (LQC) provides an extension of the inflationary paradigm to the Planck era (see, for instance, Ref. 1). Over the past decade or so, there has been a research program aimed at investigating the viability of LQC as a theory of the pre-inflationary universe. Until now, investigations of primordial perturbations generated in LQC have focused mainly at the level of the power spectrum. In this work, we extend the analysis to the level of three-point functions, namely, the bispectrum of curvature perturbations. We will analyze primarily two aspects. Firstly, we check whether next-to-leading order corrections to the power spectrum are sub-leading. Secondly, we verify that the amount of non-Gaussianity as quantified by the dimensionless quantity $f_{\rm NL}$ is compatible with the observations of cosmic microwave background (CMB) and investigate new predictions.

## 2. Computation of the Bispectrum in the Dressed Metric Approach

The system of interest is scalar perturbations $\delta\phi$ living on a Friedmann-Lemaître-Robertson-Walker (FLRW) metric sourced by a scalar field $\phi$. In LQC, such a system is described by a wavefunction $\Psi(v, \phi, \delta\phi)$, where $v \equiv a^3\,\mathcal{V}_0\,4/\kappa$ with $a$ being the scale factor and $\mathcal{V}_0$, the volume of the universe, introduced to regulate

infrared divergence. The dynamics is governed by the constraint equation, $\hat{\mathcal{H}}\,\Psi = 0$, where the Hamiltonian operator can be split in to the background and perturbed part as $\hat{\mathcal{H}} = \hat{\mathcal{H}}_{FLRW} + \hat{\mathcal{H}}_{pert}$. We are interested in solutions wherein $\Psi(v,\,\phi,\,\delta\phi) = \Psi_0(v,\,\phi,)\otimes\delta\Psi(v,\,\phi,\,\delta\phi)$, where $\Psi_0$ describes a quantum FLRW geometry and $\delta\Psi$ describes the scalar perturbations.

The states $\Psi_0$ satisfies the equation $\hat{\mathcal{H}}_{FLRW}\,\Psi_0 = 0$. It has been shown that, for states that are sharply peaked in the volume $v$ during the entire evolution, the background geometry can be described by an effective classical Hamiltonian (see e.g. Ref. 1 and references therein). In the dressed metric approach, we are interested in quantum states $\delta\Psi(v,\,\phi,\,\delta\phi)$ that are a small perturbation around such a quantum FLRW state $\Psi_0(v,\,\phi)$. A detailed analysis shows that $\delta\Psi(v,\,\phi,\,\delta\phi)$ are solutions to the Schrödinger equation, $i\hbar\,\partial_\phi\delta\Psi = \langle\Psi_0|\hat{\mathcal{H}}_{\rm pert}[N_\phi]|\Psi_0\rangle\,\delta\Psi$, where $\hat{\mathcal{H}}_{pert} = \hat{\mathcal{H}}^{(2)} + \hat{\mathcal{H}}^{(3)}$, namely the Hamiltonian at second and third order in perturbations respectively and $N_\phi$ is the lapse associated with relational time $\phi$.[2]

We are interested in computing the correlation functions of these scalar perturbations. The first step is to expand the perturbations in Fourier space and introduce creation and annihilation operators

$$\hat{\delta\phi}(\vec{x},\eta) = \int \frac{{\rm d}^3k}{(2\pi)^3}\left(\hat{A}_{\vec{k}}\;\varphi_k(\eta) + \hat{A}^\dagger_{-\vec{k}}\;\varphi^*_k(\eta)\right)e^{i\vec{k}\cdot\vec{x}}, \tag{1}$$

where $[\hat{A}_{\vec{k}},\hat{A}^\dagger_{\vec{k}'}] = \hbar\,(2\pi)^3\,\delta^{(3)}(\vec{k}+\vec{k}')$ and $[\hat{A}_{\vec{k}},\hat{A}_{\vec{k}'}] = 0$. The dynamics of perturbations are governed by the second-order Hamiltonian with the background quantities determined using the effective background Hamiltonian. The scalar power spectrum of $\hat{\delta\phi}$ is defined as

$$\langle 0|\hat{\delta\phi}_{\vec{k}}(\eta)\hat{\delta\phi}_{\vec{k}'}(\eta)|0\rangle \equiv (2\pi)^3\delta^{(3)}(\vec{k}+\vec{k}')\frac{2\pi^2}{k^3}\mathcal{P}_{\delta\phi}(k,\eta)\,, \tag{2}$$

where $|0\rangle$ is the vacuum annihilated by the operators $\hat{A}_{\vec{k}}$ for all $\vec{k}$. For the purpose of relating perturbations to the late time physics, it is convenient to express the power spectrum in terms of comoving curvature perturbations. The power spectrum of curvature perturbation, $\mathcal{R}$, in terms of inflaton perturbation $\delta\phi$, evaluated at the end of inflation is $\mathcal{P}_{\mathcal{R}}(k) \equiv \left(\frac{a(\eta_{\rm end})}{z(\eta_{\rm end})}\right)^2 \frac{\hbar\,k^3}{2\pi^2}\,|\varphi_k(\eta_{\rm end})|^2$, where $z = -\frac{6}{\kappa}\frac{p_\phi}{\pi_a}$ with $\kappa = 8\,\pi\,G$ and $p_\phi$ and $\pi_a$ are momenta conjugate to $\phi$ and $a$ respectively.

The self-interaction of scalar perturbation, at lowest order, is described by the third-order interaction Hamiltonian, $\hat{\mathcal{H}}_{\rm int} \equiv \langle\Psi_0|\hat{\mathcal{H}}^{(3)}[N_\phi]|\Psi_0\rangle$.[3] The perturbations at this order are quantified using the scalar bispectrum, $B_{\mathcal{R}}(k_1,k_2,k_3)$, that is defined in terms of curvature perturbations by

$$\langle 0|\hat{\mathcal{R}}_{\vec{k}_1}\hat{\mathcal{R}}_{\vec{k}_2}\hat{\mathcal{R}}_{\vec{k}_3}|0\rangle \equiv (2\pi)^3\delta^{(3)}(\vec{k}_1+\vec{k}_2+\vec{k}_3)\,B_{\mathcal{R}}(k_1,k_2,k_3)\,. \tag{3}$$

It is often convenient to quantify the bispectrum using a dimensionless function, $f_{\rm NL}$, which can be defined as,

$$B_{\mathcal{R}}(k_1,k_2,k_3) \equiv -\frac{6}{5}\,f_{\rm NL}(k_1,k_2,k_3)\;\times(\Delta_{k_1}\Delta_{k_2} + \Delta_{k_1}\Delta_{k_3} + \Delta_{k_2}\Delta_{k_3})\,, \tag{4}$$

where $\Delta_k \equiv \frac{2\pi^2}{k^3}\,\mathcal{P}_{\mathcal{R}}(k)$ is the dimensionful power spectrum.

In order to compute bispectrum, we need to express it in terms of $\delta\phi$ as follows,

$$\langle 0|\hat{\mathcal{R}}_{\vec{k}_1}\hat{\mathcal{R}}_{\vec{k}_2}\hat{\mathcal{R}}_{\vec{k}_3}|0\rangle = \left(-\frac{a}{z}\right)^3 \langle 0|\hat{\delta\phi}_{\vec{k}_1}\hat{\delta\phi}_{\vec{k}_2}\hat{\delta\phi}_{\vec{k}_3}|0\rangle + \left(-\frac{3}{2} + 3\frac{V_\phi\, a^5}{\kappa\, p_\phi\, \pi_a} + \frac{\kappa}{4}\frac{z^2}{a^2}\right)\left(-\frac{a}{z}\right)^4$$
$$\times\Big[\int \frac{d^3p}{(2\pi)^3}\,\langle 0|\hat{\delta\phi}_{\vec{k}_1}\hat{\delta\phi}_{\vec{k}_2}\hat{\delta\phi}_{\vec{p}}\hat{\delta\phi}_{\vec{k}_3-\vec{p}}|0\rangle + (\vec{k}_1 \leftrightarrow \vec{k}_3) + (\vec{k}_2 \leftrightarrow \vec{k}_3) + \cdots\Big], \tag{5}$$

where the symbols $(\vec{k}_i \leftrightarrow \vec{k}_j)$ indicate terms obtained by replacing $k_i$ with $k_j$ in the first term of the second line and the dots indicate higher order terms. At leading order in perturbations, the first term on RHS can be evaluated using time dependent perturbation theory

$$\langle 0|\hat{\delta\phi}_{\vec{k}_1}(\eta)\hat{\delta\phi}_{\vec{k}_2}(\eta)\hat{\delta\phi}_{\vec{k}_3}(\eta)|0\rangle = \langle 0|\hat{\delta\phi}^{\rm I}_{\vec{k}_1}(\eta)\hat{\delta\phi}^{\rm I}_{\vec{k}_2}(\eta)\hat{\delta\phi}^{\rm I}_{\vec{k}_3}(\eta)|0\rangle$$
$$- i/\hbar \int d\eta' \langle 0|\left[\hat{\delta\phi}^{\rm I}_{\vec{k}_1}(\eta)\hat{\delta\phi}^{\rm I}_{\vec{k}_2}(\eta)\hat{\delta\phi}^{\rm I}_{\vec{k}_3}(\eta), \hat{\mathcal{H}}^{\rm I}_{\rm int}(\eta')\right]|0\rangle\,, \tag{6}$$

where the superscript $I$ indicates fields in the interaction picture. Since, $\delta\phi^I$ is a Gaussian field, the first term vanishes and only the second term contributes. The second term in the RHS of Eq. (5) can be evaluated using Wick's theorem and Eq. (2). Using Eqs. (5) and (6), one can compute the bispectrum and hence the function $f_{\rm NL}$ using Eq. (4).

## 3. Numerical Method and Results

In this section, we will briefly describe our implementation of the formalism for computing $f_{\rm NL}$ and the results we obtain. In order to compute $f_{\rm NL}$ at the end of inflation, one needs to evolve the perturbations from an early time before the bounce until the perturbations leave the horizon during inflation at which point their amplitude freezes in time. We need to make three choices to do this computation. Firstly, we need to specify the potential governing the field $\phi$. We choose the quadratic potential, $V(\phi) = m^2\,\phi^2/2$, where $m = 6.4\times10^{-6} M_{P\ell}$. Secondly, we need to choose a background geometry by specifying the value of $\phi$ and energy density, $\rho$, at the bounce. We work with $\phi_{\rm B} = 7.62\, M_{P\ell}$ and $\rho_B = 1\, M^4_{P\ell}$, where subscript $B$ denotes the bounce, so that the effects due to LQC appear at observable scales while respecting the Planck constraints on power spectrum. Finally, we need to choose an initial state for perturbations, which we choose to be a Minkowski initial state. More specifically, we choose $\varphi_k(\eta_0) = \frac{1}{a(\eta_0)\sqrt{2\,k}}$ and $\varphi'_k(\eta_0) = [-i\,k + \frac{a'(\eta_0)}{a(\eta_0)}]\,\varphi_k(\eta_0)$ as initial data for the modes, at conformal time $\eta_0 = -2.8\times10^3\, T_{P\ell}$ (the bounce takes place at $\eta = 0$). The initial time was chosen so that all the modes of interest, namely those between $k_{\rm min} = k_*/10$, and $k_{\rm max} = 1000 k_*$, where $k_*/a(t_{today}) = 0.002\,{\rm Mpc}^{-1}$ is the pivot scale, were in the adiabatic regime. We have investigated the effects of varying these choices in detail in Ref. 2.

To perform this computation, we use the platform provided by `class`.[4] The computation was done in two stages. In the first stage we evolve the background from very early times to the end of inflation. In the second step, we convert the time integral in Eq. (6) to a differential equation and evolve it together with the differential equation for the fourier modes. In the remaining part of this section, we will discuss the various results.

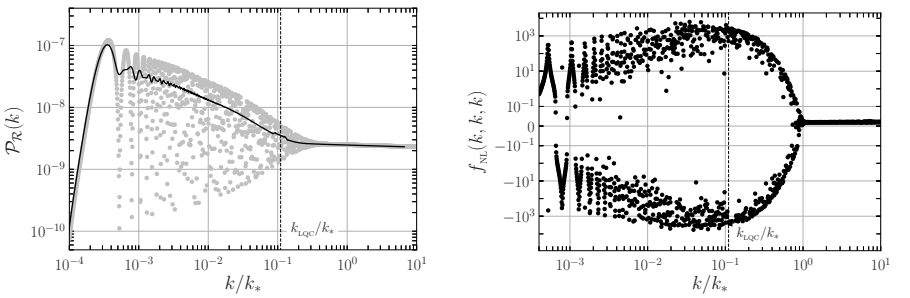

Fig. 1. The power spectrum and $f_{\rm NL}(k_1, k_2, k_3)$ evaluated in the equilateral limit.

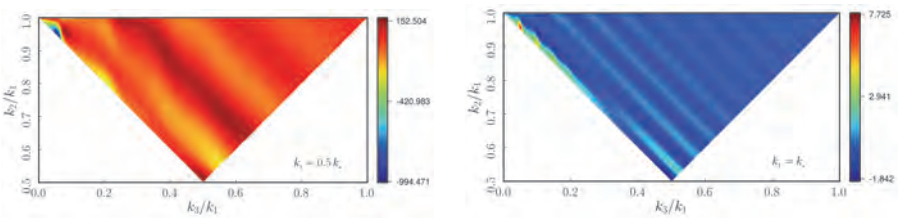

Fig. 2. The shape of the non-Gaussianity, $f_{\rm NL}(k_1, k_2, k_3)$, evaluated with $k_1 = k_*/2$ and $k_*$. The figure shows the portions allowed by the condition $\vec{k}_1 + \vec{k}_2 + \vec{k}_3 = 0$.

Fig. 1 depicts the scalar power spectrum and $f_{\rm NL}$ in the equilateral limit. One can see that for $k \leq k_{\rm LQC}$, where $k_{\rm LQC}$ is the scale set by the spacetime curvature at the bounce, the spectra are strongly scale dependent while for $k >> k_{\rm LQC}$, the spectra approach their slow roll values. At low wave numbers, the figure shows that $f_{\rm NL}$ is oscillatory. We have depicted the $f_{\rm NL}$ for all configurations in Fig. 2. In this figure, we have fixed the value of $k_1$ and varied $k_2$ and $k_3$ in such a way that they obey the triangle condition. This figure illustrates the shape of the non-Gaussianity. It can be seen that, in both the figures, the $f_{\rm NL}$ peaks in the squeezed($k_3 \ll k_1 \simeq k_2$) - flattened ($k_1 \simeq k_2 + k_3$) limit.

The primordial non-Gaussianity generated due to LQC has a characteristic enhancement of amplitude at scales comparable to $k_{\rm LQC}$. By analyzing the integrals involved in the computation of $f_{\rm NL}$, we can estimate the contribution to $f_{\rm NL}$ from the epoch around the bounce. For modes, $k \geq k_{\rm LQC}$, we can approximate the mode function as $\varphi_k \sim e^{-ik\eta}$. Then the contribution to the integral from time around

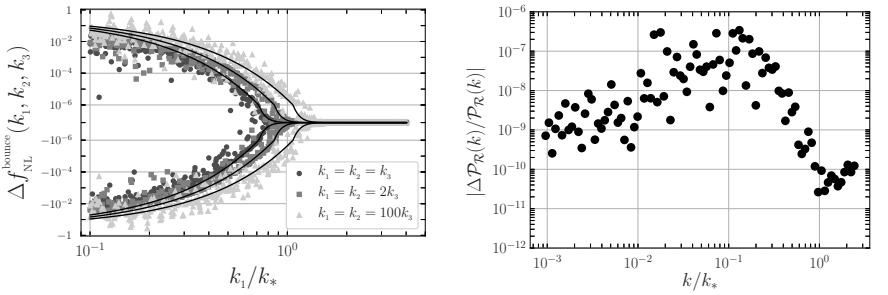

Fig. 3. On left, we have plotted a comparison of the analytical expression, $e^{-\alpha k_t/k_{\rm LQC}}$, for contribution to $f_{\rm NL}$ from the bounce to the numerical result in different configurations. On right, we compute the relative amplitude of the leading order correction to the power spectrum.

the bounce can be schematically written as,

$$I(k_1,k_2,k_3) \sim \int_{-\Delta\eta}^{\Delta\eta} {\rm d}\eta\, g(\eta)\, e^{i(k_1+k_2+k_3)\,\eta} \approx \int_{-\infty}^{\infty} {\rm d}\eta\, g(\eta)\, e^{ik_t\,\eta}\, W(\eta,\Delta), \qquad (7)$$

where, $g(\eta)$ is a combination of the functions depending on the background and the wavenumbers, $k_t \equiv k_1 + k_2 + k_3$ and $W(\eta, \Delta\eta)$ is a window function which selects only the contribution from the time range $-\Delta\eta < \eta < \Delta\eta$. This integral can be computed using Cauchy's residue theorem and the spectral dependence of the integral can be written as $e^{-\alpha k_t/k_{\rm LQC}}$. In Fig. 3, we have compared the analytical expression with numerical result and we find a good match between the two.

Finally let us compute the contribution to the power spectrum from the bispectrum. For the perturbation theory to be valid, this contribution has to be subdominant. The first perturbative correction to the two-point function of curvature perturbation is given by

$$\langle 0|\hat{\mathcal{R}}_{\vec{k}_1}\hat{\mathcal{R}}_{\vec{k}_2}|0\rangle = (2\pi)^3\delta^{(3)}(\vec{k}_1+\vec{k}_2)\,\frac{2\pi^2}{k_1^3}\,\hbar\,\left[\mathcal{P}_\mathcal{R}(k_1) + \Delta\mathcal{P}_\mathcal{R}(k_1)\right], \qquad (8)$$

where

$$\Delta\mathcal{P}_\mathcal{R}(k_1) = \hbar\,\frac{k_1^3}{\pi^2}\left[\left(-\frac{a}{z}\right)^3\left[-\frac{3}{2}+3\frac{V_\phi\,a^5}{\kappa\,p_\phi\,\pi_a}+\frac{\kappa}{4}\frac{z^2}{a^2}\right]\int\frac{{\rm d}^3p}{(2\pi)^3}\,B_{\delta\phi}(\vec{k}_1,\vec{p},-\vec{k}_1-\vec{p})\right.$$
$$\left.+\left(-\frac{a}{z}\right)^4\left[-\frac{3}{2}+3\frac{V_\phi\,a^5}{\kappa\,p_\phi\,\pi_a}+\frac{\kappa}{4}\frac{z^2}{a^2}\right]^2\int\frac{{\rm d}^3p}{(2\pi)^3}\,|\varphi_p|^2\,|\varphi_{|\vec{k}_1-\vec{p}|}|^2\right], \qquad (9)$$

where $B_{\delta\phi}(\vec{k}_1,\vec{p},-\vec{k}_1-\vec{p})$ is the bispectrum of inflaton perturbations and all the quantities on the right are evaluated at the end of inflation. We have numerically ploted the relative amplitude of the first order correction, $|\Delta\mathcal{P}_\mathcal{R}/\mathcal{P}_\mathcal{R}|$, in Fig. 3. We find that, as expected, the magnitude of first-order correction to the power spectrum is negligible. This result can be qualitatively understood as follows. The leading order contribution to $\Delta\mathcal{P}_\mathcal{R}(k_1)$ is given by the first term in Eq. (9) and it is

given by $\epsilon\, f_{\rm NL}\, \mathcal{P}_{\mathcal{R}}^2$, where $\epsilon$ is the slow roll parameter of $\mathcal{O}(10^{-2})$. Since, $f_{\rm NL} \leq 10^4$ and $\mathcal{P}_{\mathcal{R}} \leq 10^{-7}$, we obtain $\Delta\mathcal{P}_{\mathcal{R}}/\mathcal{P}_{\mathcal{R}} \leq 10^{-4}$ as in Fig. 3.

## 4. Discussion

Let us conclude by making some remarks on the robustness of the results and its implication in the light of Planck data. We have verified the robustness of the results to a variation of the basic assumptions discussed in Sec. 3.[2] For instance, we find that the effect of changing $\phi_b$ is only a shift in the scale which is sensitive to the effect of the bounce with respect to the scales observable today. An increase in $\rho_B$ also leads only to a similar shift in the scales sensitive to the curvature of the bounce, in addition, to an increase in amplitude of $f_{\rm NL}$. The Planck mission has put strong constraints on certain models of scale invariant non-Gaussianity, but, it provides little information on the scale dependent non-Gaussianity as produced in LQC.[5] Moreover, since the error bar on $f_{\rm NL}$ goes as $1/\sqrt{\ell}$, at low multipoles, where the non-Gaussianity due to LQC is expected to be large, the error bar would be large. Considering the Planck error bars at low multipoles and demanding that the enhancement in $f_{\rm NL}$ due to the LQC bounce appears at $\ell \lesssim 50$, one could try to arrive at constraints on the minimum value of scalar field at the bounce, for a given value of $\rho_{\rm B}$. Furthermore, by demanding that the imprint of the bounce should be at observable scales, we can arrive at an upper bound on $\phi_B$. For instance, for $\rho_{\rm B} = 1\, M_{\rm Pl}^4$, we obtain $7.46 M_{\rm Pl} \leq \phi_{\rm B} \leq 7.82 M_{\rm Pl}$. It should be kept in mind that the constraint described above is a very conservative estimate. Most probably, the oscillations in $f_{\rm NL}$ will relax the constraint on $\phi_{\rm B}$ discussed above. A more detailed account of this work has been published in Ref. 2.

## Acknowledgments

We thank the organizers for giving VS the opportunity to present this work. VS would also like to thank Inter-University Centre for Astronomy and Astrophysics, Pune for financial support to attend MG XV.

In this proceeding we consider a massive charged scalar field in a uniform electric field background in a de Sitter spacetime (dS). We compute the in-vacuum expectation value of the trace of the energy-momentum tensor for the created Schwinger pairs, and using adiabatic subtraction scheme the trace is regularized. The effect of the Schwinger pair creation on the evolution of the Hubble constant is investigated. We find that the production of the semiclassical pairs leads to a decay of the Hubble constant. Whereas, the production of a light scalar field in the weak electric field regime leads to a superacceleration phenomenon.

*Keywords*: de Sitter Spacetime; Schwinger Effect; Trace of the Energy-Momentum Tensor; Evolution of the Hubble Constant.

## 1. Introduction

In a flat spacetime the phenomenon of the pair creation in a strong electric field background is referred to as the Schwinger effect.[1] The presence of the strong electromagnetic and gravitational fields in the early Universe motivates the study of the Schwinger effect in dS.[2] The Schwinger effect and the induced current of the created pairs were investigated in a uniform electric field for various dimensions of the de Sitter spacetime in Refs. 3, 4, 5, 6, 7. Recently, the effect of a conserved flux magnetic field on the Schwinger effect in dS has been investigated in Ref. 8, see also Ref. 9. Without considering an electromagnetic field, the energy-momentum tensor of the created scalar particles in the gravitational background field of dS has been investigated in Refs. 10, 11, 12, 13, 14, 15, 16, 17, 18. The results of Refs. 10, 15, 16 show that the Hubble constant of dS decays due to the

particle creation. Furthermore, the gravitational backreaction effects of the quantum fluctuations may lead to a superacceleration phase, where the Hubble constant increase.[15] Using a semiclassical approach the energy-momentum tensor of the created Schwinger scalars in a dS has been computed in Refs. 6, 19, which showed that the Hubble constant decays. The trace of the induced energy-momentum tensor of the Schwinger scalars in a three dimensional dS has been investigated in Ref. 20, and the authors found that the creation of the semiclassical pairs may lead to an increase of the Hubble constant. With the aim of developing the renormalization theory in the curved spacetime, recently the Schwinger effect and the conformal anomaly for both of the scalar and spinor de Sitter QED cases have been investigated in Ref. 21. With the aim of completing the work started in Ref. 6 and with cosmological applications in mind, in this proceeding we compute the trace of the energy-momentum tensor for the Schwinger scalars created in a uniform electric field background in a four-dimensional dS. The proceeding is organised as follows: in Sec. 2 the preliminary explanation of our model is introduced. We compute the regularized trace of the induced energy-momentum tensor in Sec. 3. In Sec. 4 we give some conclusions.

## 2. Preliminaries

We begin our study by considering the scalar QED action in a four-dimensional dS as

$$S = \int d^4x\sqrt{|g|}\Big\{g^{\mu\nu}\big(\partial_\mu + ieA_\mu\big)\varphi\big(\partial_\nu - ieA_\nu\big)\varphi^* - \big(m^2 + \xi R\big)\varphi\varphi^* - \frac{1}{4}F_{\mu\nu}F^{\mu\nu}\Big\}, \quad (1)$$

where $\varphi(x)$ is a complex scalar field with mass $m$ and electric charge $e$ which is coupled to an electromagnetic vector potential background $A_\mu(x)$. The parameter $\xi$ is a dimensionless nonminimal coupling of the scalar field to the Ricci scalar $R$, and in this proceeding from now on we set $\xi = 1/6$. The $|g|$ denotes the absolute value of the metric determinant. In Secs. 2 and 3, we assume that the gravitational and electromagnetic fields are not affected by the pair creation. This assumption on the gravitational field does not hold when we discuses backreaction effects in Sec. 4. We consider the Poincaré patch of dS, whose metric reads

$$ds^2 = \Omega^2(\tau)\big(d\tau^2 - d\mathbf{x}^2\big), \qquad \Omega(\tau) = -\frac{1}{\tau H}, \qquad \tau \in (-\infty, 0), \qquad \mathbf{x} \in \mathbb{R}^3, \quad (2)$$

where $H$ is the Hubble constant and $\tau$ is the conformal time which relates to the cosmological proper time $t$ as

$$\tau = -\frac{1}{H}e^{-Ht}. \quad (3)$$

Having a uniform electric field with the constant energy density in the metric background given by Eq. (2), we choose the electromagnetic vector potential in the gauge

$$A_\mu(\tau) = -\frac{E}{H^2\tau}\delta^1_\mu, \quad (4)$$

where $E$ is a constant. The the Klein-Gordon equation for the scalar field reads from the action (1). We impose that the mode functions of the Klein-Gordon equation have the asymptotic behavior similar to those mode functions in the Minkowski spacetime at the early times, $\tau \to -\infty$. Then, these mode functions that describe the Hadamard[4] in vacuum state are given by[5,6]

$$U_{\text{in}\mathbf{k}}(x) = (2k)^{-\frac{1}{2}} e^{\frac{i\pi\kappa}{2}} \Omega^{-1}(\tau) e^{+i\mathbf{k}\cdot\mathbf{x}} W_{\kappa,\gamma}\big(2ik\tau\big), \tag{5}$$

$$V_{\text{in}\mathbf{k}}(x) = (2k)^{-\frac{1}{2}} e^{-\frac{i\pi\kappa}{2}} \Omega^{-1}(\tau) e^{-i\mathbf{k}\cdot\mathbf{x}} W_{\kappa,-\gamma}\big(-2ik\tau\big), \tag{6}$$

where $U_{\text{in}\mathbf{k}}$ and $V_{\text{in}\mathbf{k}}$ are positive and negative frequency mode functions, respectively. The function $W$ is the Whittaker function, and the variables are defined as

$$k := \big|\mathbf{k}\big|, \quad \mu := \frac{m}{H}, \quad \lambda := -\frac{eE}{H^2}, \quad r := \frac{k_x}{k}, \quad \kappa := -i\lambda r, \quad \gamma^2 := \frac{1}{4} - \mu^2 - \lambda^2. \tag{7}$$

Then we can expand the scalar field operator $\phi(x)$ as

$$\phi(x) = \int \frac{d^3k}{(2\pi)^3} \Big[ U_{\text{in}\mathbf{k}}(x) a_{\text{in}\mathbf{k}} + V_{\text{in}\mathbf{k}}(x) b^\dagger_{\text{in}\mathbf{k}} \Big], \tag{8}$$

where $a_{\text{in}\mathbf{k}}$ and $b^\dagger_{\text{in}\mathbf{k}}$ are the annihilation and creation operators for particle and antiparticles with comoving momentum $\mathbf{k}$, respectively, which satisfy the commutation relations. Then, the in vacuum state is defined by

$$a_{\text{in}\mathbf{k}}|\text{in}\rangle = b_{\text{in}\mathbf{k}}|\text{in}\rangle = 0, \qquad \forall\, \mathbf{k}. \tag{9}$$

## 3. Trace of the Induced Energy-Momentum Tensor

The induced energy-momentum tensor of the created Schwinger pairs is necessary to study evolution of the de Sitter spacetime. We will compute all of the induced energy-momentum tensor's components in a future work. However, in this proceeding we assume that the created Schwinger pairs take the form of a perfect fluid with the *vacuum* equation of state. Consequently, the energy-momentum tensor $T_{\mu\nu}$ is related to its trace $T$ as

$$T_{\mu\nu} = \frac{1}{4} T g_{\mu\nu}. \tag{10}$$

Hence, it is sufficient to compute the trace of the induced energy-momentum tensor which is defined by the variation of the action (1) with respect to the variation of the metric $\delta g_{\mu\nu}$ as

$$T := -\frac{2}{\sqrt{|g|}} g_{\mu\nu} \frac{\delta S}{\delta g_{\mu\nu}}. \tag{11}$$

In the action (1) the Maxwell term, $F_{\mu\nu}F^{\mu\nu}$, is the pure electromagnetic part of the action which is constant, and according to our assumption is not affected by the Schwinger pair creation, hence to obtain the trace of the induced energy-momentum tensor of the Schwinger pairs we do not consider this term. We then obtain

$$T = 2m^2 \varphi\varphi^*. \tag{12}$$

Substituting the scalar field operator (8) into the expression (12) and using Eq. (9) leads to

$$\langle \mathrm{in}|T|\mathrm{in}\rangle = 2m^2 \int \frac{d^3k}{(2\pi)^3}\Big|U_{\mathrm{in}\mathbf{k}}\big(x\big)\Big|^2. \tag{13}$$

Equation (13), in terms of a dimensionless integral variable $p = -k\tau$ can be written as

$$\langle \mathrm{in}|T|\mathrm{in}\rangle = \frac{H^4\mu^2}{4\pi^2}\int_{-1}^{1} dr e^{\lambda\pi r}\int_0^{\Lambda} dp\, p\Big|W_{-i\lambda r,\gamma}\big(-2ip\big)\Big|^2, \tag{14}$$

where the dimensionless momentum cutoff $\Lambda$ is defined to regularize the ultraviolet divergency. Following the integration procedure introduced in Refs. 4, 5 we obtain the unregularized expression for the trace of the induced energy-momentum tensor

$$\begin{aligned}\langle \mathrm{in}|T|\mathrm{in}\rangle = \frac{H^4\mu^2}{16\pi^2}\Big\{&4\Lambda^2 - 4\mu^2\log(2\Lambda) + 2\mu^2 - \frac{8\lambda^2}{3} + 2 + 2i\pi\mu^2 - \frac{6\gamma}{\pi}\csc(2\pi\gamma)\\ &\times\Big(\cosh(2\pi\lambda) - \frac{1}{2\pi\lambda}\sinh(2\pi\lambda)\Big) + i\csc(2\pi\gamma)\int_{-1}^{1} dr\big(3r^2\lambda^2 - \lambda^2 - \mu^2\big)\\ &\times\Big[\big(e^{2\pi\lambda r} + e^{2\pi i\gamma}\big)\psi\Big(\frac{1}{2} + i\lambda r + \gamma\Big) - \big(e^{2\pi\lambda r} + e^{-2\pi i\gamma}\big)\psi\Big(\frac{1}{2} + i\lambda r - \gamma\Big)\Big]\Big\},\end{aligned} \tag{15}$$

where $\psi$ is the digamma function. In order to remove the ultraviolet divergences from the expression (15) we apply the adiabatic subtraction scheme as introduced in Ref. 22. However, a new condition for renormalization the vacuum expectation value of the quantities in the context of de Sitter QED has been introduced in Ref. 23. The positive frequency mode function of adiabatic zeroth order is given by

$$U_{\mathrm{A}}(x) = \Omega^{-1}(\tau)\Big(2\omega(\tau)\Big)^{-\frac{1}{2}}\exp\Big(i\mathbf{k}.\mathbf{x} - i\int\omega(\tau)d\tau\Big), \tag{16}$$

where the time dependent frequency is

$$\omega(\tau) = H\Omega(\tau)\sqrt{k^2\tau^2 + 2\lambda r k\tau + \lambda^2 + \mu^2}. \tag{17}$$

Using the mode function (16) the zeroth order of the adiabatic expansion of the trace of the energy-momentum tensor is obtained

$$T_{\mathrm{A}} = \frac{H^4\mu^2}{16\pi^2}\Big(4\Lambda^2 - 4\mu^2\log(2\Lambda) + 2\mu^2 - \frac{8\lambda^2}{3}\Big). \tag{18}$$

The adiabatic regularized trace of the induced energy-momentum tensor is given by subtracting the counterterm (18) from the unregularized expression (15). We then obtain the regularized trace as

$$\begin{aligned}T = \langle \mathrm{in}|T|\mathrm{in}\rangle - T_{\mathrm{A}} = \frac{H^4\mu^2}{16\pi^2}\Big\{&2 + 2i\pi\mu^2 - \frac{6\gamma}{\pi}\csc(2\pi\gamma)\Big(\cosh(2\pi\lambda)\\ &- \frac{1}{2\pi\lambda}\sinh(2\pi\lambda)\Big) + i\csc(2\pi\gamma)\int_{-1}^{1} dr\big(3r^2\lambda^2 - \lambda^2 - \mu^2\big)\Big[\big(e^{2\pi\lambda r} + e^{2\pi i\gamma}\big)\\ &\times\psi\Big(\frac{1}{2} + i\lambda r + \gamma\Big) - \big(e^{2\pi\lambda r} + e^{-2\pi i\gamma}\big)\psi\Big(\frac{1}{2} + i\lambda r - \gamma\Big)\Big]\Big\}.\end{aligned} \tag{19}$$

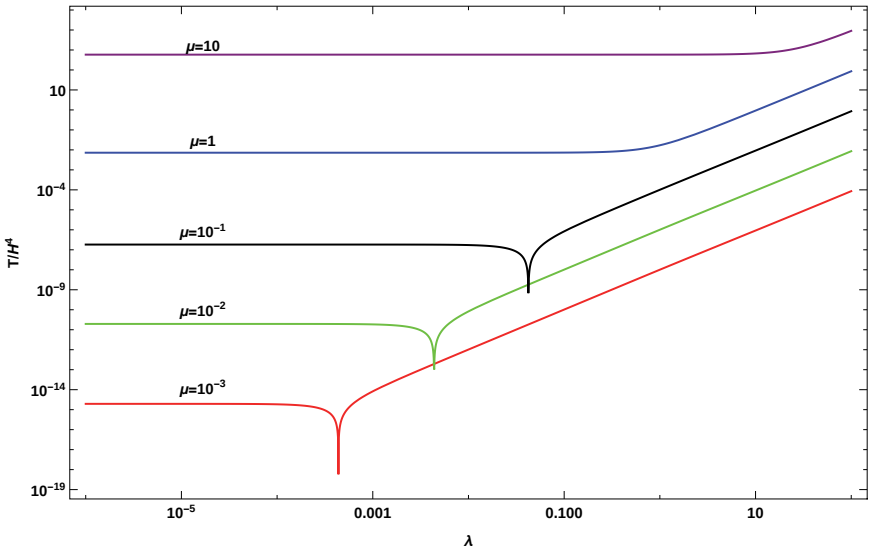

Fig. 1. The normalized trace $T/H^4$ is plotted as functions of the normalized electric field $\lambda = |-eE|/H^2$, for different values of the normalized scalar field mass $\mu = m/H$.

In Fig. 1 the regularized trace (19) is plotted as function of the electric field for different values of the scalar field mass. A numerical investigation shows that for a massive scalar field $\mu \gtrsim 1$, the sign of the trace is positive. However, for a light scalar field $\mu \lesssim 1$, the trace vanishes at $\lambda = L$. In the domain $\lambda < L$ the sign of the trace is negative, whereas in the domain $\lambda > L$ the sign of the trace is positive. Further numerical investigations illustrate that $L \simeq 0.4\mu$. Therefore in the semiclassical regime $\lambda^2 + \mu^2 \gg 1$ the sign of the trace is positive, whereas in the infrared regime $\lambda^2 + \mu^2 \ll 1$ the sign of the trace is negative.

## 4. Conclusions

These results for the trace of the energy-momentum tensor would be important for discussing the gravitational backreaction effect of the Schwinger pair creation. As a consequence of considering the *vacuum* equation of state for the created Schwinger pairs, see Eq. (10), the Einstein equation leads to the time evolution equation for the Hubble constant as[10]

$$\frac{dH}{dt} = -\frac{\pi T}{3M_{\rm P}^2}, \tag{20}$$

where $t$ is the proper cosmological time, see Eq. (3), and $M_{\rm P}$ is the Planck mass. Considering the results of Sec. 3 for the trace (19) and Eq. (20), we conclude that in the semiclassical regime $\lambda^2 + \mu^2 \gg 1$, that the sign of the trace is positive the Hubble constant decays $dH/dt < 0$. This result is in agreement with the results obtained in Ref. 6 for the decay of the Hubble constant due to the semiclassical

Schwinger pair creation. We find that in the infrared regime $\lambda^2 + \mu^2 \ll 1$, that the sign of the trace is negative, Eq. (20) implies that $dH/dt > 0$. In Ref. 15 the authors found that the gravitational backreaction effects of the quantum fluctuations may lead to a similar behavior of the Hubble constant, i.e., a period of superacceleration with $dH/dt > 0$.

Quantum corrections to the Maxwell equations induced by light-by-light (LbL) scattering can significantly modify the propagation of light in vacuum. Studying the Heisenberg-Euler Lagrangian, it can be shown that, in some configurations, the polarization of plane monochromatic waves oscillates periodically between different helicity states, due to LbL scattering. We discuss the physical implications of this finding, and the possibility of measuring this effect in optical experiments.

*Keywords*: Nonlinear optics in vacuum, light-by-light scattering, multiscale perturbative approach.

Despite the fact that the equations of the classical electromagnetic field are linear, quantum corrections due to photon-photon scattering introduce nonlinear effects in vacuum. The quantum corrections due to photon-photon scattering were calculated a long time ago by Heisenberg and Euler [1], and extensively studied by other authors [2–5]. The effective Lagrangian of the electromagnetic field, obtained retaining only one electron loop corrections, is [5]

$$L = \frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \epsilon^2\left[(F_{\mu\nu}F^{\mu\nu})^2 - \frac{7}{16}\left(F_{\mu\nu}\tilde{F}^{\mu\nu}\right)^2\right], \tag{1}$$

where $F^{\mu\nu} = A^{\mu,\nu} - A^{\nu,\mu}$ is the electromagnetic field,[a] $A^\mu$ is the electromagnetic four-potential, $\tilde{F}^{\mu\nu} \equiv \epsilon^{\mu\nu\alpha\beta}F_{\alpha\beta}$, and $\epsilon^2 = \alpha^2(\hbar/m_e c)^3/90m_e c^2$, $\alpha = e^2/4\pi\epsilon_0\hbar c \simeq 1/137$ is the fine structure constant, $\epsilon_0$ the dielectric permeability of vacuum, and $m_e$ the electron mass. The Lagrangian (1) is accurate when it is possible to neglect other quantum effects. For instance, for low energetic photons of energies $E_\gamma \ll m_e c^2$, particles creation is inhibited, and the photon-photon scattering is the only process inducing quantum correction to the Maxwell equations.

The terms $\propto \epsilon^2$ in the Lagrangian (1) take into account photon-photon scattering, and induce cubic corrections in the equations for the four-potential $A^\mu$. Since

[a] In this paper we use the covariant formalism, so that the zeroth coordinate is defined as $x^0 = c\,t$.

$\epsilon^2 \simeq 4 \times 10^{-31} m^3/J$, so that $\epsilon^2 F_{\mu\nu}F^{\mu\nu}$ is extremely small in realistic laboratory conditions, such corrections are usually negligible with high accuracy.

However, in many physical situations, tiny perturbations produce huge effects on a system, due to the action of hidden resonances. Indeed, resonances can be used to amplify the effect of extremely small perturbations. Exploiting this idea, in Refs. 6, 7 it has been shown that the dynamics described by the Lagrangian (1) is unstable for some configurations of the electromagnetic field, due to resonances.

For instance, considering two plane counterpropagating electromagnetic waves in vacuum, the nonlinear terms in (1) generate resonant (or secular) corrections in the equations of the electromagnetic field. Introducing a slow time variable, the secular terms can be treated in a multiscale scheme. In fact, the amplitudes of the two counterpropagating waves satisfy a system of nonlinear coupled ordinary differential equations in the slow time. The analysis of this system shows that, for some initial conditions, the effect of photon-photon scattering is unexpectedly relevant, and consists of a continuous oscillation in the polarization of the two beams between different helicity states.

Without loss of generality, we use the Lorentz gauge $\partial_\alpha A^\alpha = 0$; and we express the polarization vectors in terms of left and right polarizations $\hat{e}_L = (1, i, 0)/\sqrt{2}$ and $\hat{e}_R = (1, -i, 0)/\sqrt{2}$. Let us express the four-potential $A$ of the classical electromagnetic field in the form

$$A = a^\alpha + b^\alpha + c.c., \quad \text{with} \quad a = \left(a_L \hat{e}^L + a_R \hat{e}^R\right) e^{ikx}\,,\; b = \left(b_L \hat{e}^L + b_R \hat{e}^R\right) e^{ihx}, \tag{2}$$

where c.c. stands for complex conjugate. The wave vectors in (2) are given by

$$k = (k_0, 0, 0, k_3), \quad h = (h_0, 0, 0, h_3), \tag{3}$$

with $k_0/k_3 = -h_0/h_3 = 1$, so that the two waves $a$ and $b$ are counterpropagating.

When nonlinearities are neglected, (1) reduces to the Maxwell Lagrangian, and (2) is a solution when polarization vectors are constant. When nonlinearities are considered, the solutions for the Lagrangian (1) are still in the form (2), but with the polarization vectors depending on a slow time

$$y^0 \equiv \epsilon^2 x^0. \tag{4}$$

The dependence of the polarization vectors from the slow time is given by the following system

$$\begin{aligned}
&i\partial_{y^0} a_L + 16 k_0 h_0^2 \left(-3\, a_L \left(|b_L|^2 + |b_R|^2\right) + 22\, a_R b_L \bar{b}_R\right) = 0 \\
&i\partial_{y^0} a_R + 16 k_0 h_0^2 \left(-3\, a_R \left(|b_L|^2 + |b_R|^2\right) + 22\, a_L b_R \bar{b}_L\right) = 0 \\
&i\partial_{y^0} b_L + 16 k_0^2 h_0 \left(-3\, b_L \left(|a_L|^2 + |a_R|^2\right) + 22\, b_R a_L \bar{a}_R\right) = 0 \\
&i\partial_{y^0} b_R + 16 k_0^2 h_0 \left(-3\, b_R \left(|a_L|^2 + |a_R|^2\right) + 22\, b_L a_R \bar{a}_L\right) = 0\,.
\end{aligned} \tag{5}$$

that has been obtained by a multi-scale perturbative expansion of the equations of motion[6,7]. We recall that the multiscale approach is useful when the dynamics evolves on widely different scales. In this case, the time dependence of the electromagnetic field is split into fast and slow time variables $x^0$ and $y^0$.

Let us study (5) in detail. It is quite immediate to recognize that the energy densities $< \rho_a >= k_0^2 \left(|a_L|^2 + |a_R|^2\right)$ and $< \rho_b >= h_0^2 \left(|b_L|^2 + |b_R|^2\right)$ are constant. Therefore, the intensities of the two plane waves $a^\mu$ and $b^\mu$ are conserved separately. Furthermore, the spin conservation implies that the quantity $S = k_0 \left(|a_L|^2 - |a_R|^2\right) + h_0 \left(|b_L|^2 - |b_R|^2\right)$ is also constant. Exploiting these relations, the system can be simplified and then integrated, see Refs. 6, 7. However, to understand the dynamics under study, it is sufficient to solve (5) numerically.

We choose the initial conditions in such a way that, at least one of the products $a_L\, a_R$ or $b_L\, b_R$ is nonzero at the initial time. Numerical solutions show that, in such case, the polarizations of the two counterpropagating waves change periodically. In Fig. 1, we plot $|a_L|^2/|a_L^0|^2 + |a_R^0|^2$ and $|a_R|^2/|a_L^0|^2 + |a_R^0|^2$ for the solution of (5) with realistic initial values of the electromagnetic potential, that is $|a_L^0|^2 = 10^3 J/m$, $a_R^0 = 0$, $|b_L^0|^2 = |b_R^0|^2 = 10^3 J/m$, $k_0 = h_0 = 10^7\, m^{-1}$, corresponding to a laser of intensity $I \simeq 10^{23}\, W/cm^2$ and wavelenght $\lambda \sim 1\, \mu m$. We see that $|a_R|$ is initially zero, but it grows to $|a_R| = |a_L^0|$, while $|a_L|$ goes from $|a_L^0|$ to zero. Thus, the $a$ beam, initially in the left-handed polarization, switches to the right-handed polarization. It remains in this state most of the time, until it returns to its initial left-handed configuration. The variation of the $b$ beam is depicted in Fig. 2, where we plot $|b_L|^2/|b_L^0|^2 + |b_R^0|^2$ and $|b_R|^2/|b_L^0|^2 + |b_R^0|^2$ for the same initial values. The beam $b$ is initially circularly polarized, since $|b_L^0|^2 = |b_R^0|^2$, but it rapidly goes to a left-handed configuration with $|b_R| = 0$ and $|b_L|^2 = 2|b_L^0|^2$. It remains in this state most of the time, until it returns to its initial state. This dynamics is repeated periodically.

Thus, the beam $a$ oscillates between left and right polarizations, while the beam $b$ switches periodically between linear and right-handed helicities. The period of such polarization oscillations is $\Delta y^0 \simeq 10^{-26}\, m^4/J$ in the slow time $y^0$. This value is in good agreement with theoretical estimations $\Delta y^0 \sim inf\left\{1/k_0 h_0^2 |b_0|^2, 1/k_0^2 h_0 |a_0|^2\right\}$ obtained in Refs. 6, 7. The corresponding period in the physical time $x^0 = t$ is $T = \Delta y^0/\epsilon^2\, c \simeq 10^{-4}\, s$.

Finally, we consider the possibility of observing the polarization oscillations in optical experiments. The search for signatures of the photon-photon scattering in optics is in progress[8–32]. We can estimate the time of recurrence of the polarization oscillations for light beams produced in petawatt class lasers, which will be available in the near future. The intensities attainable in these lasers reach $I \sim 10^{23}\, W/cm^2$ [33,34], giving a recurrence time $T_i \sim 4 \times 10^2\, (\lambda/m)\, s$, where $\lambda/m$ is the laser wavelength in meters (we used $k \sim h \sim 2\pi/\lambda$ and $k^2 a^2 \sim k^2 b^2 \sim < \rho > \sim I/c$). Therefore, for realistic lasers with $\lambda \sim 1\, \mu m$, observation times can be of the order of $10^{-3}\, s$; to be compared with those estimated

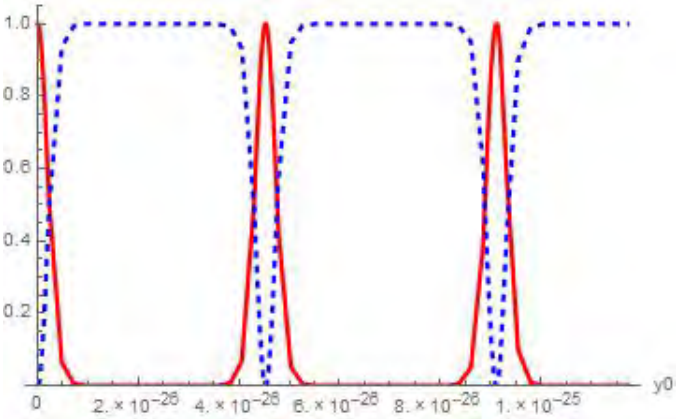

Fig. 1. We plot the evolution of $|a_L|^2/|a_L^0|^2+|a_R^0|^2$ (solid red line) and $|a_R|^2/|a_L^0|^2+|a_R^0|^2$ (dashed blue line) against $y^0$ (in units of $m^4/J$) for $|a_L^0|^2 = 10^3 J/m$, $a_R^0 = 0$, $|b_L^0|^2 = |b_R^0|^2 = 10^3 J/m$, $k_0 = h_0 = 10^7\, m^{-1}$.

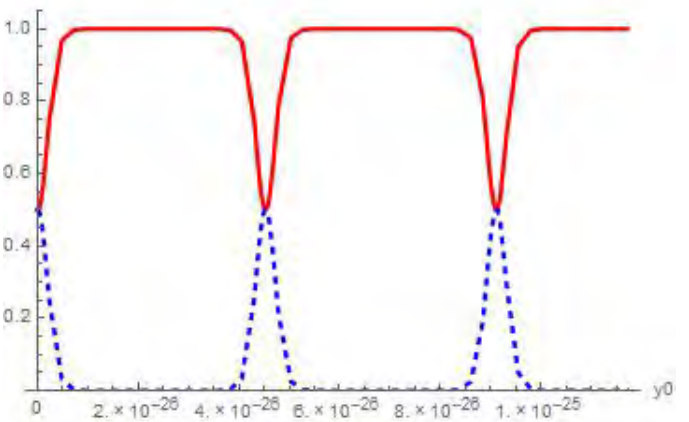

Fig. 2. We plot the evolution of $|b_L|^2/|b_L^0|^2+|b_R^0|^2$ (solid red line) and $|b_R|^2/|b_L^0|^2+|b_R^0|^2$ (dashed blue line) against $y^0$ (in units of $m^4/J$) for $|a_L^0|^2 = 10^3 J/m$, $a_R^0 = 0$, $|b_L^0|^2 = |b_R^0|^2 = 10^3 J/m$, $k_0 = h_0 = 10^7\, m^{-1}$.

in Ref. 14. This lets us hope to be able to observe polarization oscillations in two counterpropagating petawatt laser beams.

In conclusion, the extremely weak photon-photon interaction might be responsible for surprisingly strong deviations from the free dynamics of electromagnetic waves. In the case of two counterpropagating laser beams, the evolution of the electromagnetic waves can change dramatically with respect to the linear Maxwell equations, entailing slow oscillations of the polarizations of the beams.

Using the symmetry of the near-horizon geometry and applying quantum field theory of a complex scalar field, we study the spontaneous pair production of charged scalars from near-extremal rotating, electrically and/or magnetically charged black holes. Analytical expressions for pair production, vacuum persistence and absorption cross section are found, and the spectral distribution is given a thermal interpretation. The pair production in near-extremal black holes has a factorization into the Schwinger effect in AdS and Schwinger effect in Rindler space, measuring the deviational from extremality. The associated holographical correspondence is confirmed at the 2-point function level by comparing the absorption cross section ratio as well as the pair production rate both from the gravity and the conformal field theories. The production of monopoles is discussed.

*Keywords*: Charged black holes; Schwinger pair production; AdS/CFT correspondence.

## 1. Introduction

Black holes, as a consequence of vacuum fluctuations, create all species of particle pairs near their horizons, half of which radiate to the spatial infinity, leading to the so-called Hawking radiation.[1,2] Schwinger mechanism has also been known for long that virtual pairs created from vacuum fluctuations could be physically separated by a strong external electric field and substantiated as real pairs leading to spontaneous pair production.[3–5] Charged black hole thus provide both strong gravitational and electric fields resulting in either the Hawking radiation and/or Schwinger pair production, which intermingles part of quantum gravity effects and strong field quantum electrodynamics (QED) effects. The emission of charges from charged black holes has been studied independently of the Hawking radiation[6–10] and intensively studied since then both for nonextremal and extremal cases[11–14] (for a review and references, see Refs. 15 and 16).

In this paper, we review the emission of scalar charges from near-extremal charged black holes from the view point of quantum field theory in near-horizon geometry. A near-extremal black hole has an extremely small Hawking temperature, and therefore its Hawking radiation is exponentially suppressed. On the other

hand, the electric field on the horizon becomes strong enough to trigger the emission of charges dominantly through the Schwinger mechanism. This study differs from those early works in the following aspect. A conventional wisdom was to calculate the tunneling probability of virtual particles in negative energy states of the Dirac sea into positive energy states, whose mass gap is modified by the charged black hole to allow finite tunneling probability.[8–14] In the phase-integral method the leading contribution to the pair production comes from the poles near the horizon.[17] In our approach, we make use of the local geometry near the horizon: the geometry of a near-extremal charged black hole has the structure of $\mathrm{AdS}_2 \times \mathrm{S}^2$ for a nonrotating one and it has the warped $\mathrm{AdS}_3$ for a rotating one, while the geometry of a non-extremal charged black hole is $\mathrm{Rindler}_2 \times \mathrm{S}^2$ for a nonrotating one. Hence, the symmetry of near-horizon geometries allows the separation of quantum fields, which leads to analytical expressions for the in-vacuum and the out-vacuum and thereby the spectral distribution of spontaneously created pairs. The Schwinger mechanism and QED vacuum polarization in $\mathrm{dS}_2$ and $\mathrm{AdS}_2$ and their relation to black holes are discussed in Ref. 17.

The Schwinger mechanism and the Hawking radiation as quantum tunneling[18] are, however, intertwined for the spontaneous pair production occurring in charged black holes, whose dominant contribution comes from the near-horizon region. Here we review and study the scalar particle emission in the spacetime of the near-horizon region of the near-extremal charged black holes. The simplest model is the scalar production in Reissner-Nordström (RN) black holes[19] (see Ref. 20 for spinor production). In this case the spacetime has an $\mathrm{AdS}_2 \times \mathrm{S}^2$ structure and the electric field is constant near the horizon. Using the symmetry of geometry, one can analytically solve the Klein-Gordon (KG) equation and give an exact expression for the production rate. The analysis can be generalized to Kerr-Newman (KN) black holes[21] and also include a magnetic charge.[22] Then, the angular momentum deforms the near-horizon spacetime geometry to be a warped $\mathrm{AdS}_3$, but the KG equation still can be separated and solved analytically. The pair production has a remarkable thermal interpretation based on the discussions in Refs. 23, 24, 25, 26 and 17. Moreover, the scalar production has a nice conformal field theory (CFT) dual picture supporting the KN/CFTs correspondence.[27,28]

## 2. Emission of Charges from near-extremal KN black holes

The near-horizon geometry of a near-extremal dyonic KN black hole has the structure of a warped $\mathrm{AdS}_3$ as in Ref. 22

$$ds^2 = \Gamma(\theta)\left[-(\rho^2 - B^2)d\tau^2 + \frac{d\rho^2}{\rho^2 - B^2} + d\theta^2\right] + \gamma(\theta)(d\varphi + b\rho d\tau)^2, \tag{1}$$

$$A_{[1]} = -\frac{Q(r_0^2 - a^2\cos^2\theta) - 2Pr_0 a\cos\theta}{\Gamma(\theta)}\rho d\tau - \frac{Qr_0 a\sin^2\theta - P(r_0^2 + a^2)\cos\theta \pm P\Gamma(\theta)}{\Gamma(\theta)}d\varphi, \tag{2}$$

where

$$\Gamma(\theta) = r_0^2 + a^2\cos^2\theta, \qquad \gamma(\theta) = \frac{(r_0^2+a^2)^2\sin^2\theta}{r_0^2 + a^2\cos^2\theta},$$
$$b = \frac{2ar_0}{r_0^2+a^2}, \qquad r_0 = \sqrt{Q^2+P^2+a^2}. \tag{3}$$

Here, $a$ is the angular momentum parameter and $Q, P$ are the electric and magnetic charges of the original dyonic KN black holes, and $B$ measures a deviation from the extremal limit and acts as the new horizon $\rho_H = B$ in this geometry. The zero magnetic charge ($P = 0$) corresponds to the KN black hole while the zero angular momentum ($a = 0$) corresponds to the RN black hole with both electric and magnetic charges and the gauge potential for the electric charge and Dirac monopole in the near-horizon geometry

$$A_{[1]} = -Q\rho d\tau + P\big(\cos\theta \mp 1\big)d\varphi. \tag{4}$$

Associated to the black hole thermodynamics, the Hawking temperature, entropy, angular velocity, and chemical potentials ($\bar{\Phi}_{\rm H}$ is given from the Hodge dual of Maxwell field $dA_{[1]}$ in the original KN metric) are

$$T_{\rm H} = \frac{B}{2\pi}, \qquad S_{\rm BH} = \pi(r_0^2 + a^2 + 2Br_0), \qquad \Omega_{\rm H} = -\frac{2ar_0B}{r_0^2+a^2},$$
$$\Phi_{\rm H} = \frac{Q(Q^2+P^2)B}{r_0^2+a^2}, \qquad \bar{\Phi}_{\rm H} = \frac{P(Q^2+P^2)B}{r_0^2+a^2}. \tag{5}$$

The thermodynamical variables (5), as the metric (1) and the gauge field (2) do, contain the KN black hole, RN black hole as well as dyonic RN black hole with both electric and magnetic charges in the limit of $P = 0$, $a = P = 0$, and $a = 0$, respectively. The KG equation for scalar dyons can be exactly solved. An effective potential due to the electromagnetic and gravitational interactions induces tunneling processes for the pair production. By imposing a suitable boundary condition, one can obtain the production rate from the incoming and outgoing fluxes on the horizon and the asymptotic boundary of the near-horizon geometry.[19] For instance, without an incoming flux at the asymptotic outer boundary, the relative ratio of the outgoing (transmitted) flux in the asymptotic region to the incoming (reflected) flux at the horizon counts the spontaneously produced particles while the ratio of the outgoing (incident) flux to the incoming flux at the horizon gives the vacuum persistence amplitude due to vacuum fluctuations. On the other hand, the group velocity for created fermions leads to the relative ratio of the outgoing flux in the asymptotic region to the outgoing flux at the horizon for the fermion production probability.

We now focus on production of bosonic particles. Following Ref. 29, the flux conservation

$$|D_{\rm incident}| = |D_{\rm reflected}| + |D_{\rm transmitted}|, \tag{6}$$

is related to the Bogoliubov relation

$$|\mathcal{A}|^2 - |\mathcal{B}|^2 = 1, \tag{7}$$

where the vacuum persistence amplitude $|\mathcal{A}|^2$ and the mean number of produced pairs $|\mathcal{B}|^2$ are given by the ratios of the flux components

$$|\mathcal{A}|^2 \equiv \frac{|D_{\text{incident}}|}{|D_{\text{reflected}}|}, \qquad |\mathcal{B}|^2 \equiv \frac{|D_{\text{transmitted}}|}{|D_{\text{reflected}}|}. \tag{8}$$

Moreover, from the viewpoint of scattering of an incident flux from the asymptotic boundary, we can define the absorption cross section ratio as

$$\sigma_{\text{abs}} \equiv \frac{|D_{\text{transmitted}}|}{|D_{\text{incident}}|} = \frac{|\mathcal{B}|^2}{|\mathcal{A}|^2}. \tag{9}$$

In comparison, the group velocity for fermions leads to the vacuum persistence amplitude and the mean number of produced fermion pairs

$$|\mathcal{A}|^2 \equiv \frac{|D_{\text{reflected}}|}{|D_{\text{incident}}|}, \qquad |\mathcal{B}|^2 \equiv \frac{|D_{\text{transmitted}}|}{|D_{\text{incident}}|}, \tag{10}$$

where the fluxes $D_{\text{incident}}, D_{\text{reflected}}$ and $D_{\text{transmitted}}$ are computed from the spin-diagonal equations.

Using the following ansatz (hereafter parameters $m, q$, and $p$ are the mass, electric and magnetic charges of a scalar field)

$$\Phi(\tau, \rho, \theta, \varphi) = \mathrm{e}^{-i\omega\tau + i[n \mp (qP - pQ)]\varphi} R(\rho) S(\theta), \tag{11}$$

a straightforward calculation leads to the Bogoliubov coefficients and the absorption cross section ratio as (the derivation in detail can be found in Ref. 22)

$$|\mathcal{A}|^2 = \frac{\cosh(\pi\kappa - \pi\mu)\cosh(\pi\tilde{\kappa} + \pi\mu)}{\cosh(\pi\kappa + \pi\mu)\cosh(\pi\tilde{\kappa} - \pi\mu)}, \tag{12}$$

$$|\mathcal{B}|^2 = \frac{\sinh(2\pi\mu)\sinh(\pi\tilde{\kappa} - \pi\kappa)}{\cosh(\pi\kappa + \pi\mu)\cosh(\pi\tilde{\kappa} - \pi\mu)}, \tag{13}$$

$$\sigma_{\text{abs}} = \frac{|\mathcal{B}|^2}{|\mathcal{A}|^2} = \frac{\sinh(2\pi\mu)\sinh(\pi\tilde{\kappa} - \pi\kappa)}{\cosh(\pi\kappa - \pi\mu)\cosh(\pi\tilde{\kappa} + \pi\mu)}, \tag{14}$$

where three essential parameters are ($\lambda_l$ being a separation constant)

$$\tilde{\kappa} = \frac{\omega}{B}, \quad \kappa = \frac{(qQ+pP)(Q^2+P^2) - 2nar_0}{r_0^2 + a^2}, \quad \mu = \sqrt{\kappa^2 - m^2(r_0^2 + a^2) - \lambda_l - \frac{1}{4}}, \tag{15}$$

in which $\mu^2$ is positive due to the BF bound violation in the $\mathrm{AdS}_2$ spacetime.[22]

Following our previous studies,[19,21] the mean number of produced pairs (13) can be rewritten as

$$\mathcal{N} = |\mathcal{B}|^2 = \left(\frac{\mathrm{e}^{-2\pi\kappa + 2\pi\mu} - \mathrm{e}^{-2\pi\kappa - 2\pi\mu}}{1 + \mathrm{e}^{-2\pi\kappa - 2\pi\mu}}\right)\left(\frac{1 - \mathrm{e}^{-2\pi\tilde{\kappa} + 2\pi\kappa}}{1 + \mathrm{e}^{-2\pi\tilde{\kappa} + 2\pi\mu}}\right). \tag{16}$$

Note that the mean number (16) has a similar form as those of charged scalars with $\lambda_l = l(l+1)$ for spherical harmonics in a near-extremal RN black hole[19] and with

the same quantum number in KN black hole[21] since the near-horizon geometry has an $\mathrm{AdS}_2 \times S^2$ and a warped $\mathrm{AdS}_3$ for the near-extremal RN and KN black holes, respectively. According to Refs. 24 and 25, one may introduce an effective temperature and its associated counterpart

$$T_{\mathrm{KN}} = \frac{\bar{m}}{2\pi\kappa - 2\pi\mu} = T_U + \sqrt{T_U^2 + \frac{\mathcal{R}}{8\pi^2}}, \quad \bar{T}_{\mathrm{KN}} = \frac{\bar{m}}{2\pi\kappa + 2\pi\mu} = T_U - \sqrt{T_U^2 + \frac{\mathcal{R}}{8\pi^2}}, \tag{17}$$

where the effective mass $\bar{m}$ is

$$\bar{m} = \sqrt{m^2 - \frac{\lambda + 1/4}{2}\mathcal{R}}, \tag{18}$$

and the corresponding Unruh temperature $T_U$ and AdS curvature $\mathcal{R}$ are

$$T_U = \frac{\kappa}{2\pi\bar{m}(r_0^2 + a^2)} = \frac{(qQ + pP)(Q^2 + P^2) - 2nar_0}{2\pi\bar{m}(r_0^2 + a^2)^2}, \quad \mathcal{R} = -\frac{2}{r_0^2 + a^2}. \tag{19}$$

Note that an AdS space binds a pair and thus increases the effective mass in contrast to a dS space which separates a pair and reduces the effective mass.

Finally, we may introduce a thermal interpretation by factorizing the mean number (16) as

$$\mathcal{N} = \mathrm{e}^{\frac{\bar{m}}{T_{\mathrm{KN}}}} \times \underbrace{\left( \frac{\mathrm{e}^{-\frac{\bar{m}}{T_{\mathrm{KN}}}} - \mathrm{e}^{-\frac{\bar{m}}{T_{\mathrm{KN}}}}}{1 + \mathrm{e}^{-\frac{\bar{m}}{T_{\mathrm{KN}}}}} \right)}_{\text{Schwinger effect in } \mathrm{AdS}_2} \times \underbrace{\left\{ \frac{\mathrm{e}^{-\frac{\bar{m}}{T_{\mathrm{KN}}}} \left( 1 - \mathrm{e}^{-\frac{\omega - q\Phi_{\mathrm{H}} - p\bar{\Phi}_{\mathrm{H}} - n\Omega_{\mathrm{H}}}{T_{\mathrm{H}}}} \right)}{1 + \mathrm{e}^{-\frac{\omega - q\Phi_{\mathrm{H}} - p\bar{\Phi}_{\mathrm{H}} - n\Omega_{\mathrm{H}}}{T_{\mathrm{H}}}} \mathrm{e}^{-\frac{\bar{m}}{T_{\mathrm{KN}}}}} \right\}}_{\text{Schwinger effect in Rindler}_2}. \tag{20}$$

The first parenthesis is the Schwinger effect with the effective temperature $T_{\mathrm{KN}}$ in $\mathrm{AdS}_2$[23] and the second parenthesis is the Schwinger effect in the Rindler space,[30] in which the Unruh temperature is given by the Hawking temperature and charges have the chemical potentials $\Phi_{\mathrm{H}}, \bar{\Phi}_{\mathrm{H}}$, and $\Omega_{\mathrm{H}}$ while the effective temperature for the Schwinger effect due to the electric field on the horizon is still given by $T_{\mathrm{KN}}$. The extremal KN black hole can be obtained by taking the limit $T_{\mathrm{H}} = 0$ and $\tilde{\kappa} = 0$, in which the second parenthesis multiplied by the prefactor becomes unity. An interesting physics is the monopole production: upon the Dirac quantization $(ep) = 2\pi$ of charges and a small electric coupling $\alpha = e^2 = 1/137$, the symmetry of the pair production of electric and magnetic charges from dyonic black holes is broken due to $e/p = \alpha/2\pi$. Monopole production and related physics go beyond the scope of this paper and will be addressed elsewhere.

## 3. KN/CFT duality

According to the KN/CFTs duality,[28,31] the absorption cross section ratio of scalar field in Eq. (14) corresponds to that of its dual operator in the dual two-dimensional

CFT with left- and right-hand sectors

$$\sigma_{\rm abs}\sim\frac{T_{\rm L}^{2h_{\rm L}-1}T_{\rm R}^{2h_{\rm R}-1}}{|\Gamma(2h_L)||\Gamma(2h_R)|}\sinh\left(\frac{\tilde{\omega}_{\rm L}}{2T_{\rm L}}+\frac{\tilde{\omega}_{\rm R}}{2T_{\rm R}}\right)\left|\Gamma\left(h_{\rm L}+i\frac{\tilde{\omega}_{\rm L}}{2\pi T_{\rm L}}\right)\right|^2\left|\Gamma\left(h_{\rm R}+i\frac{\tilde{\omega}_{\rm R}}{2\pi T_{\rm R}}\right)\right|^2, \tag{21}$$

where $T_{\rm L},T_{\rm R}$ are the temperatures, $h_{\rm L},h_{\rm R}$ are the conformal dimensions of the dual operator, $\tilde{\omega}_{\rm L}=\omega_{\rm L}-q_{\rm L}\Phi_{\rm L}$ and $\tilde{\omega}_{\rm R}=\omega_{\rm R}-q_{\rm R}\Phi_{\rm R}$ are the total excited energy in which $(q_{\rm L},q_{\rm R})$ and $(\Phi_{\rm L},\Phi_{\rm R})$ are respectively the charges and chemical potentials (both including the electric and the magnetic contributions for the dyonic KN black hole case) of the dual left and right-hand operators. The complex conformal dimensions $(h_{\rm L},h_{\rm R})$ of the dual operator be read out from the asymptotic expansion of the bulk dyonic charged scalar field at the AdS boundary[22]

$$h_{\rm L}=h_{\rm R}=\frac{1}{2}\pm i\mu. \tag{22}$$

For dyonic KN black holes, there are in general three different pictures, namely $J$-, $Q$- and the $P$-pictures, in the dual CFTs descriptions. Here, we only show the result of $J$-picture (for the other two pictures, see Ref. 22).

In the $J$-picture, the left- and right-hand central charges of the dual CFT are determined by the angular momentum[28,31]

$$c_{\rm L}^J=c_{\rm R}^J=12J, \tag{23}$$

and the associated left- and right-hand temperatures for the near-extremal dyonic KN black hole are

$$T_{\rm L}^J=\frac{r_0^2+a^2}{4\pi a r_0},\qquad T_{\rm R}^J=\frac{B}{2\pi a}. \tag{24}$$

The CFT microscopic entropy from the Cardy formula

$$S_{\rm CFT}=\frac{\pi^2}{3}(c_{\rm L}^JT_{\rm L}^J+c_{\rm R}^JT_{\rm R}^J)=\pi(r_0^2+a^2+2r_0B), \tag{25}$$

agrees with the macroscopic entropy (5) of the near-extremal KN black hole.

Besides, by matching the first law of black hole thermodynamics with that of the dual CFT, i.e., $\delta S_{\rm BH}=\delta S_{\rm CFT}$, the following relation holds

$$\frac{\delta M-\Omega_{\rm H}\delta J-\Phi_{\rm H}\delta Q-\bar{\Phi}_{\rm H}\delta P}{T_{\rm H}}=\frac{\tilde{\omega}_{\rm L}}{T_{\rm L}}+\frac{\tilde{\omega}_{\rm R}}{T_{\rm R}}, \tag{26}$$

where the angular velocity and chemical potentials at $\rho=B$ are given in Eq. (5). To probe the rotation we need to turn off the charges of the probe scalar field and set $T_{\rm L}=T_{\rm L}^J$ and $T_{\rm R}=T_{\rm R}^J$, then for the dyonic KN black hole $\delta M=\omega,\ \delta J=n,\ \delta Q=0,\ \delta P=0$. Thus, we have

$$\tilde{\omega}_{\rm L}^J=n\quad\text{and}\quad\tilde{\omega}_{\rm R}^J=\frac{\omega}{a}\quad\Rightarrow\quad\frac{\tilde{\omega}_{\rm L}^J}{2T_{\rm L}^J}=-\pi\kappa\quad\text{and}\quad\frac{\tilde{\omega}_{\rm R}^J}{2T_{\rm R}^J}=\pi\tilde{\kappa}, \tag{27}$$

where $q,p$ are set to zero. Consequently, the agreement between the absorption cross section ratio (14) of the scalar field (with $q=p=0$) in the near-extremal dyonic KN black hole and that of its dual scalar operator in Eq. (21) is confirmed in the $J$-picture.

## 4. Conclusion

We have reviewed and studied the emission of charges from near-extremal dyonic KN black holes within the framework of the quantum field in the near-horizon geometry.[22] The symmetry of the near-horizon geometry of near-extremal black holes leads to analytic expressions for the solutions and therefrom the in-vacuum and the out-vacuum and pair production rate. This makes a drastic difference from the conventional wisdom which computes the tunneling probability of virtual particles from the Dirac sea in charged black holes.[6–16] In fact, the phase-integral formulation or the Hamilton-Jacobi equation for spinless charges has simple poles near the horizon, whose residues determine the leading term of pair production. On the other hand, the quantum field theory in the near-horizon geometry exhibits a rich structure of the spectral distribution of produced particles. A caveat, however, is that the exact solutions in the near-horizon are not the solutions in the original global spacetime of black holes but carry the essential information of pair production that occurs the near horizon and that the back-reaction due to produced pairs and the induced current is not considered.

The near-horizon region contains a causal horizon and the electric field effect near the horizon dominantly gives rise to both the Hawking radiation and the Schwinger mechanism. By imposing the proper boundary condition on the exact solutions, the pair production, vacuum persistence amplitude and absorption cross section can be obtained from the relative ratios of the fluxes on the asymptotic boundary and horizon. This approach provides one with a systematic method for the pair production and vacuum polarization in a proper-time integral representation.[17,23] The thermal interpretation of the pair production rate for the near-extremal dyonic KN black holes consists of the Schwinger effect in the $AdS_2$ space mainly due to the electromagnetic field of black holes and the Schwinger effect in the Rindler space due to the Hawking temperature. The dual CFTs descriptions of the Schwinger pair production of the near-extremal KN black hole[21] can be generalized into the threefold dual CFTs pictures for the dyonic KN black hole which includes an additional magnetic charge. The third $P$-picture is associated with the dual gauge potential, a new "magnetic hair" of the dyonic KN black hole and a $U(1)$ fiber on the base manifold. Based on the threefold dyonic KN/CFTs duality, the dual CFTs descriptions of the absorption cross section ratios and the pair production rate of the dyonic charged scalar field can be confirmed in the $J$-, $Q$-, and $P$-pictures, respectively.

The near-extremal dyonic KN black hole is the most general model in the sense that the zero magnetic charge limit corresponds to the KN black hole and the zero angular momentum (nonrotating) limit recovers the RN black hole with both electric and magnetic charge. Further restricting to zero angular momentum and magnetic charge reduces to the RN black hole. The formulae in this paper have such limits by replacing the separation parameter $\lambda_l$ by $l(l+1)$ for spherical harmonics for nonrotating black holes. The magnetic charge has the Dirac monopole for the

black hole, and the quantization condition $ep = 2\pi$ of electric charges and the fine structure constant $e^2 = \alpha$ leads to $e/p = \alpha/2\pi$, which implies the magnetic charge is larger by order of three than the electric charge. Then, the monopole production from a magnetic black hole is suppressed since the Unruh temperature is proportional to $p/P$ compared to $e/Q$ of an electric black hole. The physics related to production of electric charges and magnetic monopoles from dyonic black holes will be addressed in a future publication.

## Acknowledgments

The authors would like to thank Gary Gibbons and Remo Riffini for pointing out that Schwinger mechanism was studied independently before Hawking radiation was discovered and also to express thanks to Alexei Gaina for informing us many relevant works related to this review article. We consider pair production phenomena in spatially homogeneous strong electric fields. We focus on spinor QED in two-dimensions and discuss the potential ambiguity in the adiabatic order assignment for the electromagnetic potential required to fix the renormalization subtractions. This ambiguity can be univocally fixed by imposing, at the semiclassical level, stress-energy conservation when both electric and gravitational backgrounds are present.

*Keywords*: Schwinger effect; pair creation; adiabatic renormalization; semiclassical Maxwell equations.

## 1. Introduction

A time-dependent gravitational field yields the creation operators of quantum fields to evolve into a superposition of creation and annihilation operators. This produces the spontaneous creation of particle-antiparticle pairs out of the vacuum. This effect was first discovered, including the precise probability distribution of the produced particles, in the physical context of an expanding universe [1]. A similar superposition of creation and annihilation operators takes place if the quantized field is coupled to a time-varying gauge field background [2]. In this contribution we want to focus on the particle creation phenomena induced by electric fields in presence of gravity, which are of major relevance in astrophysics and cosmology [3].

A fundamental problem in the physical understanding of gravitational particle creation processes is the calculation of the expectation values $\langle T_{\mu\nu} \rangle$. The computations require methods of regularization and renormalization to deal with new ultraviolet divergences (UV) not present in Minkowski space. Equivalently, in a time-dependent electric field the fundamental problem is to evaluate the renormalized electric current $\langle j_\mu \rangle$, which acts as the proper source of the semiclassical Maxwell equations.

In this work we discuss an improvement of the adiabatic regularization method, originally introduced in cosmological scenarios and for quantized scalar fields [4], to include homogeneous electric fields and Dirac quantized fields. We will reexamine the method to consistently deal with both electric and gravitational fields. By doing this we will fix an inherent ambiguity of the method. The adiabatic order assignment of the vector potential has been traditionally assumed in the literature of order zero. We will argue that the correct adiabatic order assignment is one, instead of zero, at least if a gravitational field is present. This problem has been discussed

for scalar fields in Refs. 5, 6. Here we extend the discussion to Dirac fields. To focus on the main ideas we will restrict the analysis to two-dimensional spacetime.

## 2. Spinor QED$_2$ and the adiabatic renormalization scheme

We consider two-dimensional spinor QED in an expanding spacetime described by the metric $ds^2 = dt^2 - a^2(t)dx^2$. The classical action is given by

$$\mathcal{S} = \int dx^2 \sqrt{-g} \left( -\frac{1}{4} F_{\mu\nu} F^{\mu\nu} + i\bar{\psi} \not{D} \psi - m\bar{\psi}\psi \right) , \tag{1}$$

and the corresponding Dirac equation reads

$$(i\underline{\gamma}^{\mu} D_{\mu} - m)\psi = 0 , \tag{2}$$

where $D_\mu \equiv \partial_\mu - \Gamma_\mu - iqA_\mu$ and $\Gamma_\mu$ is the spin connection. $\underline{\gamma}^{\mu}(x)$ are the spacetime-dependent Dirac matrices satisfying the anticommutation relations $\{\underline{\gamma}^{\mu}, \underline{\gamma}^{\nu}\} = 2g^{\mu\nu}$. These gamma matrices are related with the Minkowskian ones by $\underline{\gamma}^{0}(t) = \gamma^0$ and $\underline{\gamma}^{1}(t) = \gamma^1/a(t)$, and the components of the spin connections are $\Gamma_0 = 0$ and $\Gamma_1 = (\dot{a}/2)\gamma_0\gamma_1$. Therefore, $\underline{\gamma}^{\mu}\Gamma_\mu = -\frac{\dot{a}}{2a}\gamma_0$. It is very convenient to fix the gauge for the vector potential as $A_\mu = (0, -A(t))$. The Dirac equation (2) becomes[5,7]

$$\left( i\gamma^0\partial_0 + \frac{i}{2}\frac{\dot{a}}{a}\gamma^0 + \left( \frac{i}{a}\partial_1 + \frac{qA_1}{a} \right) \gamma^1 - m \right) \psi = 0. \tag{3}$$

From now on we will use the Weyl representation (with $\gamma^5 \equiv \gamma^0\gamma^1$)

$$\gamma^0 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad \gamma^1 = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \qquad \gamma^5 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix} .$$

We expand the quantized field in momentum modes

$$\psi(t,x) = \int_{-\infty}^{\infty} dk \left[ B_k u_k(t,x) + D_k^{\dagger} v_k(t,x) \right] , \tag{4}$$

where the two independent spinor solutions are

$$u_k(t,x) = \frac{e^{ikx}}{\sqrt{2\pi a}} \begin{pmatrix} h_k^I(t) \\ -h_k^{II}(t) \end{pmatrix}, \qquad v_k(t,x) = \frac{e^{-ikx}}{\sqrt{2\pi a}} \begin{pmatrix} h_{-k}^{II*}(t) \\ h_{-k}^{I*}(t) \end{pmatrix} , \tag{5}$$

and $B_k$ and $D_k$ the creation and annihilation operators which fulfill the usual anti-commutation relations. The field equations (3) are now converted into

$$\begin{aligned} \dot{h}_k^I - \frac{i}{a}\left(k + qA\right) h_k^I - imh_k^{II} = 0 \\ \dot{h}_k^{II} + \frac{i}{a}\left(k + qA\right) h_k^{II} - imh_k^{I} = 0 . \end{aligned} \tag{6}$$

We also assume the normalization condition $|h_k^I|^2 + |h_k^{II}|^2 = 1$. The classical electric current is given by $j^\nu = -q\bar{\psi}\underline{\gamma}^{\nu}\psi$, and the formal expression for the vacuum expectation value of $\langle j^x \rangle$ is

$$\langle j^x \rangle \ = \frac{q}{2\pi a^2} \int_{-\infty}^{\infty} dk \left( \left| h_k^{II} \right|^2 - \left| h_k^{I} \right|^2 \right) . \tag{7}$$

The above expression possesses, as expected, UV divergences. To obtain the finite, physical values, we have to perform appropriate subtractions

$$\langle j^x \rangle_{ren} = \frac{q}{2\pi a^2} \int dk \left( |h_k^{II}|^2 - |h_k^I|^2 - SUBSTRACTIONS \right) . \tag{8}$$

The semiclassical Maxwell equations for $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ are

$$\nabla_\mu F^{\mu\nu} = \langle j^\nu \rangle_{ren}. \tag{9}$$

Equations (6) and (9) determine the continuous interchange of energy between the electric field and matter, via charged pair production and backreaction. Now, the main problem is to obtain the required subtractions consistently. In this context, the most natural way to determine the renormalization subtractions is the adiabatic regularization method. The basic principles for scalar fields can be borrowed from Ref. 8, while for spin-1/2 fields one can see Refs. 7, 9. The main idea here is to consider an adiabatic expansion of the mode functions. For scalar fields, this expansion is based on the WKB-type ansatz , namely

$$h_k(t) = \frac{1}{\sqrt{\Omega_k(t)}} e^{-i\int^t \Omega_k(t')dt'}, \qquad \Omega_k(t) = \omega_k^{(0)} + \omega_k^{(1)} + \omega_k^{(2)} + \cdots \tag{10}$$

where the order of the expansion is determined by the number of derivatives of the background fields. A different type of expansion is required for fermionic fields[7,9]. A very crucial point to properly define the adiabatic expansion, for both scalar and Dirac fields, is to fix the leading order. The zeroth order adiabatic term is determined by $\omega_k^{(0)}$.

## 3. Two attempts toward the backreaction equations in Minkowski space

Let us first assume for simplicity that we are in Minkowski space and $a(t) = 1$. Therefore, the gauge field is now the only background field. In this scenario it is very natural to define $\omega_k^{(0)} = \sqrt{(k + qA)^2 + m^2}$. This means that the adiabatic order assignment for the gauge field $A(t)$ has been implicitly chosen as 0, as first assumed in Ref. 10 and in all subsequent papers on this topic. Therefore, $\dot{A}(t)$ should be of order 1, etc. The proposed renormalized current is then given by

$$\langle j^x \rangle_{ren}^I = q \int_{-\infty}^{\infty} \frac{dk}{2\pi} \left( |h_k^{II}|^2 - |h_k^I|^2 - \frac{(k + qA)}{\omega_k^{(0)}} \right) \tag{11}$$

Plugging this expression into the semiclassical Maxwell equations (9), we get the following backreaction equation,

$$-\dot{E} = \ddot{A} = q \int_{-\infty}^{\infty} \frac{dk}{2\pi} \left[ |h_k^{II}|^2 - |h_k^I|^2 - \frac{(k + qA)}{\sqrt{(k + qA)^2 + m^2}} \right] , \tag{12}$$

together with the equation for the field modes (6). It is important to stress that the above semiclassical Maxwell equations are compatible with the conservation of the

energy if the renormalized stress-energy tensor is constructed by subtracting up to the zero adiabatic order

$$\langle\rho\rangle^I_{ren} = \langle T_{00}\rangle^I_{ren} = \frac{1}{2\pi}\int_{-\infty}^{\infty} dki\left[h_k^{II}\dot{h}_k^{II*} + h_k^I\dot{h}_k^{I*}\right] + \omega_k^{(0)} \ . \tag{13}$$

It is easy to check that $\partial_\mu\langle T^{\mu\nu}\rangle_{ren} + \partial_\mu T^{\mu\nu}_{elec} = 0$, where $T^{elec}_{\mu\nu} = \frac{1}{2}E^2\eta_{\mu\nu}$.

Alternatively, we can define

$$\omega_k^{(0)} = \sqrt{k^2+m^2} \equiv \omega, \tag{14}$$

which assumes that $A$ is of adiabatic order 1, and proceed according to the rules of the adiabatic expansion. With this choice we obtain

$$\langle j^x\rangle^{II}_{ren} = q\int_{-\infty}^{\infty}\frac{dk}{2\pi}\left(|h_k^{II}|^2 - |h_k^I|^2 - \frac{k}{\omega} - \frac{qm^2}{\omega^3}A\right) \ . \tag{15}$$

Hence, the semiclassical Maxwell equation reads $-\dot{E} = \ddot{A} = \langle j^x\rangle^{II}_{ren}$, and the mode functions $h_k^I$ and $h_k^{II}$ satisfy again Eq. (6). The choice (14) is also compatible with the conservation of energy, defined now by subtracting up to second adiabatic order

$$\langle T_{00}\rangle^{II}_{ren} = \frac{1}{2\pi}\int dki\left[h_k^{II}\dot{h}_k^{II*} + h_k^I\dot{h}_k^{I*}\right] + \omega + \frac{kqA}{\omega} + \frac{m^2q^2A^2}{2\omega^3} \ . \tag{16}$$

It is immediate to see that the fermionic currents (11) and (15) are equivalent,

$$\triangle\langle j^x\rangle_{ren} = q\int_{-\infty}^{-\infty}\frac{dk}{2\pi}\left[\frac{k}{\omega} - \frac{(k+qA)}{\sqrt{(k+qA)^2+m^2}} + \frac{m^2qA}{\omega^3}\right] = 0 \ . \tag{17}$$

The first two terms of the equation above correspond to linearly divergent integrals, differing by a constant shift, and hence, their difference is finite $-q^2A(t)/\pi$. On the other hand, the last term is a finite integral, which cancels out with the previous quantity. In conclusion, in Minkowski space the choice of the adiabatic order of the background field $A(t)$ does not affect the physical observables and, therefore, both options are equally valid. However, this conclusion is misleading as soon as one introduces the gravitation field.

## 4. The role of gravity

Now, let us assume that our space-time is a two-dimensional expanding universe with metric $ds^2 = dt^2 - a^2(t)dx^2$. In this case, the prescription for $a(t)$ is to fix it at adiabatic order 0, and the rules for the adiabatic subtraction terms are univocally fixed according to the scaling dimension of the relevant operators. The stress-energy tensor must be renormalized at second adiabatic order[11], while the electric current should be renormalized at adiabatic order 1. With this restrictions, the only possibility is to choose $A(t)$ of adiabatic order 1, in the same footing as $\dot{a}(t)$. That is, we should have a hierarchy between the two background fields. The leading order corresponds to gravity, and consequently one should replace the definition (14) by

$$\omega_k^{(0)} = \sqrt{k^2/a^2+m^2} \equiv \omega \ , \tag{18}$$

instead of the naive generalization $\omega_k^{(0)} = \sqrt{(k+qA)^2/a^2+m^2}$ . This point has been overlooked in the literature, as recently stressed in Ref. 5. The gauge field should enter at the next to leading order in the adiabatic expansion.

Therefore, the renormalized expression for the electric current should be

$$\langle j^x\rangle_{ren} = \frac{q}{2\pi a^2}\int_{-\infty}^{\infty} dk\left(|h_k^{II}|^2 - |h_k^I|^2 - \frac{k}{a\omega} - \frac{qm^2}{a\omega^3}A\right) , \tag{19}$$

and the backreaction equations are

$$-\dot{E} = \frac{\ddot{A}}{a} - \frac{\dot{A}}{a}\frac{\dot{a}}{a} = \frac{q}{2\pi a}\int_{-\infty}^{\infty} dk\left(|h_k^{II}|^2 - |h_k^I|^2 - \frac{k}{a\omega} - \frac{qm^2}{a\omega^3}A\right) \quad , \tag{20}$$

together with the equation for the field modes (6).

As in Minkowski space, one should expect stress-energy conservation, namely $\nabla_\mu\langle T^{\mu\nu}\rangle_{ren} + \nabla_\mu T^{\mu\nu}_{elec} = 0$, with $T^{elec}_{\mu\nu} = \frac{1}{2}E^2 g_{\mu\nu}$. After the required adiabatic subtractions, one obtain the following expressions for the diagonal components of $\langle T_{\mu\nu}\rangle$:

$$\langle T_{00}\rangle_{ren} = \frac{1}{2\pi a}\int_{-\infty}^{\infty} dki\left[h_k^{II}\dot{h}_k^{II*} + h_k^I\dot{h}_k^{I*}\right] + \omega + \frac{kqA}{\omega} + \frac{m^2q^2A^2}{2a^2\omega^3} - \frac{k^2m^2\dot{a}^2}{8a^4\omega^5}, \tag{21}$$

$$\begin{aligned}\langle T_{11}\rangle_{ren} = \ & \frac{1}{2\pi}\int_{-\infty}^{\infty} dk(k+qA(t))\left(|h_k^I|^2 - |h_k^{II}|^2\right) + \frac{k^2}{a\omega} + \frac{km^2qA}{a\omega^3} + \frac{kqA}{a\omega} - \frac{m^4\ddot{a}}{4\omega^5} \\ & + \frac{m^2\ddot{a}}{4\omega^3} + \frac{5m^6\dot{a}^2}{8a\omega^7} - \frac{3m^4\dot{a}^2}{4a\omega^5} + \frac{m^2\dot{a}^2}{8a\omega^3} + \frac{3m^4q^2A^2}{2a\omega^5} - \frac{m^2q^2A^2}{2a\omega^3} \ .\end{aligned} \tag{22}$$

The conservation equation for the zeroth component can be decomposed as

$$\nabla_\mu\langle T^{\mu 0}\rangle_{ren} + \nabla_\mu T^{\mu 0}_{elec} = \partial_0\langle T_{00}\rangle_{ren} + \frac{\dot{a}}{a}\langle T_{00}\rangle_{ren} + \frac{\dot{a}}{a^3}\langle T_{11}\rangle_{ren} + \partial_0 T^{elec}_{00} = 0. \tag{23}$$

Plugging (21) and (22) into (23) and using the equations (6) we get

$$\nabla_\mu\langle T^{\mu 0}\rangle_{ren} + \nabla_\mu T^{\mu 0}_{elec} = \frac{\dot{A}}{a}\left(\frac{\ddot{A}}{a} - \frac{\dot{A}\dot{a}}{a^2} - \langle j^x\rangle_{ren}\right) = 0 \ . \tag{24}$$

Note that the factor in parentheses is precisely the semiclassical Maxwell equation for the electric field (20). A similar result is trivially obtained for the remaining component: $\nabla_\mu\langle T^{\mu 1}\rangle_{ren} + \nabla_\mu T^{\mu 1}_{elec} = 0$. Therefore, the semiclassical Maxwell equations must be satisfied to ensure stress-energy conservation.

If one assumes that $A(t)$ is of adiabatic order 0, the stress-energy conservation does not hold anymore. With this alternative adiabatic assignment, and renormalizing $\langle T^{\mu\nu}\rangle$ up to and including the second adiabatic order, one obtains

$$\nabla_\mu\langle T^{\mu 0}\rangle_{ren} + \nabla_\mu T^{\mu 0}_{elec} \neq 0 \ . \tag{25}$$

In this case, the left-hand side in the above equation is proportional to $E\langle j^x\rangle^{(2)}$, where $\langle j^x\rangle^{(2)}$ is the second adiabatic order of the electric current, which cannot be properly absorbed into the renormalization substractions of the electric current. We note that another inconsistency is the disagreement with the trace anomaly [5] in the massless limit.

## 5. Conclusions

The role of gravity is essential to fix the ambiguity in the adiabatic order assignment of the electromagnetic potential $A(t)$, and therefore to obtain the correct renormalization subtractions of physical observables. Although in absence of a gravitational background the two different prescriptions for the adiabatic subtraction terms are equivalent, when gravity is incorporated into the game only the adiabatic order assignment 1 for the gauge field $A(t)$ is compatible with stress-energy conservation.

In this proceedings article, we review the results presented in [Fabienne Schneiter et al. 2018 Class. Quantum Grav. 35 195007] on the gravitational field of light in a laser beam, modeled as a solution to Maxwell's equations perturbatively expanded in the beam divergence. Using this approach, wave properties of light, such as diffraction, are taken into account that have been neglected in earlier studies. Interesting features of the gravitational field of laser beams become apparent like frame-dragging due to the intrinsic angular momentum of light and the deflection of parallel co-propagating test beams for short distances to the source beam.

*Keywords*: Gravitational properties of light, laser beams, linearized gravity.

## 1. Introduction

The gravitational field of a light beam has first been studied in Ref. 15 by Tolman, Ehrenfest and Podolski in 1931, who described the light beam as a one-dimensional "pencil of light". Later in Ref. 3 by Bonnor, a description for the gravitational field of a cylindrical beam of light of a finite radius was presented. Light was modeled as a continuous fluid moving at the speed of light. A central feature of the models of Ref. 15 and Ref. 3 is the lack of diffraction; the beams do not diverge. This corresponds to the short wavelength limit where all wavelike properties of light are neglected. Further studies to the gravitational field of light that share this feature include the investigation of two co-directed parallel cylindrical light beams of finite radius[2,10], spinning non-divergent light beams[9], non-divergent light beams in the framework of gravito-electrodynamics[5] and the gravitational field of a point like particle moving with the speed of light[1,17].

In contrast, the wavelike properties of light were taken into account in Ref. 16, where the gravitational field of a plane electromagnetic wave was investigated. An approach to take finite wavelengths into account for the case of a laser pulse was given in Refs. 11, 12, where, however, diffraction was neglected. Here, we describe the laser beam as a solution to Maxwell's equations. This is done perturbatively by an expansion in the beam divergence, which is considered to be small. The zeroth order of the expansion corresponds to the paraxial approximation and coincides

with the result of Ref. 3. In the first order in the beam divergence, frame-dragging due to the internal angular momentum of circularly polarized beams occurs. In the forth order, a parallel co-propagating test beam of light is found to be deflected by the gravitational field of the laser beam.

## 2. The model

In the following, we will employ dimensionless coordinates by dividing the Cartesian coordinates corresponding to the lab reference by the beam waist $w_0$ as $\tau = ct/w_0$, $\xi = x/w_0$, $\chi = y/w_0$ and $\zeta = z/w_0$, where $c$ is the speed of light. A laser beam in its simplest mode is accurately described by a Gaussian beam. The Gaussian beam is an almost monochromatic electromagnetic plane wave which has the property that its intensity distribution decays with a Gaussian factor with the distance to the beamline. It is obtained as a perturbative solution of Maxwell's equations, an expansion in the beam divergence $\theta$, the opening angle of the beam, which is assumed to be small. When the beam divergence is small, the beam may be thought of as a bunch of almost, but not exactly, parallel propagating rays of light. The electromagnetic four-vector potential describing the Gaussian beam is obtained by a plane wave multiplied by an envelope function, which is assumed to be varying slowly in the direction of propagation, in agreement with the property that the divergence of the beam is small. Corresponding to these features, we make the ansatz for the four-vector potential $A_\alpha = \mathcal{A} v_\alpha(\xi, \chi, \theta\zeta) \exp(2i(\zeta - \tau)/\theta)$, were $\mathcal{A}$ is the amplitude, $v_\alpha$ the envelope function, and the exponential factor describes a plane wave propagating in $\zeta$-direction with angular wave number $k = 2/\theta$, where $w_0$ is the beam waist at its focal point, a measure of the radius of the beam (see Fig. 1).

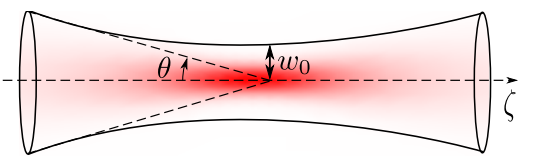

Fig. 1. Schematic illustration of the Gaussian beam, the beam waist $w_0$ and the beam divergence $\theta$. More specifically, the figure illustrates the scalar envelope function $v_0$ of the vector potential of the Gaussian beam in a plane that contains the optical axis (represented by the dashed horizontal line). Due to the rotational symmetry of the envelope function around the optical axis, the vertical axis can be any direction transversal to the optical axis. The thick curved lines mark the distance $w(\zeta) = w_0\sqrt{1 + (\theta\zeta)^2}$ from the optical axis at which the absolute value of the envelope function reaches $1/e$ times its maximum.

In the following, the beam waist is kept constant. In this case, since the beam divergence is small, the angular wave number is large. As for any beam of radiation in flat spacetime, the four-vector potential satisfies the wave equations

$\left(\partial_\xi^2+\partial_\chi^2+\partial_\zeta^2-\partial_\tau^2\right)A_\mu = 0$, which follow from Maxwell's equations when the Lorenz gauge is chosen. The wave equations for the four-vector potential reduce to a Helmholtz equation for the envelope function, $\left(\partial_\xi^2+\partial_\chi^2+\theta^2\partial_{\theta\zeta}^2+4i\partial_{\theta\zeta}\right)v_\alpha = 0$. We assume that the envelope function is slowly varying in the direction of propagation, i.e. $v_\alpha$ is a function of $\theta\zeta$. Then, the Helmholtz equation can be solved iteratively by writing the envelope function as a power series in the divergence angle $\theta$ (see Ref. 4). For each term in the expansion of the envelope function, one obtains a Helmholtz equation with a source term. These source terms are proportional to terms of lower order in the expansion of the envelope function, and even and odd orders do not mix. We start from the zeroth order solution, which we assume to have a Gaussian profile in the focus plane, and derive the vector potential up to fourth order in the divergence angle.

To obtain the gravitational field of the laser beam, the energy momentum tensor $T_{\alpha\beta}$ has to be calculated from the field strength $F_{\alpha\beta} = \partial_\alpha A_\beta - \partial_\beta A_\alpha$. We only consider vector potentials with field strength tensors that are eigenfunctions with eigenvalue $\lambda = \pm 1$ of the generator of the duality transformation of the electromagnetic field, which in our case is given by $F_{\alpha\beta} \mapsto -i\epsilon_{\alpha\beta\gamma\delta}F^{\gamma\delta}/2$, where $\epsilon_{\alpha\beta\gamma\delta}$ is the completely anti-symmetric tensor with $\epsilon_{0123} = -1$. In that case the rapidly oscillating contributions of the plane wave factor in the vector potential drop out and the energy momentum tensor assumes the simple form $T_{\alpha\beta} = c^2\epsilon_0 \,\mathrm{Re}\left(F_\alpha{}^\sigma F^*_{\beta\sigma} - \frac{1}{4}\eta_{\alpha\beta}F^{\delta\rho}F^*_{\delta\rho}\right)/2$. We interpret the eigenvalues $\lambda$ of the generator duality transformation as the helicity of the beam since the standard notion of circular polarization is recovered in the zeroth order in $\theta$.

## 3. The gravitational field

Since the energy of a laser beam is small, we may expect its gravitational field to be weak. The spacetime metric describing the gravitational field is thus assumed to consist of the metric for flat spacetime in the rescaled coordinates $\eta = w_0^2\mathrm{diag}(-1,1,1,1)$ plus a small perturbation $h_{\alpha\beta}$, where small means $|h_{\alpha\beta}| \ll w_0^2$ for all $\alpha$ and $\beta$. Terms quadratic in the metric perturbation are neglected; this is the linearized theory of general relativity. When the Lorenz-gauge $\partial^\alpha h_{\alpha\beta} = \frac{1}{2}\partial_\beta h^\alpha{}_\alpha$ is chosen, Einstein's field equations reduce to wave equations for the metric perturbation[8]: $\left(\partial_\xi^2+\partial_\chi^2+\partial_\zeta^2-\partial_\tau^2\right)h_{\alpha\beta} = -\kappa w_0^2 T_{\alpha\beta}$, where $\kappa = 16\pi G/c^4$ and $G$ is Newton's constant. Solving the linearized Einstein equations for the energy momentum tensor of the laser beam with emitter and absorber at general positions can be quite cumbersome. Therefore, we consider two different limiting situations instead; the distance between emitter and absorber being very large in one case and very small in the case.

For a large distance between emitter and absorber, we can neglect the rapid change of the field strength at the emitter and the absorber. Then we can take into account that $T_{\alpha\beta}$ is changing slowly in $\zeta$. In particular, we have $T^\lambda_{\alpha\beta} = T^\lambda_{\alpha\beta}(\xi,\chi,\theta\zeta)$.

Therefore, the metric perturbation can be expanded in orders of the beam divergence angle as $h_{\alpha\beta} = \sum_{n=0}^{\infty} \theta^n h_{\alpha\beta}^{(n)}$. The linearized Einstein equations lead to the differential equations

$$\left(\partial_\xi^2 + \partial_\chi^2\right) h_{\alpha\beta}^{\lambda(0)} = -w_0^2 \kappa\, t_{\alpha\beta}^{\lambda(0)} \,, \tag{1}$$

$$\left(\partial_\xi^2 + \partial_\chi^2\right) h_{\alpha\beta}^{\lambda(1)} = -w_0^2 \kappa\, t_{\alpha\beta}^{\lambda(1)} \,, \tag{2}$$

$$\left(\partial_\xi^2 + \partial_\chi^2\right) h_{\alpha\beta}^{\lambda(n)} = -w_0^2 \kappa\, t_{\alpha\beta}^{\lambda(n)} - \partial_{\theta\zeta}^2 h_{\alpha\beta}^{\lambda(n-2)} \,, \text{ for n} > 1 \,, \tag{3}$$

where the $t_{\alpha\beta}^{\lambda(n)}(\xi, \chi, \theta\zeta)$ are given by $T_{\alpha\beta}^{\lambda}(\xi, \chi, \theta\zeta) = \sum_{n=0}^{\infty} \theta^n t_{\alpha\beta}^{\lambda(n)}(\xi, \chi, \theta\zeta)$. The solutions $h_{\alpha\beta}^{\lambda(n)}$ of Eqs. (1), (2) and (3) can be found by direct calculation as we did in Ref. 13. These solutions have to be constructed such that the components of the Riemann curvature tensor vanish at infinite distance from the beamline. The Riemann curvature tensor governs the spread and the contraction of the trajectories of test particles. This means, if the Riemann tensor vanishes, parallel geodesics stay parallel and there is no physical effect as the only reference for a test particle in linearized gravity can be another test particle. As the energy distribution of the laser beam decays like a Gaussian function with the distance from the beamline, no gravitational effect should remain at infinite spatial distances from the beamline. Therefore, we have to ensure that the Riemann curvature tensor $R^{\mu}{}_{\rho\sigma\alpha}$ vanishes for $\rho \to \infty$. General solutions of Eqs. (1), (2) and (3) can be given in terms of the free space Green's function for the Poisson equation in two dimensions as

$$h_{\alpha\beta}^{\lambda(n)}(\xi, \chi, \theta\zeta) = \frac{1}{4\pi} \int_{-\infty}^{\infty} d\xi' d\chi' \log\left((\xi - \xi')^2 + (\chi - \chi')^2\right) Q_{\alpha\beta}^{\lambda(n)}(\xi', \chi', \theta\zeta') \,, \tag{4}$$

where $Q^{\lambda(n)}$ are the right hand sides of Eqs. (1), (2) and (3), respectively.

In the second situation, where we assume a short distance between emitter and absorber, the rapid change of the field strength at emitter and absorber cannot be neglected. Then, we solve the linearized Einstein equations by making use of the corresponding Green's function.

Iteratively solving the Poisson equations for the terms in the expansion of the metric perturbation up to a given order in the divergence angle, we obtain an expression for the spacetime metric which contains all information about the gravitational field of the laser beam to the given order. Knowing the spacetime metric allows us to study the motion of test particles in the gravitational field of the laser beam; their world lines $\gamma^\mu$ satisfy the geodesic equations which depend on the Christoffel symbols, and the distance between two initially parallel geodesics is governed by the geodesic deviation equation which is given in terms of the Riemann curvature tensor. Both Christoffel symbols and curvature tensor are expanded in orders of the divergence angle $\theta$.

## 4. Conclusions

In zeroth order in $\theta$, all non-vanishing components of the metric perturbation are equal up to a sign. Explicitly, we have $h_{\tau\tau}^{(0)} = h_{\zeta\zeta}^{(0)} = -h_{\zeta\tau}^{(0)} = -h_{\tau\zeta}^{(0)} =: I^{(0)}$. For

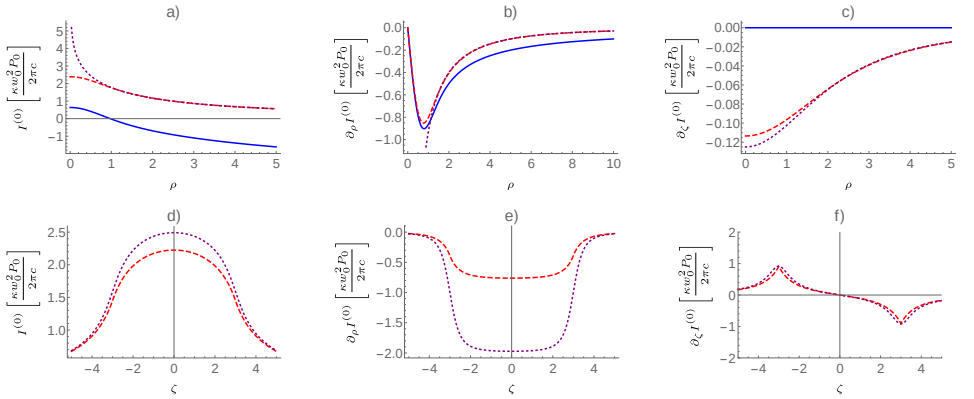

Fig. 2. These plots show the value of the leading order of the metric perturbation $I^{(0)}$ and its first derivatives for the Gaussian beam with infinite distance between emitter and absorber (plain, blue), the Gaussian beam with short distance between emitter and absorber (dashed, red), and the infinitely thin beam (dotted, purple). $\rho$ is defined as $\sqrt{\xi^2+\chi^2}$. In the second and the third case, the distance between emitter and absorber is chosen to be $6w_0$. In the first row, the functions are plotted for $\zeta = 1$ and in the second row for $\rho = 1/2$. The second row does not contain plots for large distances between emitter and absorber as there is no dependence of $I^{(0)}$ on $\zeta$ in that case. We find that the values for $I^{(0)}$ and its first derivatives are usually larger for the infinitely thin beam than for the other two cases. This is due to the divergence at the beamline for the case of the infinitely thin beam. In the other two cases, the gravitational field is spread out as the sources are. In b), we see that the absolute value of the first $\rho$-derivative of $I^{(0)}$ reaches a maximum at a finite distance from the beamline. Note that $\partial_\rho I^{(0)}$ is proportional to the acceleration that a test particle experiences if it is initially at rest at a given distance $\rho$ to the beamline. We see that the acceleration is always directed towards the beamline. It is larger in the case of an infinite distance between emitter and absorber than in the case of a finite distance, which we can attribute to the larger extension of the source (and thus the larger amount of energy) in the former than in the latter. In d), which shows plots for finite distance between emitter and absorber, we see that $\partial_\rho I^{(0)}$ still is the largest at the center between emitter and absorber and decays quickly once their positions at $\zeta = \pm 3$ are passed.

small values of the beam waist and for $\theta = 0$, which corresponds to the paraxial approximation in our case, our solution for the laser beam corresponds to the solution for the infinitely thin beam[15]. If we consider the laser beam to be infinitely long and assume $\theta = 0$, we recover the solution for an infinitely long cylinder[3]. In Fig. 2, the function $I^{(0)}$ and its derivatives are illustrated for the three cases of the infinitely long Gaussian beam, the Gaussian beam with short distance between emitter and absorber, and the infinitely thin beam.

In first order in the divergence angle, we find frame dragging due to spin angular momentum of the circular polarized laser beam. This is similar to the result of Ref. 14 for beams with intrinsic orbital angular momentum. In contrast to frame dragging induced by orbital angular moment, the effect that we find decays like a Gaussian with the distance from the beamline.

The statement of Ref. 15 by Tolman et al. that a non-divergent light beam does not gravitationally deflect a co-directed parallel light beam has been recovered

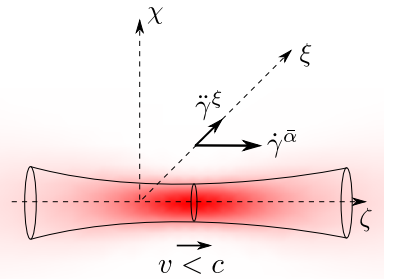

Fig. 3. Schematic illustration of the laser beam and the parallel co-propagating test ray of light: We look at the deflection of the test ray of light due to the gravitational field of the laser beam.

in different contexts: two co-directed parallel cylindrical light beams of finite radius[2,3,10], spinning non-divergent light beams[9], non-divergent light beams in the framework of gravito-electrodynamics[5] and parallel co-propagating light-like test particles in the gravitational field of a one-dimensional light pulse[11]. In fourth order in the divergence angle, we find a deflection of parallel co-propagating test beams. This shows that the result of Ref. 15 and Ref. 3 only holds up to the third order in the divergence angle. This could have been expected from the fact that the group velocity of light in a Gaussian beam along the beamline is not the speed of light[6,7]. However, the deflection of parallel co-propagating light beams by light in a focused laser beam decays like a Gaussian with the distance from the beamline. This means that the effect does not persist outside of the distribution of energy given by the laser beam.

In Ref. 13, we compare the result to the deflection that one obtains from a rod of matter boosted to a speed close to the speed of light. We conclude that focused light does not simply behave like massive matter moving with the reduced velocity identified in Refs. 11, 14. We argue that this difference is due to the divergence of the laser beam along the beamline which leads to additional non-zero components of the metric perturbation which do not appear in the case of the boosted rod. These additional contributions cancel the effect of the reduced propagation speed of light in the focused beam for large distances from the beamline.

# Schwinger effect impacting primordial magnetogenesis

Clément Stahl

*Instituto de Física, Pontificia Universidad Católica de Valparaíso, Casilla 4950, Valparaíso, Chile*

*clement.stahl@pucv.cl*

We explore the enhancement of an electromagnetic field in an inflationary background with an anti-conductive plasma of scalar particles. The scalar particles are created by Schwinger effect in curved spacetime and backreact to the electromagnetic field. The possibility of a negative conductivity was recently put forward in the context of the renormalization of the Schwinger induced current in de Sitter spacetime. While a negative conductivity enhances the produced magnetic field, we find that it is too weak to seed the observed intergalactic magnetic field today. This result on pair creation in inflationary scenario is however important for primordial scenarii of magnetogenesis as the presence of a conductivity alters the spectral index of the magnetic field. This also shows on a specific example that backreaction can increase the electromagnetic field and not only suppress it.

*Keywords*: Cosmology, Quantum field theory in curved spacetime, Inflation, Magnetogenesis, Backreaction.

## 1. Introduction

The generation of cosmological scale magnetic fields is an open question nowadays[1]. From blazar observation, it is possible to put a lower bound on the intergalactic magnetic field today: $B_0 > 10^{-18}$ G[2]. A primordial (inflationary) generation of magnetic fields is appealing because it would explain the large coherence length of the present magnetic field. However, most scenarii are plagued with the so-called backreaction problem and strong coupling problem[3]. On the other hand, if strong electromagnetic fields are present during inflation, they may trigger particle production also known as Schwinger effect. In inflationary spacetime, the production of particles has very peculiar effects: negative conductivity, infrared-hyperconductivity that could lead to exotic phenomenology.

In this proceeding, we report on Ref. 4, which investigated the backreaction of particles produced via Schwinger mechanism to the electromagnetic field. It is found that: provided that the particules are produced in a weak electric field regime (assumption required in order to have a negative conductivity), the electromagnetic field is enhanced. But not enough to seed the observed present magnetic field. Our model is specific in the sense that it does *not* break the conformal invariance by hand but with backreaction effects. Besides, it shows on a specific example how the electromagnetic fields is impacted by particle production. A more complete numerical investigation was carried out in Ref. 5.

In section 2, we review the latest results on Schwinger effect in de Sitter space. In section 3, we present the basic equations for our setup and calculate the electromagnetic power spectra at the end of inflation. Eventually in section 4, we give some concluding remarks and discuss some possible extensions of this work.

## 2. Schwinger effect

We consider the production of charged scalar particles $\varphi$ of mass $m$ in $1+3$ D under the influence of a constant electric field in dS:

$$S = \int \sqrt{-g} d^4x \left[ -\frac{1}{4\pi} F_{\mu\nu} F^{\mu\nu} + g^{\mu\nu} (\partial_\mu - ieA_\mu) \varphi^* (\partial_\nu + ieA_\nu) \varphi - m^2 \varphi^2 \right]. \quad (1)$$

The scale factor $a$ of the de Sitter metric reads:

$$a(\eta) = -\frac{1}{1 - H\eta}, \quad (2)$$

where $\eta$ is the conformal time running from $-\infty$ to $H^{-1}$ and $H$ is the Hubble constant. The gauge field $A_\mu$ ($\mu = 0, 1, 2, 3$) is considered pointing in the z-direction with a constant amplitude $E^2$. We will discuss in more detail in section 3 the relevance of modeling the electric field as a constant one. In dS, (2), it reads:

$$A_\mu = -\frac{E}{H} \left( a(\eta) - 1 \right) \delta^z_\mu. \quad (3)$$

With such as choice, the Lorentz and Coulomb gauge conditions are satisfied: $A_0 = \partial_i A_i = 0$. In order to quantize, the rescaled complex scalar field $\chi = a\varphi$ is expanded on modes function:

$$\chi(\eta, \mathbf{x}) = \int \frac{d^3\mathbf{k}}{(2\pi)^3} e^{i\mathbf{x}.\mathbf{k}} \left( \chi_{\mathbf{k}}(\eta) b_{\mathbf{k}} + \chi^*_{\mathbf{k}}(\eta) d^\dagger_{-\mathbf{k}} \right) \quad (4)$$

The commutation relation for the annihilation and creation operators are:

$$\left[ b_{\mathbf{k}}, b^\dagger_{\mathbf{k}'} \right] = \left[ d_{\mathbf{k}}, d^\dagger_{\mathbf{k}'} \right] = (2\pi)^3 \delta^{(3)}(\mathbf{k} - \mathbf{k}'), \quad (5)$$

the other commutators being 0. Varying the action (1) with respect to the scalar field gives the Klein-Gordon equation for each modes:

$$\left[ \partial^2_\eta + \omega^2_{\mathbf{k}}(\eta) \right] \chi_{\mathbf{k}} = 0, \quad (6)$$

where the effective pulsation is: $\omega^2 = \mathbf{p}^2 + \frac{\beta}{1-H\eta} + \frac{\gamma}{(1-H\eta)^2}$, the shifted momentum is: $\mathbf{p} = \mathbf{k} + (0, 0, \frac{eE}{H})$, $\alpha = m^2 + \left(\frac{eE}{H}\right)^2$ and $\beta = -2\frac{eE}{H} p_z$. Changing the time variable to $z = -2ip\left(\frac{1}{H} - \eta\right)$, two independent solutions to (6) are the Whittaker functions $\mathcal{W}_{\kappa,\mu}$ and $\mathcal{M}_{\kappa,\mu}$ which are hypergeometric functions. The Maxwell current is defined as:

$$J_\mu = ie \left[ (D_\mu \varphi)^\dagger \varphi - \varphi^\dagger D_\mu \varphi \right], \quad (7)$$

where $D_\mu = \partial_\mu + ieA_\mu$. This current can be shown to be conserved and the only non-vanishing component of it is the z-component. It is possible to calculate it in term of the solutions to the Klein-Gordon equation (6):

$$< J_i >= \frac{2e}{a^2} \int \frac{d^3\mathbf{k}}{(2\pi)^3} (k_i + eA_i) |\chi_{\mathbf{k}}|^2. \quad (8)$$

With the ingredients given above, it is in principle a mechanical task to calculate the current (8). But this current is UV divergent and needs to be renormalized. The issue of renormalization is not as well understood in curved spacetime than in flat spacetime, as Prof. Navarro-Salas also discussed during his talk of the session[6,7], see also Ref. 8 for related issues. While, the exact details of the renormalization scheme are still debated, it seems that most of the groups[9–11] agree that the current (8) in the weak electric field regime ($\frac{eE}{H^2} \ll 1$) is *negative*:

$$\mathcal{J} = -\frac{8}{9\pi} M^3 \exp(-2\pi M) L, \tag{9}$$

where we further defined the dimensionless electric field and mass: $M = \frac{m}{H}$, $L = \frac{eE}{H^2}$. This results will be our starting point to investigate how magnetogenesis is impacted by the presence of such a negative current. A negative current is somehow counter-intuitive because it would means that charged particles move opposite to the electric field, which gives intuitively an anti-screening of the electromagnetic field. This effect exist only in the infrared regime of de Sitter and therefore deserve special attention because of its peculiarity.

## 3. Inflationary magnetogeneis

We now also use the action (1) but focus on the electromagnetic side of the theory. We will be using the results of section 2 for Schwinger effect in dS: at each Hubble time, pairs are created. Since those pairs were derived for a constant electric field, our model is not valid for any situation: the typical time of pair creation $t_{\rm pair} = \frac{1}{H}$ has to be much smaller that the typical time of evolution of the electromagnetic field $t_E = \frac{1}{k}$. In other words, our model is valid, as soon as one focuses large scales. Intuitively, particle creation is a local quantum process, therefore the time variation of the electric field have to be on scale larger than the scale of production of the pairs. Besides, as we investigate the possibility of a negative conductivity as in equation (9) which appears in the weak electric field limit: $L \ll 1$, this avoids, in passing, the backreaction problem present in many models of magnetogenesis. Inspired by (9), we assume that a Maxwell current of the form

$$J_i = H\sigma E_i. \tag{10}$$

$\sigma$ is a dimensionless negative constant. It depends on the details of the pair creation process. The conformal invariance prevents perturbations of a gauge-field to develop, however here, the Schwinger mechanism breaks it with quantum fluctuations inducing a current and leading to the possibility of parametric amplification of the gauge field. The case of a strong electric field ($L \gg 1$) leads to a positive conductivity which screens the amplification of the EM field[12,13].

Varying (1), including the Maxwell current and changing variable to the canonical one, one gets[4]:

$$\mathcal{A}''(k,\eta) + \left[k^2 - H^2 a^2 \left(\frac{\sigma}{2}\right)\left(1 - \frac{\sigma}{2}\right)\right] \mathcal{A}(k,\eta) = 0 \tag{11}$$

which is the equation of an harmonic oscillator with a time dependent frequency. The detailed calculation for the quantization procedure can found in Ref. 14. It is possible to solve explicitly (11) to eventually find the electric and magnetic power spectra.

$$P_E \propto H^4 \left(\frac{k}{aH}\right)^{\sigma+4} \tag{12}$$

$$P_B \propto H^4 \left(\frac{k}{aH}\right)^{5-|\sigma+1|} \tag{13}$$

**Discussion of the parameters** We define the electric and magnetic spectral index $n_E$ and $n_B$ as $n_{E/B} \equiv \frac{\partial \log P_{E/B}}{\partial \log k}$. To avoid the backreaction problem and validate the scheme of pair production considered by taking an induced current of the form (10), one needs to consider a scenario where the electric field does not dominate the dynamics: $n_E > 0$ implying: $\sigma \in ]-4, 0]$. The strong coupling problem is also solved for these values. In that case $n_B \in ]2, 5]$: the magnetic spectrum is blue, dominated by UV contributions and is more damped than its electric counter part. For those values, it has been shown however that the maximal magnetic field today at Mpc scales would be $10^{-32}$ G[3], which is lower than the observed lower bound[2]. In more standard scenarii, where conformal symmetry is broken by hand, for instance by a non-minimal kinetic term $I$ parameterized as $I(\eta) \propto a^n$, the same equation of motion for the gauge field (11) would hold provided that $2n = \sigma$. This is an important result of this work as particle creation is expected as soon as the gauge field is present and our result is a clear backreaction results on how the gauge field dynamics would change in the presence of this particle: the spectral index of the magnetic field for instance would be shifted by $\frac{\sigma}{2}$. Similar results were found in Ref. 5.

## 4. Conclusion

In this proceeding, we reported on the backreaction of the particles produced by Schwinger effect in de Sitter to the electromagnetic field[4]. We showed that Schwinger effect impacts on the amplification of the EM quantum fluctuations. In Ref. 12, it was already remarked that strong electric fields constrain a branch of the IFF scenarios in a similar manner than the backreaction problem. In this work, we completed this statement by considering negative conductivity (for weak electric fields) as a way to break the conformal invariance and to amplify EM quantum fluctuations. The presence of a negative conductivity is either motivated by a new implementation of the adiabatic subtractions in the renormalization of the electric current presented in Ref. 10 or by the presence of non-linear terms generalizing the Einstein-Maxwell equation and a logarithmic running of the coupling constant $e$[11]. We found models where both the strong coupling and the backreaction problem are avoided for $\sigma \in ]-4, 0]$ however these models do not fulfill the lower bound of observed magnetic fields[2].

Those results are also relevant for primordial magnetogenesis model builder as the pair creation process depicted here matters as soon as EM fields are present during inflation. While in the case, of strong (backreacting) electric fields, one expects a dwindling of the EM field[12], for weaker fields this effects could add up to any other way to break the conformal invariance. The global effect of Schwinger pair creation on the power spectrum of quantum fluctuations would be to have a redder spectral index, more concretely: $n_B \to n_B + \frac{\sigma}{2}$.

Several directions are fruitful for the future. Prof. Navarro-Salas showed during his talk that the electric field (as any connection) has to be taken to be adiabatic order 1 in order to recover the trace anomaly[6]. Prof. Bavarsad discussed during his talk that backreaction can also happen to the gravitational field and Schwinger pairs could challenge the stability of de Sitter space[15], see also Ref. 16 for recent results. Producing Schwinger particles from a SU(2) gauge field and not U(1) leads to a different phenomenology[17] and in particular, it is known that SU(2) particles typically produce huge amount of gravitational waves, which may be constrained by the standard cosmological observables (CBM...). Finally, directly coupling the particle produced to the inflaton, with the Schwinger-Keldysh formalism, allow to produce a unique type of non-gaussianities[18] which in principle allow to measure Schwinger effect in the CMB or in LSS.

## Acknowledgments

It is a pleasure to thank all the participants and speakers of this session for stimulating scientific discussions ans interaction during the meeting and during the nights. I am also very grateful to all the people who organized the Marcel Grossmann meeting: professors, staffs, secretaries, students.

We investigate the influence of the surface electrical charge in the static equilibrium configuration of white dwarfs, this is possible by solving numerically the hydrostatic equilibrium equation for the charged case. We consider that the fluid in the star is described by a fully degenerate electron gas and that the electric charge is distributed close to the surface of the white dwarf. We found that super-Chandrasekhar mass white dwarfs are found for a large surface electrical charge.

*Keywords*: White dwarfs; stellar structure.

## 1. Introduction

### 1.1. *Super-Chandrasekhar white dwarfs*

In the last few years have been disclosed observations concerning the existence of a particular event in the universe, the super-luminous type Ia supernovae (SNIa)[1–4]. These events are very interesting because their explosion are the more foreseeables and frequently the brightest incidents in the sky. Some authors argue that the possible progenitor of the event SNIa is the super-Chandrasekhar white dwarf, star which ultrapass the standard Chandrasekhar mass limit, $1.44\,M_\odot$[5,6]. It is estimated that the super-Chandrasekhar white dwarfs' masses are in the range $2.1-2.8\,M_\odot$[7,8].

Several authors hint models to explain super-Chandrasekhar white dwarfs. In literature, for example, we found white dwarf models where are considered a strong magnetic field[9,10], in rotation and with different topologies for magnetic field[11–14] and with a electric charge distribution[15].

It is found that white dwarfs with an uniform and very strong magnetic field can attain masses of $\sim 2.9\,M_\odot$. Although these objects exceeds significantly the Chandrasekhar limit, they suffer from severe stability[16–20]. The effect of the rotation and different topology for the magnetic field help to reach white dwarfs' masses around $5M_\odot$[11–14]. A similar effect to the ones aforementioned are produced by the electric charge, which produces a force which helps to the one generated by the fluid pressure to counteract more mass and thus avoid gravitational collapse[15].

### 1.2. *This work*

Such as is realized in Ref. 15, in this article we also studied the influence of the electric charge in the structure of white dwarfs. The main difference between these two works is the profile of the electric charge. Instead of consider the electric charge density proportional to the energy density, $\rho_e = \alpha\rho$, with $\alpha$ being a dimensionless constant, such as is considered in Ref. 15, here we consider that the electric charge is distributed at the star's surface[21] of the form:

$$\rho_e = k\, exp\left[-\frac{(r-R)^2}{b^2}\right], \tag{1}$$

where $r$ and $R$ represent the radial coordinate and the total radius of the uncharged star. Moreover, $b$ represents the width of the electric charge distribution, here we consider that $b = 10\,[\mathrm{km}]$. The charge profile (1) is taking into account since electrons and ions at white dwarfs could important producing surface's strong electric fields.

With the aim of found $k$, we use the equality:

$$\sigma = \int_0^\infty 4\pi r^2 \rho_e dr, \tag{2}$$

where $\sigma$ bears the magnitude directly proportional to the electric charge distribution. Considering Eq. (1) in Eq. (2), it is found:

$$k = \frac{\sigma}{4\pi}\left(\frac{\sqrt{\pi}\, b\, R^2}{2} + \frac{\sqrt{\pi}\, b^3}{4}\right)^{-1}. \tag{3}$$

As can be seen, Eq. (3) connects $k$ and $\sigma$.

For the fluid, we consider that the fluid pressure and fluid energy density within the object are given by the relations:

$$p(k_F) = \frac{1}{3\pi^2\hbar^3}\int_0^{k_F} \frac{k^4}{\sqrt{k^2+m_e^2}} dk, \tag{4}$$

$$\rho(k_F) = \frac{1}{\pi^2\hbar^3}\int_0^{k_F} \sqrt{k^2+m_e^2}\, k^2 dk + \frac{m_N \mu_e}{3\pi^2\hbar^3} k_F^3, \tag{5}$$

with $m_e$, $m_N$, $\hbar$, $\mu_e$ and $k_F$ being respectively the electron mass, the nucleon mass, the reduced Planck constant, the ratio between the nucleon number and atomic number for ions and the Fermi momentum of the electron[22]. It is important to say that we consider $\mu_e = 2$.

## 2. Stellar structure equations

We shall study the stellar equilibrium configuration of charged white dwarfs using the profile of the electric charge and the equation of state showed in the previous section. We consider that within the star the charged fluid is described by the energy-momentum tensor (EMT):

$$T_{\mu\nu} = (\rho + p)u_\mu u_\nu + p g_{\mu\nu} + \frac{1}{4\pi}\left(F^{\mu\gamma}F_{\varphi\gamma} - \frac{1}{4} g_{\mu\nu} F_{\gamma\beta}F^{\gamma\beta}\right), \tag{6}$$

where $\rho$ and $p$ represent respectively the energy density and fluid pressure. In addition, $u_\mu$ beings the fluid's four velocity, $g_{\mu\nu}$ stands the metric tensor and $F^{\mu\gamma}$ represents the Faraday-Maxwell tensor.

The interior space-time of the charged star is described, in Schwarzschild coordinates, by the following line element:

$$ds^2 = -e^{\nu(r)}dt^2 + e^{\lambda(r)}dr^2 + r^2\left(d\theta^2 + \sin^2\theta d\phi^2\right), \tag{7}$$

as indicated, the functions $\nu(r)$ and $\lambda(r)$ dependent on the radial coordinate $r$ only.

For the line element (7), the nonzero components of the Maxwell-Einstein equation are given by the equalities:

$$q'(r) = 4\pi\rho_e(r)r^2e^{\lambda(r)/2}, \tag{8}$$

$$m'(r) = 4\pi r^2\rho(r) + \frac{q(r)q'(r)}{r}, \tag{9}$$

$$p'(r) = -(p(r)+\rho(r))\left(4\pi rp(r) + \frac{m(r)}{r^2} - \frac{q^2(r)}{r^3}\right)e^{\lambda(r)} + \frac{q(r)q'(r)}{4\pi r^4}, \tag{10}$$

with the potential metric of the form:

$$e^{-\lambda(r)} = 1 - \frac{2m(r)}{r} + \frac{q^2(r)}{r^2}, \tag{11}$$

primes indicate the derivations with respect to $r$. The functions $q$ and $m$ represent the electric charge and the mass inside the sphere of radial coordinate $r$. Moreover, Eq. (10) represents the hydrostatic equilibrium equation, known also as the Tolman-Oppenheimer-Volkoff equation[23,24]. This equation is modified from its original version to include the electrical part[25].

## 3. Results and conclusions

The static equilibrium configurations of charged white dwarfs are presented in Fig. 1. On the left and on the right hand side are shown the behavior of total mass $M/M_\odot$

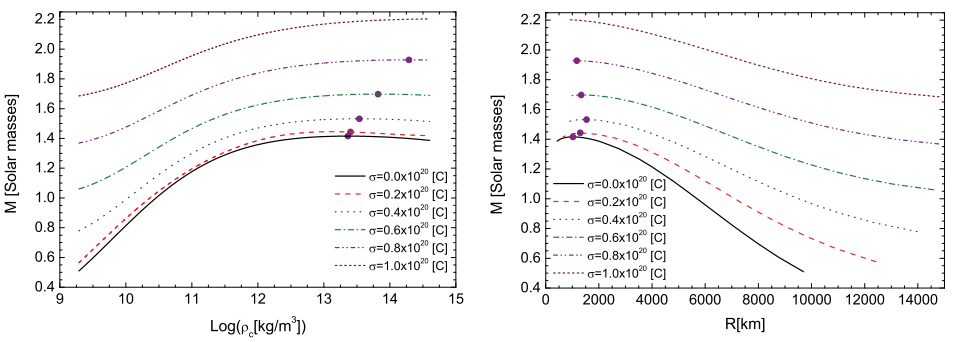

Fig. 1. The mass as a function of the central energy density and against the radius are plotted on the left and right hand side, respectively. The full circles represent the maximum mass points. In both figures are used different values of $\sigma$.

versus with central energy density $\rho_c$ and with the radius $R$, respectively, for different values of $\sigma$. For $\sigma$ lower than $0.8 \times 10^{20}$ [C], it can be observed that $M/M_\odot$ grows with $\rho_c$ until to attain $M_{\max}/M_\odot$ (marked with a full circles in purple), after that point, $M/M_\odot$ begins to decreases with the increment of $\rho_c$. At the same time, it is important to say that for $\sigma = 1.0 \times 10^{20}$ [C], $M/M_\odot$ increases monotonically with $\rho_c$, in this way, not maximum mass point is found. In addition, we highlight that the maximum mass found in this model is $2.199 M_\odot$, which is obtained using $\sigma = 1.0 \times 10^{20}$[C]. This total mass in the interval masses estimated for the super-Chandrasekhar white dwarfs, 2.1-2.8$M_\odot$, check Refs. 8, 7.

In Fig. 1 we can also note that in the uncharged case we obtain a maximum mass is found in a central energy density $\rho_c^*$, in turn, in the charged cases this points are attained for $\rho_c > \rho_c^*$. Additionally, such as happen for the total mass, the radius change with the total charge.

From the results aforementioned, we can conclude that the electric charge affects notably the static equilibrium configuration of white dwarfs. For a larger $\sigma$, white dwarfs with larger masses are found. This can be understand since $\sigma$ is directly related with the total charge in the star. An increment of the electric charge produce an increment of a force which helps to the fluid pressure to support more mass, thus avoiding the gravitational collapse. More details are presented in Ref. 26.

# Possible formation of lowly luminous highly magnetized white dwarfs by accretion leading to SGRs/AXPs

B. Mukhopadhyay[1*], M. Bhattacharya[2], A. R. Rao[3], S. Mukerjee[1] and U. Das[4]

*4. University of Colorado, Boulder, USA*

We sketch a possible evolutionary scenario by which a highly magnetized super-Chandrasekhar white dwarf could be formed by accretion on to a commonly observed magnetized white dwarf. This is an exploratory study, when the physics in cataclysmic variables (CVs) is very rich and complex. Based on this, we also explore the possibility that the white dwarf pulsar AR Sco acquired its high spin and magnetic field due to repeated episodes of accretion and spin-down. We show that strong magnetic field dramatically decreases luminosity of highly magnetized white dwarf (B-WD), letting them below the current detection limit. The repetition of this cycle can eventually lead to a B-WD, recently postulated to be the reason for over-luminous type Ia supernovae. A spinning B-WD could also be an ideal source for continuous gravitational radiation and soft gamma-ray repeaters (SGRs) and anomalous X-ray pulsars (AXPs). SGRs/AXPs are generally believed to be highly magnetized, but observationally not confirmed yet, neutron stars. Invoking B-WDs does not require the magnetic field to be as high as for neutron star based model, however reproducing other observed properties intact.

*Keywords*: White dwarfs; strong magnetic fields; CVs; pulsars; SGRs/AXPs.

## 1. Introduction

Several independent observations repeatedly argued in recent past for the existence of highly magnetized white dwarfs (B-WDs). Examples are overluminous type Ia supernovae[1,2], white dwarf pulsars[3,4] etc. Also soft gamma-ray repeaters (SGRs) and anomalous X-ray pulsars (AXPs) could be explained as B-WDs[5–7], while they are generally believed to be highly magnetized neutron stars[8] without however any direct detection of underlying required high surface field $B_s \sim 10^{15}$ G. Interestingly, explaining SGR/AXP by a magnetized white dwarf requires a lower $B_s \lesssim 10^{12}$ G, which may however correspond to central field $\gtrsim 10^{14}$ G. Nevertheless, the origin of such fields in a white dwarf remains a question, when the observed confirmed surface field is $\lesssim 10^9$ G.

Here we explore a possible evolution of a conventionally observed magnetized white dwarf to a B-WD by accretion, which may pass through a phase exhibiting currently observed AR Sco. This is an exploratory study, and the present venture is based more on an idealized situation, when the physics in accreting white dwarfs, i.e. cataclysmic variables (CVs), is very rich and complex. We also show, based on some assumption, that the thermal luminosity of such a B-WD could be very small, below their current detection limit. However, due to high field and rotation, their spin-down luminosity could be quite high. Hence, they could exhibit SGRs/AXPs.

## 2. Accretion induced evolution

The detailed investigation of the accretion induced evolution faces several difficulties including nova eruptions (hence nonsteady increase of mass) and the eruption and ejection of accumulated shells. Nevertheless, the discovery of AR Sco, which is a fast rotating magnetized white dwarf, argues for the possibility of episodic increase of mass in a CV. Hence, we sketch a tentative evolutionary scenario with repeated episodes of accretion phase leading to the high magnetic field via flux freezing and spin-power phase decreasing field. Eventually this mechanism can plausibly lead to a B-WD. Note that there are already observational evidences for transitions between spin-power and accretion-power phases in a binary millisecond pulsar[9]. The conservation laws controlling the accretion-power phase around the stellar surface of radius $R$ and mass $M$, which could be inner edge of accretion disk, are given by

$$l\Omega(t)^2 R(t) = \frac{GM(t)}{R(t)^2},\ I(t)\Omega(t) = \text{constant},\ B_s(t)R(t)^2 = \text{constant}, \tag{1}$$

where $l$ takes care of inequality due to dominance of gravitational force over the centrifugal force in general, $I$ is the moment of inertia of star and $\Omega$ the angular velocity of the star which includes the additional contribution acquired due to accretion as well. Solving the conservation laws given by equation (1) simultaneously, we obtain the time evolution of radius (or mass), magnetic field and angular velocity during accretion. Accretion stops when

$$-\frac{GM}{R^2} = \frac{1}{\rho}\frac{d}{dr}\left(\frac{B^2}{8\pi}\right)|_{r=R} \sim -\frac{B_s^2}{8\pi R\rho}, \tag{2}$$

where $\rho$ is the density of inner edge of disk.

For a dipolar fixed field, $\dot{\Omega} \propto \Omega^3$ [7], where over-dot implies time derivative. Generalizing for the present purpose it becomes $\dot{\Omega} = k\Omega^n$ with $k$ being constant. Therefore, during the phase of spin-power pulsar (when accretion inhibits), the time evolution of angular velocity and surface magnetic field may be given by

$$\Omega = \left[\Omega_0^{1-n} - k(1-n)(t-t_0)\right]^{\frac{1}{1-n}},\ B_s = \sqrt{\frac{5c^3 Ik\Omega^{n-m}}{R^6 \sin^2\alpha}}, \tag{3}$$

where $\Omega_0$ is the angular velocity when accretion just stops at the beginning of spin-power phase at time $t = t_0$, $k$ is fixed to constrain $B_s$ at the beginning of first spin-powered phase, which is determined from the field evolution in the preceding accretion-power phase, $\alpha$ is the angle between magnetic and spin axes. Note that $n = m = 3$ corresponds to dipole field.

Figure 1 shows a couple of representative possible evolutions of angular velocity and magnetic field with mass (time). It is seen that initial larger $\Omega$ with accretion drops significantly during spin-power phase (when accretion stops and hence no change of mass), followed by its increasing phase. Similar trend is seen in $B_s$ profiles with a sharp increasing trend (with value $\sim 10^{11}$ G) at the last cycle leading to the increase of $B_c$ as well, forming a B-WD. At the end of evolution, it could be left

out as a super-Chandrasekhar B-WD and/or a SGR/AXP candidate with a higher spin frequency. Of course, in reality they may depend on many other factors and the current picture does not match exactly with what is expected in AR Sco itself.

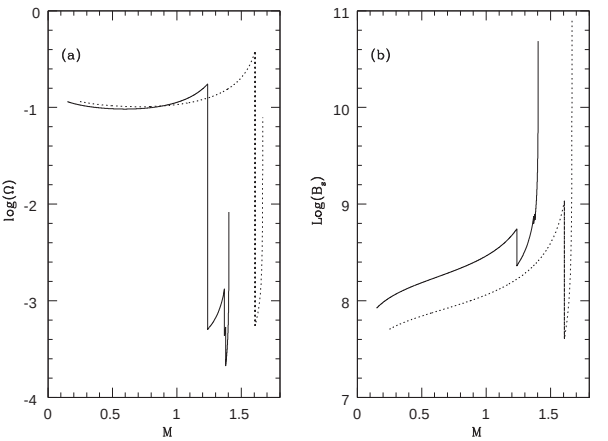

Fig. 1. Time evolution of (a) angular velocity in $s^{-1}$, (b) magnetic field in G, as functions of mass in units of solar mass. The solid curves correspond to $n = 3$, $m = 2.7$, $\rho = 0.05$ gm cm$^{-3}$, $l = 1.5$ and dotted ones to $n = 3$, $m = 2$, $\rho = 0.1$ gm cm$^{-3}$, $l = 2.5$; $k = 10^{-14}$ CGS, $\dot{M} = 10^{-8} M_{\odot} \mathrm{Yr}^{-1}$, $\alpha = 10$ degree and $R = 10^4$ km at $t = 0$. This is reproduced from a previous work[7].

## 3. Luminosity

With the increase of mass, the radius of white dwarfs, hence B-WDs, becomes very small[4,10]. Indeed, the increase of magnetic field is due to decreasing radius via flux-freezing. Now due to smaller radius, UV-luminosity of B-WDs turns out to be very small if the surface temperature is same as their nonmagnetic counterpart[7]. However more interestingly, from the conservation of energy, it is expected that the presence of strong magnetic field enforces decreasing thermal energy and hence lowering luminosity in stable equilibrium.

Combining the magnetostatic and photon diffusion equations in the presence of magnetic field but ignoring tension, we obtain

$$\frac{d}{dT}\left(P + P_B\right) = \frac{4ac}{3}\frac{4\pi GM}{L}\frac{T^3}{\kappa}, \tag{4}$$

which we solve to obtain the envelop properties. Here $P$ is the matter pressure, $P_B$ the magnetic pressure, $\kappa$ the opacity, $T$ the temperature, $a$ the radiation constant, $M$ the mass of white dwarf within the core radius $r$, which is practically the whole mass of white dwarf because the envelop is very thin, and $L$ is the luminosity. For the strong field considered here, the radiative opacity variation with $B$ can be modelled similarly to neutron stars as $\kappa = \kappa_B \approx 5.5 \times 10^{31} \rho T^{-1.5} B^{-2}$ cm$^2$g$^{-1}$ [11].

We use a field profile proposed earlier for neutron stars[12] to enumerate the field magnitude at a given density (radius), irrespective of other complicated effects, given by

$$B\left(\frac{\rho}{\rho_0}\right) = B_s + B_0\left[1 - \exp\left(-\eta\left(\frac{\rho}{\rho_0}\right)^{\gamma}\right)\right], \tag{5}$$

where $B_0$ (similar to central field) is a parameter with the dimension of $B$, other parameters are set as $\eta = 0.1$, $\gamma = 0.9$, $\rho_0 = 10^9$ g cm$^{-3}$ for all the calculations. Further equating the electron pressure for the non-relativistic electrons on both sides of the core-envelop interface gives

$$\rho_*(B_*) \approx 1.482 \times 10^{-12}\, T_*^{1/2} B_s \tag{6}$$

at interface. Now we solve equation (4) along with the photon diffusion equation

$$\frac{dT}{dr} = -\frac{3}{4ac}\frac{\kappa(\rho + \rho_B)}{T^3}\frac{L}{4\pi r^2}, \tag{7}$$

with boundary conditions $\rho(T_s) = 10^{-10}$ g cm$^{-3}$, $r(T_s) = R = 5000$ km and $M = M_\odot$, where $T_s$ is the surface temperature, and obtain $\rho - T$ and $r - T$ profiles. Further $T_*$ and $\rho_*$ can be obtained by solving for the $\rho - T$ profile along with equation (6), as shown in Fig. 2, and knowing $T_*$, we can obtain $r_*$ from the $r - T$ profile. We see that interface moves inwards ($r_*$ decreases) with increasing $B$ and $L$. But $\rho_*$ increases with increasing $L$ and/or $B$, as $\rho_* \propto T_*^{1/2} B$.

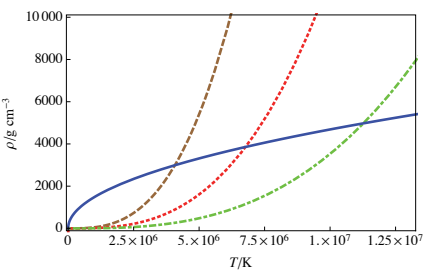

Fig. 2. Variation of density with temperature for $B \equiv (B_s, B_0) = (10^{12}\,\mathrm{G}, 10^{14}\,\mathrm{G})$ and $L = 10^{-5}L_\odot$ (dashed line), $10^{-4}L_\odot$ (dotted line) and $10^{-3}L_\odot$ (dot-dashed line). The solid line represents equation (6). This is reproduced from a previous work[13].

With above benchmarking, we now explore, based energy conservation, if the luminosity of a magnetized white dwarf or B-WD changes. For $B = 0$ and $L = 10^{-5}L_\odot$, we have $r_* = 0.9978R$, $\rho_* = 170.7$ g cm$^{-3}$ and $T_* = 2.332 \times 10^6$ K. Using the same boundary condition as described above, we now solve equations (4) and (7) with $B \neq 0$, but vary $L$ in order to fix $r_* = 0.9978R$. We find interestingly that $L$ decreases for $B \neq 0$, as shown in Table 1. Physically this corresponds to increasing $B$, and thence magnetic energy, is compensated by decreasing thermal energy (decreasing $T_*$) and thence $L$, when total energy is conserved. Similarly,

increasing $B$ may be compensated by decreasing gravitational energy (decreasing $r_*$). In either of the cases, $L$ decreases.

Table 1. Variation of luminosity with magnetic field for fixed $r_* = 0.9978R$

| $B/\mathrm{G} = (\mathrm{B_s/G}, \mathrm{B_0/G})$ | $L/L_\odot$ | $T_*/\mathrm{K}$ | $\rho_*/\mathrm{g\,cm^{-3}}$ | $T_\mathrm{s}/\mathrm{K}$ |
|---|---|---|---|---|
| $(0, 0)$ | $1.00 \times 10^{-5}$ | $2.332 \times 10^{6}$ | $1.707 \times 10^{2}$ | $3.85 \times 10^{3}$ |
| $(10^9, 6 \times 10^{13})$ | $2.53 \times 10^{-7}$ | $4.901 \times 10^{5}$ | $1.037 \times 10^{0}$ | $1.53 \times 10^{3}$ |
| $(5 \times 10^9, 2 \times 10^{13})$ | $3.96 \times 10^{-8}$ | $3.262 \times 10^{5}$ | $4.232 \times 10^{0}$ | $9.65 \times 10^{2}$ |
| $(10^{10}, 10^{13})$ | $1.02 \times 10^{-6}$ | $7.189 \times 10^{5}$ | $1.257 \times 10^{1}$ | $2.17 \times 10^{3}$ |
| $(2 \times 10^{10}, 8 \times 10^{12})$ | $4.40 \times 10^{-9}$ | $2.063 \times 10^{5}$ | $1.346 \times 10^{1}$ | $5.57 \times 10^{2}$ |
| $(5 \times 10^{10}, 4 \times 10^{12})$ | $2.59 \times 10^{-8}$ | $3.185 \times 10^{5}$ | $4.182 \times 10^{1}$ | $8.68 \times 10^{2}$ |
| $(5 \times 10^{11}, 10^{12})$ | $2.93 \times 10^{-9}$ | $2.206 \times 10^{5}$ | $3.480 \times 10^{2}$ | $5.03 \times 10^{2}$ |

## 4. SGRs/AXPs as B-WDs

Paczynski[5] and Usov[6] independently proposed that SGRs and AXPs are moderately magnetized white dwarfs but following Chandrasekhar's mass-radius relation[14]. Many features of SGRs/AXPs are explained by their model at relatively lower magnetic fields, while the more popular magnetar model[8] requires field $\gtrsim 10^{15}$ G, which is not observationally well established yet. Nevertheless, such a white dwarf based model suffers from a deep upper limit on the optical counterparts of some AXPs/SGRs, e.g. SGR 0418+5729, due to their larger moment of inertia.

Now B-WDs established here could be quite smaller in size and hence have smaller moment of inertia. Therefore, their optical counterparts, with very low UV-luminosities, are quite in accordance with observation. Hence, the idea of B-WD brings a new scope of explain SGRs/AXPs at smaller magnetic fields, which are observationally inferable, compared to highly magnetized magnetar model. For details see the work by Mukhopadhyay & Rao[7].

## 5. Continuous Gravitational Radiation

Due to smaller size compared to their regular counterpart, B-WDs rotate relatively faster. Now if the rotation and magnetic axes are misaligned, they serve as good candidates for continuous gravitational radiation due to their quadrupole moment, characterized by the amplitude[15]

$$h_+(t) = \frac{h_0}{2}(1 + \cos^2\alpha_0)\cos\Phi(t),\ h_\times(t) = h_0\cos\alpha_0\sin\Phi(t),\ h_0 = \frac{4\pi^2 G I_{zz}\epsilon}{c^4 P_s^2 D}, \quad (8)$$

where $\alpha_0$ is the inclination of the star's rotation axis with respect to the observer, $\Phi(t)$ is the signal phase function, $\epsilon$ amounts the ellipticity of the star, $I_{zz}$ is the moment of inertial about z-axis, and $D$ is the distance between the star and detector.

A B-WD of mass $\sim 2M_\odot$, polar radius $\sim$ 700 km, spin period $P_s \sim 1$ s[16], $\epsilon \sim 5 \times 10^{-4}$ and $D \sim 100$ pc would produce $h_0 \sim 10^{-22}$, which is within the

sensitivity of the Einstein@Home search for early Laser Interferometer Gravitational Wave Observatory (LIGO) S5 data[15]. However, DECIGO/BBO would give a firm confirmation of their gravitational wave because they are more sensitive in their frequency range. In fact, if the polar radius is $\sim 2000$ km with $P_s \sim 10$ s and other parameters intact, DECIGO/BBO can detect it with $h_0 \sim 10^{-23}$. Nevertheless, (highly) magnetized rotating white dwarfs approaching B-WDs are expected to be common and such white dwarfs of radius $\sim 7000$ km, $P_s \sim 20$ sec and $D \sim 10$ pc could produce $h_0 \gtrsim 10^{-22}$ which is detectable by LISA.

## 6. Summary

The idea of B-WD has been proposed early this decade, mainly to explain observed peculiar type Ia supernovae inferring super-Chandrasekhar progenitor mass. Lately it has been found with various other applications, e.g. SGRs/AXPs, white dwarf pulsars like AR Sco, continuous gravitational wave etc. Here we have attempted to sketch a plausible evolution scenario to explain the formation of such a highly magnetized, smaller size white dwarf. In our simplistic picture, ignoring many complicated CV features, we are able to show that a commonly observed magnetized white dwarf could be evolved to a B-WD via accretion. Hence, the existence of highly magnetized, rotating, smaller white dwarfs is quite plausible.

# The effect of positrons in hot white dwarfs

Sílvia P. Nunes* and Manuel M. Malheiro

*Technological Institute of Aeronautics,*
*São José dos Campos, SP, Brazil*
**E-mail: silviapn@ita.br*

White dwarf stars are widely studied as being composed of an ion lattice embedded in a degenerate fermion gas. However, at the beginning of their lives these stars are subject to temperatures that can reach up to $T = 10^9 K$. In this limit there is no longer total degeneracy and a temperature-dependent equation of state (EOS) is needed to take in account the Fermi-Dirac occupation factor of fermion levels. In this article, we will study this regime, in particular the effect of positrons in the EOS and in the hot white dwarf structure.

*Keywords*: White Dwarfs, Hot White Dwarfs.

## 1. Introduction

White dwarfs (WDs) are known as stars that have mass of about one solar mass, radii of about 5000 km and mean densities around $10^6$ g/cm$^3$. These stars are also associated, after thermonuclear detonation in their interior, with supernova Ia formation [2]. As any other star, the WD also have a life, they are born with AGBs stars or even in mergers [2] and pass their lives cooling until they reach a totally degenerate state. Until this cold matter state is reached, the star can reach temperatures of about $10^8 K$ in the core, as already studied in Ref. 3, 4. Furthermore, temperatures of about $2 \times 10^9$ K have already been discussed in the white dwarf interior. [5]

In this article we propose the WD star may reach temperatures of $10^9$K and study the consequences of this value for the stellar interior, as the degeneracy breaks down. Also, we ended up struggling with a possible positron presence in the edge of the star, and analyzed their consequences in the star structure.

## 2. The relativistic frame

The Schwarzschild metric describes a spherical body with no rotation and can be used for WDs [6]

$$ds^2 = c^2\left(1 - \frac{2GM}{c^2 r}\right)dt^2 - \left(1 - \frac{2GM}{c^2 r}\right)^{-1} dr^2 - r^2 d\Omega^2 \tag{1}$$

from which we can derive the Tolman-Oppheimer-Volkoff equation and the mass conservation in the relativistic frame

$$\frac{dP(r)}{dr} = -\frac{4\pi r^3 G}{c^2}\frac{P(r)/c^2 + M(r)}{r^2\left(1 - \frac{2GM(r)}{c^2 r}\right)}\left[\varepsilon(r) + P(r)\right], \tag{2}$$

$$\frac{dM(r)}{dr} = 4\pi\rho r^2. \tag{3}$$

## 3. Chandrasekhar EOS at T=0

In the final state of a WD, the composition of this star can be described as a Fermi gas having degenerate matter, also known as the ideal Fermi gas. This was first described by Chandrasekhar in 1964 and the equation of state, responsible for the matter description as a function of the Fermi momentum $p_F$ is

$$P = P_e = \frac{1}{3\pi^2\hbar^3}\int_0^{p_F}\frac{p^4}{\sqrt{(mc^2)+(pc)^2}}, \tag{4}$$

$$n_e = \frac{1}{\pi^2\hbar^3}\int_0^{p_F} p^2 dp, \tag{5}$$

$$\varepsilon \simeq \varepsilon_N = \frac{A}{Z} m_u n_e, \tag{6}$$

where $P_e$ is the electron pressure, $A$ the mass number, $Z$ the atomic number, and $m_u = 1.6604 \times 10^{-24}$g the unified atomic mass.

Although the degenerate approximation is good for temperatures below $10^6$ K, there is a limit where this can not be used. In Fig. 1 we show the limit where the matter can be degenerate in the hatched area, with the condition $\rho_\star = (2.4 \times 10^{-8} g\ cm^{-3})\mu_e T_\star^{3/2}$. As the temperature arises, more the star will be nondegenerate. For temperatures below about $10^6 K$ a small part of the star is nondegenerate, which does not interfere with the star structure.

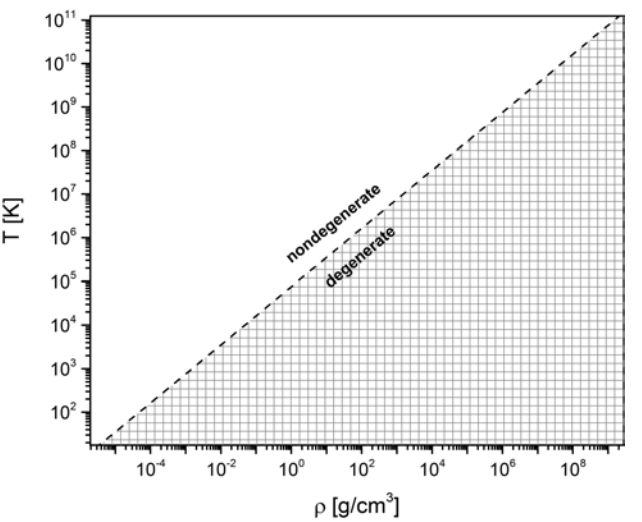

Fig. 1. The effects of nondegeneracy inside the WD star with a Fermi gas matter.

## 4. The equation of state for hot stars

For temperatures above $10^6$ the degenerate matter does not represent the whole star. So, the thermodynamics parameters have the Fermi-Dirac distribution instead of using the one particle per quantum level until the Fermi momentum. The pressure and the number density of the Fermi gas will be

$$P = P_e = \frac{1}{3\pi^2\hbar^3}\int_0^{p_F} \frac{p^4}{\sqrt{(mc^2)+(pc)^2}} \frac{1}{\exp\frac{(E-\mu)}{kT}+1}, \tag{7}$$

$$n_e = \frac{1}{\pi^2\hbar^3}\int_0^{p_F} p^2 \frac{1}{\exp\frac{(E-\mu)}{kT}+1} dp, \tag{8}$$

where $\frac{1}{\exp\frac{(E-\mu)}{kT}+1}$ is the Fermi-Dirac occupation factor. The same approximation can be used as Chandrasekhar for the energy density, as there are no new particles contributing. In Fig. 2 we can see the degeneracy behavior at different temperatures. For temperatures until $10^6 K$ the curves converge for densities above $10^2$ g/cm$^3$ which tells us that this may not influence on the star structure. The difference between the curves for small densities increases with the temperature. Using the

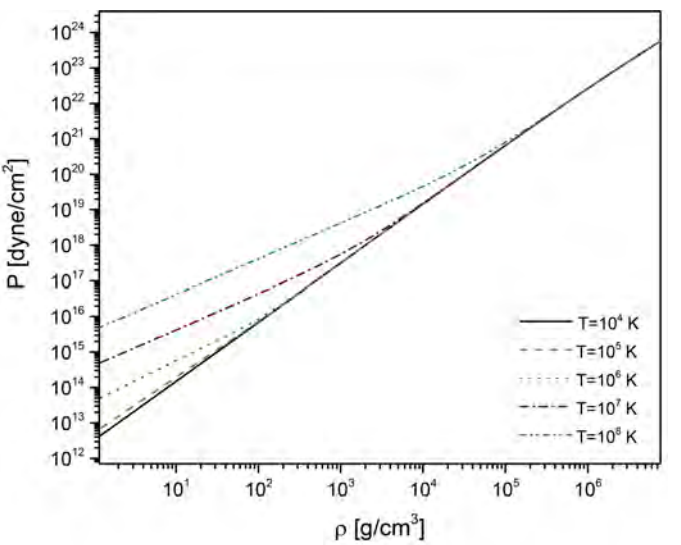

Fig. 2. The equation of state of a $C^{12}$ Fermi gas for various temperatures.

TOV equation, it is possible to find the mass as a function of the radius and the central density as shown in Fig. 3. In the left figure we can see that the radius of the star increases as the temperature increases. Furthermore, this effect is more noticeable for higher temperatures as $T = 10^8 K$.

The stability criteria can be determined considering a density $\rho^\star$, where $dM/d\rho = 0$, then, configurations with densities $\rho_c > \rho^\star$ are considered stable against

perturbation. We can notice in the right panel of Fig. 3 that the star stable region decreases with the temperature increasing.

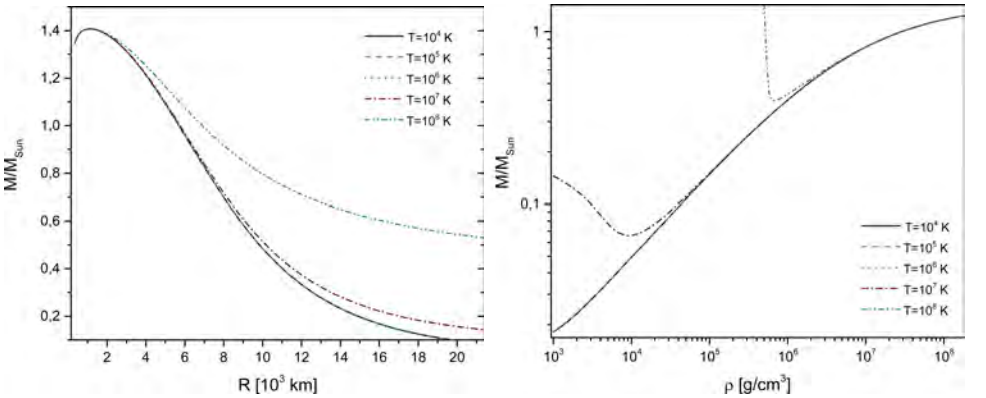

Fig. 3. Mass as a function of radius and mass as a function of central density for selected values of temperature in several stars.

### 4.1. *High temperatures inside white dwarfs*

The above treatment was done for temperatures above $10^8$, where the degenerate region still consists of a great part of the star. Considering now temperatures in the range $10^8$ to $10^9 K$ we show the equation of state in Fig. 4.

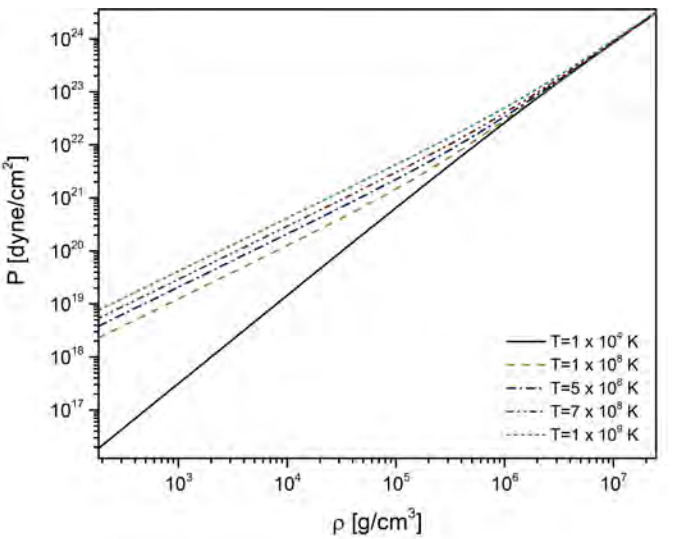

Fig. 4. The equation of state for a $C^12$ WD with high temperatures.

Increasing the white dwarf temperature we are struggling with a negative chemical potential in the end of the star. This can be understood if we consider a photon annihilation, where $\gamma \leftrightarrows e^- + e^+$. Since the photon has zero chemical potential, the positron chemical potential is related with the electron one as $\mu_{e^+} = -\mu_{e^-}$. So, the negative chemical potential indicates an antimatter (positron) presence.

To investigate the effect of positrons, we calculated the same equation of state with the negative chemical potential. In Fig. 5 we present the mass as function of the star radius and central density. The same conclusion can be made in relation to the stability, the increasing temperature generates a smaller stability region. The increase of the radius to a fixed mass is more noticeable when the thermal effects arise.

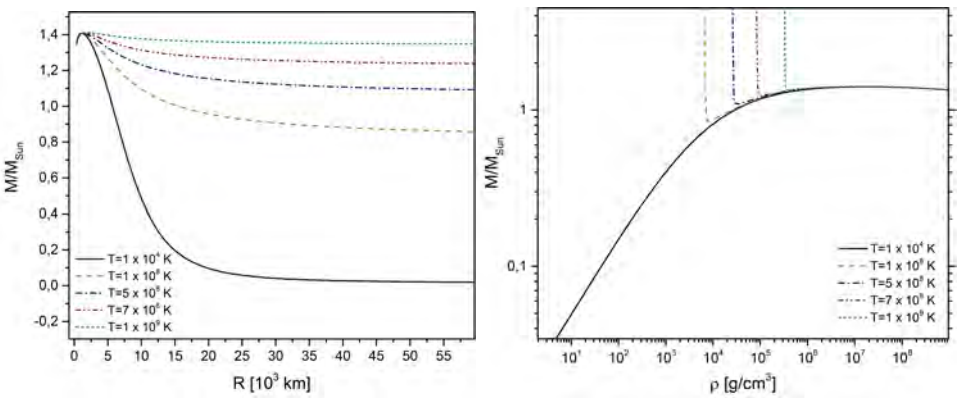

Fig. 5. Mass as a function of radius and mass as a function of central density for selected values of temperature in several stars.

### 4.2. *The effect of positrons in hot white dwarfs*

The negative chemical potential, as already discussed, is interpreted as a positron presence. This particle presence will give a residual positive charge in the last layers of the star. Instead of using equations 2 and 3, we will use a modified TOV, derived in the Reissner-Nordström spacetime solution, that includes new terms related to the electrostatic contribution

$$\frac{dq}{dr} = 4\pi\rho_e r^2 e^{\lambda/2}, \tag{9}$$

$$\frac{dm}{dr} = 4\pi r^2\rho + \frac{q}{r}\frac{dq}{dr}, \tag{10}$$

$$\frac{dP}{dr} = -(P+\rho)\left(4\pi r\rho + \frac{m}{r^2} - \frac{q^2}{r^3}\right)e^{\lambda} + \frac{q}{4\pi r^4}\frac{dq}{dr}, \tag{11}$$

where $q$ is the charge and $\rho_e$ the charge density.

We considered the charge density as

$$\rho_e = -en_{e^+}, \tag{12}$$

where $e$ is the electron charge and $n_{e^+}$ the positron number density. Here we find a hindrance, since the metric term $e^{\lambda} = (1 - \frac{2m}{r} + \frac{q^2}{r^2})^{-1}$ reaches negative values, and so the square root has an imaginary value.

## Conclusion

In this preliminary study we concluded that the effects of positrons in the high temperature regime need to be better studied, since they are complex. In the next steps of this work we are going to study carefully the degenerate effects and the cooling of these stars under the antimatter presence.

## Acknowledgments

We would like to thank the Marcel Grossman Meeting for the opportunity to present this work, and the CNPq and ITA for financial support. This work is supported in thematic project "Superdensity matter in the universe," FAPESP number 2013/26258–4.

Anomalous X-ray pulsars (AXPs) and soft-gamma repeaters (SGRs) form together a single class of astrophysical sources characterized by the emission of strong X-ray bursts and persistent emission with luminosity $10^{31}$–$10^{36}$ erg/s in the 0.2–10 keV energy range. These objects are commonly associated to magnetars, i.e. neutron stars endowed with ultra-strong magnetic fields. New-generation X-ray polarimeters like IXPE (NASA SMEX program), to be launched in 2021, will play a key role in assessing the nature of these sources by directly probing the star magnetic field. In fact, in the highly magnetized environment radiation is expected to be strongly polarized and such a measure will be easily within reach of IXPE. Polarization measurements will eventually confirm the presence of ultra-strong magnetic fields, probing the magnetar scenario. In this work I will discuss theoretical expectations, within the magnetar scenario, for the polarization signature of AXPs and SGRs and present numerical simulations for the response of the new-generation polarimeters currently under construction. I will also show how these sources can be used to test vacuum birefringence, a QED effect predicted by Heisemberg and Euler in the '30s and not experimentally verified as yet.

*Keywords*: Polarization – instrumentation: polarimeters – X-rays: stars – stars: magnetars.

## 1. Introduction

Soft gamma repeaters (SGRs) and anomalous X-ray pulsars (AXPs) are commonly considered to be different manifestations of the same class of isolated neutron stars (NSs), called magnetars.[1] They show a number of common distinctive properties, such as long (2–12 s) spin periods and large ($10^{-13}$–$10^{-10}$ s/s) spin-down rates, which lead to magnetic dipole fields up to $10^{14}$–$10^{15}$ G, and persistent X-ray luminosities ($10^{31}$–$10^{36}$ erg/s in the 0.2–10 keV range) that exceed the rotational energy loss rate (see e.g. Ref. 2 for a review). Persistent spectra are usually fitted by the superposition of a thermal (blackbody) component (with temperature $\approx 0.5$ keV) at lower energies and a power-law like tail (with photon index $\approx 2$–4) at higher ones. However, purely thermal spectra, characterized by the superposition of two BBs with similar temperatures, have been observed in the case of transient sources,[3] which undergo quite long ($\sim 1$ yr) outburst phases in which the persistent flux can be enhanced up to a factor of 1000 with respect to quiescence.

The most peculiar observational manifestation of AXPs and SGRs is the emission of short (0.1–1 s), energetic ($10^{38}$–$10^{41}$ erg/s) X-ray bursts and longer (1–100 s), even more energetic ($10^{41}$–$10^{43}$ erg/s) flares. In the case of three SGRs, giant flares,

characterized by peak luminosities up to $\approx 10^{47}$ erg/s and long-lasting (100–1000 s) pulsating tails, modulated at the spin frequency of the star, have been detected. This phenomenology has been successfully explained in terms of the twisted magnetosphere model,[4] which invokes the occurrence of resonant Compton scattering (RCS) onto electrons flowing along the NS twisted magnetic field lines. Moreover, according to this model short bursts and intermediate/giant flares can originate either in plastic displacements of the crust (deformed under the action of the internal field toroidal component) or in sudden reconnections of the field lines high in the magnetosphere.[5,6]

In the presence of magnetar-like magnetic fields, radiation emitted from the NS surface and propagating in vacuo is expected to be linearly polarized at a high degree.[7,8] The polarization state of propagating photons (which can change due to interactions with magnetospheric particles) depends on the dielectric and magnetic properties of the vacuum around the star. These are affected by vacuum birefringence, a quantum electro-dynamics (QED) effect predicted by Heisenberg & Euler in the 1930's[9] and never tested yet, which becomes important for magnetic fields in excess of the quantum critical field $B_{\rm Q} \simeq 4.414 \times 10^{13}$ G. New polarimetric techniques developed in the last years promise to open a new window in astrophysical observations of compact objects like magnetars,[10] improving the contributions of previous X-ray polarimetry missions[11] which failed in achieving conclusive results. In this work we discuss in particular the observational prospects of the NASA SMEX mission IXPE,[12] scheduled for launch in 2021, which will allow to test vacuum birefringence and probe the existence of ultra-strong magnetic fields around magnetars.

In section 2 we illustrate the theoretical model. The issue of the polarization properties of magnetar emission is addressed in section 3. Finally, we discuss the results of some numerical simulations performed until now for IXPE in section 4 and present our conclusions in section 5.

## 2. Theoretical model

According to the twisted magnetosphere model,[4] the strong (up to $\approx 10^{16}$ G) internal magnetic field of magnetars is expected to be highly wound-up, with a toroidal component of the same order of magnitude of the poloidal one. This can exert a magnetic stress on the conductive surface, that can deform the crust displacing small portions of the star surface, at which the external magnetic field lines are anchored. As a result, the external field acquires in turn a toroidal component, becoming twisted. Although the twist is reasonably localized into bundles of field lines, for the sake of simplicity we will consider in the following the case of a global twist, which is characterized by the twist angle

$$\Delta\phi_{\rm N-S} = \lim_{\theta\to 0} \int_{\theta}^{\pi} \frac{B_{\phi}}{\sin\theta B_{\theta}} {\rm d}\theta \,, \tag{1}$$

where $\boldsymbol{B} = (B_{\rm r}, B_\theta, B_\phi)$ is the star magnetic field expressed in polar components ($\theta$ is the magnetic colatitude). Magnetar bursts and flares could also originate in the crustal displacements induced by the strong internal magnetic field. In fact, according to the model discussed in Ref. 5 these deformations would inject in the magnetosphere an Alfvén pulse, which dissipates into an electron-positron pair plasma, magnetically confined within the closed field line region (the so-called "trapped fireball"). The presence of this fireball can also explain the pulsating tails observed in the spectra of many burst-emitter sources (see e.g. Ref. 6 and references therein).

Since a twisted magnetic field is non-potential (i.e. $\boldsymbol{\nabla} \times \boldsymbol{B} \neq 0$), currents must flow along the closed magnetic field lines, contrary to the case of ordinary NSs, where potential (dipolar) fields are believed to be more likely. For simplicity, we assumed that the charge carriers are electrons and ions lifted from the star surface (uni-directional flow, see Refs. 4, 13, 14). These particles make the medium in which photons propagate optically thick for RCS: a scattering occurs once the resonance condition is met, i.e. when the photon energy equals the particle cyclotron energy in the particle rest frame. In particular, for a surface magnetic field strength $\approx 10^{14}$ G one finds that photons scatter onto electrons typically at a distance $r_{\rm res} \approx 10\, R_{\rm NS}$. Numerical simulations[15] show that RCS onto magnetospheric electrons can indeed account for the power-law tails observed in the soft X-ray spectra of many objects.[2,16] Resonant scatterings onto ions may also occur; however, ions are much heavier than electrons and they are lifted at much smaller heights above the star surface. At variance with electrons, one can expect that scattering onto ions can rather give origin to narrow absorption features in the spectra.[15]

## 3. Polarization of radiation in strong magnetic fields

Photons emitted from the surface of an ultra-magnetized NS and propagating in vacuo turn out to be linearly polarized in two normal modes, the ordinary (O) and the extraordinary (X) ones, in which the photon electric field oscillates either parallel or perpendicular to the $\boldsymbol{k}$-$\boldsymbol{B}$ plane, respectively,[7,8] where $\boldsymbol{k}$ is the photon propagation direction. The evolution of the polarization state of photons during propagation is determined by the wave equation, which can be written as

$$\boldsymbol{\nabla} \times (\bar{\boldsymbol{\mu}} \cdot \boldsymbol{\nabla} \times \boldsymbol{E}) = \frac{\omega^2}{c^2} \boldsymbol{\epsilon} \cdot \boldsymbol{E}\,, \tag{2}$$

with $\boldsymbol{E}$ the photon electric field, $\omega$ their frequency, $\boldsymbol{\epsilon}$ the dielectric tensor of the medium in which photons propagate, $\bar{\boldsymbol{\mu}}$ the inverse of the magnetic permeability tensor and $c$ the speed of light. In general, $\boldsymbol{\epsilon}$ is expected to deviate from unity due to terms which account for plasma effects (e.g. collisions, radiation damping, etc., see Ref. 8). Photons can also change their polarization state upon scatterings with particles which flow along the closed magnetic field lines.[13–15] However, in the presence of strong magnetic fields further additional terms appear in both $\boldsymbol{\epsilon}$ and $\bar{\boldsymbol{\mu}}$, due to the vacuum polarization effect.[9] In fact, virtual electron-positron pairs, that are present in the vacuum around the star, are polarized by the strong NS field,

modifying the dielectric and magnetic properties of the vacuum. It can be shown that, close to the surface of magnetars, vacuum contributions in the dielectric tensor are by far dominant with respect to those of plasma (see e.g. Ref. 13 and references therein). Hence, neglecting the plasma terms in $\boldsymbol{\epsilon}$ one can reduce equation (2) to a simpler differential equation system,

$$\begin{aligned}\frac{\mathrm{d}Q}{\mathrm{d}z} &= -\frac{k_0\delta}{2}(2PV)\\ \frac{\mathrm{d}U}{\mathrm{d}z} &= -\frac{k_0\delta}{2}(N-M)V\\ \frac{\mathrm{d}V}{\mathrm{d}z} &= \frac{k_0\delta}{2}\left[2PQ+(N-M)U\right],\end{aligned} \tag{3}$$

where $k_0 = \omega/c$, $\delta = \alpha_\mathrm{F}\,(B/B_\mathrm{Q})^2/(45\pi)$ (with $\alpha_\mathrm{F}$ the fine-structure constant), $Q$, $U$ and $V$ are the photon Stokes parameters and $M$, $N$ and $P$ are coefficients that depend on the star magnetic field and the $\boldsymbol{\epsilon}$ and $\bar{\boldsymbol{\mu}}$ components (see e.g. Ref. 14).

Equations (3) show that, due to vacuum polarization effects, the photon electric field evolves along a typical scale-length $\ell_\mathrm{A} = 2/(k_0\delta)$, which depends on $B^{-2}$ and, through it, on the distance $r$ from the star. So, it should be compared with the scale-length $\ell_B = B/|\boldsymbol{k}\cdot\boldsymbol{\nabla}B|$ along which the star magnetic field itself changes along the photon trajectory. This comparison allows to divide the photon propagation region into three zones:[13,17] close to the star surface, in the *adiabatic region*, $\ell_\mathrm{A} \ll \ell_\mathrm{B}$, so that the photon electric field can instantaneously adapt to the star magnetic field (which is in turn evolving along the photon trajectory), leaving unchanged the original polarization state; outward, in the *intermediate region*, $\ell_\mathrm{A} \simeq \ell_\mathrm{B}$ and the photon electric field cannot adapt so promptly as before to the star magnetic field, causing a deviation of the polarization states with respect to the emission ones; finally, in the *external region* (far from the star surface) $\ell_\mathrm{A} \gg \ell_\mathrm{B}$ and the photon electric field is practically frozen with respect to the star magnetic field, so that the polarization states can change (also dramatically) with respect to those at the emission. In fact, if the magnetic field topology in the external region is still rather chaotic the observed polarization degree turns out to be strongly reduced (even for 100% intrinsic polarization degree), due to the Stokes parameter rotation.[17]

This scenario can be further simplified by introducing the adiabatic radius,[17] or polarization limiting radius,[13] i.e. the distance at which $\ell_\mathrm{A} = \ell_\mathrm{B}$,

$$r_\mathrm{a} \simeq 4.8\, B_{\mathrm{p},11}^{2/5} E_1^{1/5} R_{10}^{1/5} R_\mathrm{NS}\,, \tag{4}$$

where $B_{\mathrm{p},11}$ is the polar magnetic field strength in units of $10^{11}$ G, $E_1$ is the photon energy in units of 1 keV and $R_{10}$ is the NS radius in units of 10 km. Looking at equation (4) it can be seen that the adiabatic radius is larger for NSs with a stronger magnetic field and for photons with higher energy. Since the farther from the NS surface the more uniform the magnetic field topology, one can expect to observe more polarized X-ray photons for stronger magnetized NSs, with $r_\mathrm{a}$ placed at a sufficiently large distance from the star surface to prevent the original polarization pattern to be washed out by geometrical effects (see e.g. Ref. 17).

## 4. Numerical simulations

To implement our numerical simulations, we used the Monte Carlo code developed by Nobili, Turolla & Zane,[15] with the addition of a specific module to account for the polarization transport described in section 3. We used a globally twisted magnetic field, with the polar strength $B_{\rm p}$, the twist angle $\Delta\phi_{\rm N-S}$ and the corresponding velocity $\beta$ of the magnetospheric particles as input parameters. Since for the ultra-strong magnetic fields expected in the case of magnetars the free-free opacity for X-mode photons turns out to be much suppressed with respect to that of the O-mode ones, we assumed that the emitted photons are 100% polarized in the X-mode at the surface.[13] Furthermore, owing to the fact that, in the case of interest, the adiabatic radius largely exceeds the typical radius $r_{\rm res}$ at which RCS onto magnetospheric electrons may occur, we treated separately the change in polarization state of photons due to scatterings and the evolution of the Stokes parameters determined by vacuum effects. The outputs of the Monte Carlo code are eventually reprocessed in an IDL script to account for the viewing geometry, i.e. the angles $\chi$ and $\xi$ that the NS rotation axis makes with the observer line-of-sight (LOS) and the star magnetic axis, respectively.

We computed the observed flux, polarization degree and polarization angle (as functions of the photon energy and the rotational phase) in the case of the AXP 1 RXS J170849.0-400910 ($B_{\rm p} = 4.7 \times 10^{14}$ G, $\Delta\phi_{\rm N-S} = 0.5$, $\beta = 0.34$,

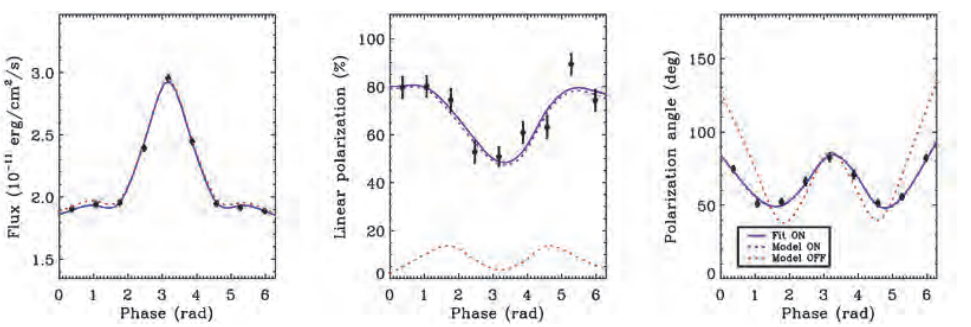

Fig. 1. Flux (left), linear polarization fraction (center) and polarization angle (right) simulated for a 250 ks observation with IXPE of the AXP 1 RXS J170849.0-400910, for $\chi = 90°$, $\xi = 60°$ and in the 2–6 keV range (filled circles with error bars). The model from which data are extracted (blue-dashed line) and that obtained for the same values of the input parameters but without accounting for QED effects (red-dashed line) are also shown. The best fit of data obtained using the entire model archive is marked by a blue, solid line.

Table 1. Input and best fit parameters of the simulation shown in Figure 1.

| | $\chi$ (deg) | $\xi$ (deg) | $\Delta\phi_{\rm N-S}$ (rad) | $\beta$ | $\chi^2_{\rm red}$ |
|---|---|---|---|---|---|
| Input | 90 | 60 | 0.5 | 0.34 | – |
| Best fit | $90.36 \pm 2.16$ | $59.12 \pm 1.21$ | $0.49 \pm 0.02$ | $0.37 \pm 0.07$ | 1.25 |

see Refs. 18, 19), and simulated the response of the IXPE polarimeter for this source (for $\chi = 90°$ and $\xi = 60°$) exploiting the instrumental effective area and modulation factor. The results are shown in Figure 1: the simulated data in the 2–6 keV energy range (filled circles with error bars) are plotted as functions of the rotational phase together with the model from which they are extracted (blue-dashed line) and the same model but with QED effects turned off (red-dashed line).[14,17] A best fit of the simulated data has been then performed, using an archive of models obtained leaving the input parameters $\chi$, $\xi$, $\Delta\phi_{N-S}$ and $\beta$ free to vary over a wide range of values. The fit (blue-solid line in Fig. 1) recovers the original input parameters within an acceptable degree of accuracy (within $1\sigma$, see Table 1), showing the strength of X-ray polarization measurements in extracting the physical and geometrical information of the source. Moreover, the QED-off case turns out to be ruled out at a high confidence level; this would allow us to say to have tested vacuum birefringence effects for the source at hand.

## 5. Discussion and conclusions

In this work we illustrated the commonly accepted theoretical model to explain the phenomenology of AXPs and SGRs, isolated NSs endowed with ultra-strong magnetic fields (magnetars). We focused in particular on the polarization of the X-ray photons emitted from these sources. In fact, radiation from magnetars is expected to be highly polarized and, due to their strong magnetic fields, these NSs are believed to be the best targets to test vacuum polarization effects, which has not been detected at the magnetic field strengths currently achievable in laboratory.

After having presented the twisted magnetosphere model and discussed the polarization evolution for photons propagating in the magnetized vacuum, we showed the output of our code in the case of the AXP 1 RXS J170849.0-400910, simulating the response of the NASA SMEX polarimeter IXPE, scheduled for the launch in 2021. Throughout our investigation, we assumed, for the sake of simplicity, that photons are emitted from the star surface 100% polarized in the X-mode. However, we point out that our code can also account for different intrinsic polarization patterns. A detailed analysis based on different, more realistic surface emission models is currently under development.

Our plots (see Fig. 1) show that X-ray polarization measurements are potentially able to distinguish between the expectations of our model with and without accounting for vacuum polarization effects. Besides to extract important information on the physics and geometry of the source (such as the values of the viewing angles $\chi$ and $\xi$ and the parameters $\Delta\phi_{\rm N-S}$ and $\beta$, see Table 1), X-ray polarimetry will allow to test QED effects in strong magnetic fields for the first time. Furthermore, since vacuum birefringence can prevent the geometrical depolarization of the collected radiation more effectively for stronger magnetized NSs, (see Sec. 3), the detection of a high degree of polarization can be considered as an indirect evidence for ultra-strong magnetic fields in magnetars.

The persistent emission of the anomalous X-ray pulsar 4U 0142+61 extends over a broad range of energy, from mid-infrared up to hard X-rays. In particular, this object is unique among soft gamma-ray repeaters (SGRs) and anomalous X-ray pulsars (AXPs) in presenting simultaneously mid-infrared emission and also pulsed optical emission. In spite of having many propositions to explain this wide range of emission, it is still lacking one that reproduces simultaneously all the observations. Filling this gap, we present a model that is able, for the first time, to reproduce simultaneously the entire spectral energy distribution of 4U 0142+61 using plausible physical components and parameters. We propose that the persistent emission comes from an accreting white dwarf (WD) surrounded by a debris disk. This model is thoroughly discussed at Ref. 2 and assumes that: (i) the hard X-rays are due to the bremsstrahlung emission from the post-shock region of the accretion column; (ii) the soft X-rays are originated by hot spots on the WD surface; and (iii) the optical and infrared emissions are caused by an optically thick dusty disk, the WD photosphere, and the tail of the post-shock region emission. In this scenario, 4U 0142+61 harbors a fast-rotator near-Chandrasekhar WD, which is highly magnetized. Such a WD can be formed by a merger of two less massive WDs.

*Keywords*: Accretion, magnetic field, rotation, white dwarfs.

## 1. Introduction

4U 0142+61 is an Anomalous X-ray Pulsar (AXP) that presents quiescent emission in a broad range of energy, from mid-infrared up to hard X-rays. In particular, this object is unique among SGR/AXPs in presenting simultaneously mid-infrared emission and pulsed optical emission, which are rare features for the class. Its period is 8.68 s, the spin-down is around $2.0 \times 10^{-12}$ s.s$^{-1}$ and the soft X-rays luminosity is about $10^{35}$ erg.s$^{-1}$ [23].

The emission nature of AXP/SGRs is still reason for debate and several scenarios have been proposed to explain their observed spectra and properties, such as the magnetars[8], accreting NSs[28], quark stars[24], or WD pulsars[5,20]. All the

current models fail to explain the entire spectral range of 4U 0142+61. That problem is not exclusive of 4U 0142+61, since no scenario presents a complete model for the SGR/AXPs class. In this context, we propose that the persistent emission of 4U 0142+61 comes from an accreting isolated WD surrounded by a debris disk, having gas and dusty regions. This scenario is inspired by the periodic flux modulation and by the presence of mid-infrared emission, which is rare for NSs. In fact, apart from the SGR/AXP class in which only 1E 2259+586 and 4U 0142+61 have mid-infrared;[19,30], only three isolated NSs have detected mid-infrared: the radio pulsars Crab, Vela, and Geminga[6,27]. Thus, mid-infrared appears in about 0.3% of all isolated NSs. On the other hand, the presence of mid-infrared in WDs is quite common. Ref. 7 found that about 7% of all isolated WDs presents mid-infrared excess detected by *WISE*, which reinforces the WD origin for 4U 0142+61. This proceedings presents a study of 4U 0142+61 emission in the context of a WD nature. It is organized as follows. In section 2, we describe the WD accreting model we use to fit 4U 0142+61 data. In section 3, we show the spectral fit of 4U 0142+61. In section 4, we summarize our findings.

## 2. An accreting WD model for 4U 0142+61

We propose that the components of 4U 0142+61 persistent emission are the WD photosphere, a disk, and an accretion column. The disk is formed by a dusty external region and a gaseous internal region. The dusty disk is optically thick and emits such as a multi-temperature blackbody. The temperature of its inner radius is the grain sublimation temperature, which is about 1500 K for silicates. Conversely, the internal gaseous disk is optically thin and its emission can be neglected. The inner radius of the gaseous disk is equal to the magnetosphere radius. From that point on, the matter flows into the WD surface following the magnetic field lines and the debris disk ceases to exist.

Close to the WD photosphere, the in-falling flow of matter produces a shock, forming an extremely hot region, the so called post-shock region that emits bremsstrahlung. About half of that energy reaches the WD surface, where it is reprocessed, forming a hot spot. Once the high-energy emission for 4U 0142+61 is pulsed, with two peaks per phase, we assume that there are two accreting regions. Thus, we can express the total flux by:

$$F_{total} = F_{disk} + F_{wd} + F_{spot} + F_{brem}. \quad (1)$$

The WD photosphere ($F_{wd}$) and the hot spots ($F_{spot}$) emit as blackbodies, in which the intensity for a given wavelength $\lambda$ and temperature $T$ is the Planck function, $B(\lambda, T)$, whereas the post-shock region emits by thermal bremsstrahlung ($F_{brem}$). According to Ref. 21, the bremsstrahlung emitted power is:

$$P(\lambda, T_{brem}) = 2.051 \times 10^{-22} g_{ff} n_e^2 \lambda^{-1} T_{brem}^{-1/2} exp\left(\frac{-143.9}{\lambda T_{brem}}\right). \quad (2)$$

Assuming that the region is cylindrical, with a height $H_{brem}$, the optical depth of the bremsstrahlung emission, $\tau_{brem}$, is:

$$\tau_{brem} = \frac{H_{brem} P(\lambda, T_{brem})}{4\pi B(\lambda, T_{brem})}. \quad (3)$$

Assuming that the radius is $R_{brem}$, and the electron number density is $n_e$, the flux of the bremsstrahlung emission can be written as

$$F_{brem}(n_e, R_{brem}, H_{brem}, T_{brem}, d) = \\ = (1 - e^{-\tau_{brem}}) B(\lambda, T_{brem}) \pi \left(\frac{R_{brem}}{d}\right)^2. \quad (4)$$

At last, we have the multi-temperature disk component $(F_{disk})^4$:

$$F_{disk}(\nu, T_{in}, T_{out}, T_{wd}, R_{wd}, d) = 12\pi^{1/3} \cos(i) \left(\frac{R_{wd}}{d}\right)^2 \\ \times \left(\frac{2kT_{wd}}{3h\nu}\right)^{8/3} \left(\frac{h\nu^3}{c^2}\right) \int_{x_{in}}^{x_{out}} \frac{x^{5/3}}{e^x - 1} dx. \quad (5)$$

In this equation, $x = h\nu/kT$, where $T$ is the debris disk temperature, which ranges from $T_{out}$ to $T_{in}$ and $T_{wd}$ is the WD effective temperature. The model, as well as the parameters for each flux component, are described thoroughly in Ref. 2.

## 3. Fitting 4U 0142+61 SED

As the model parameters for each spectral region are not the same, we opted to fit spectral regions separately. To fit the SED of 4U 0142+61, we use the data presented in Figure 1. These data are dereddened and deabsorbed. We have used Markov Chain Monte Carlo MCMC -[14] to estimate the parameters and their uncertainties. The results are shown in Table 1 and Figure 1. We consider a distance of 3.78 kpc[2] and $N_H = 6.4 \times 10^{21}$ cm$^{-2}$.[9]

The fit quality of the hard X-rays increases for high bremsstrahlung temperatures, which can only be achieved for near-Chandrasekhar white dwarfs. We adopt a WD having mass of 1.41 $M_\odot$ and radius of 1021 km[3]. This corresponds to a bremsstrahlung temperature of 674.5 keV, which was considered as a fixed parameter.

After modelling the hard X-rays, we find the best fit for soft X-rays. The bremsstrahlung component is also included in the fit of the soft X-ray SED. To be consistent with the double peak in the soft X-rays light curve, we use two blackbodies components, which can have different temperatures and radii.

To fit the optical and infrared emission, we use the WD photosphere blackbody and the debris disk. The high-energy components are included in the fit and the tail of bremsstrahlung component from the post-shock region also contributes to the optical emission as shown in Figure 1. The flux of the disk is given by Eq. (5). We use the same values of $R_{wd}$ derived from the bremsstrahlung fit.

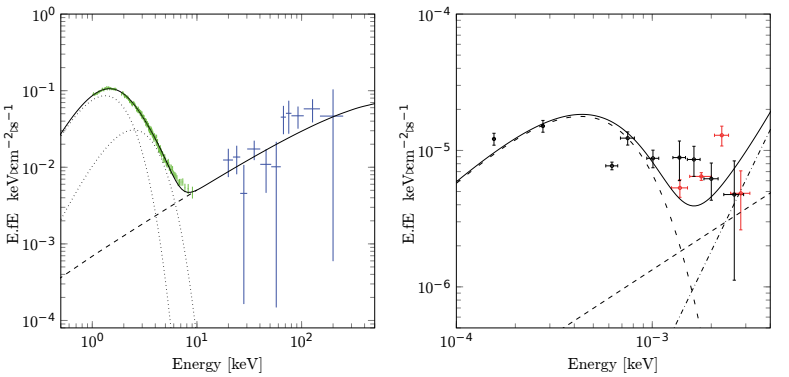

Fig. 1. Derreddened and deabsorbed SED of 4U 10142+61 along with the best fit. The continuous black curve is the complete fit, the long-dashed curve is the disk component, the dot-dashed curve is the WD photosphere, the two dotted curves are the hot spots components, and the short-dashed curve is the bremsstrahlung component. The black crosses are the data in low-energies used to fit the model and are from *Spitzer* (mid-infrared)[30], *Gemini* (near-infrared)[10] and *GTC* (optical)[22]; green crosses represent the soft X-ray data from *Suzaku*[11]; the blue crosses are the *INTEGRAL* data. *Left-bottom panel:* Zoom at the high-energy end. *Right-bottom panel:* Optical and infrared region. The red data[15,16] is displayed for comparison.

## 4. Conclusions

We obtained a good fit for the entire SED of 4U 0142+61. The optical/infrared emission of 4U 0142+61 comes from the WD itself and from the debris disk with a non-negligible contribution from the low-energy tail of the post-shock region. The hard X-rays is emitted by the accretion column and the soft X-rays by two hot spots in the WD photosphere.

The hard X-rays bremsstrahlung implies a near-Chandrasekhar WD, assumed to have a mass of 1.41 $M_{\odot}$ and a radius of 1021 km. Moreover, from the optical/infrared emission, we obtain an WD effective temperature of $9.4 \times 10^4$ K. Those radius and temperature point out to an young WD. The inner and outer disk temperatures are 1 991 K and 285 K.

In short, we were able to present a model that explains all the quiescent emission of 4U 0142+61, as well as the observed spin-down. Such a WD can be understood as the result of a recent merger of two less massive WDs.

Table 1. Parameters of the fitting of 4U 0142+61 in the accreting WD model.

| Parameter | Description | Value |
|---|---|---|
| | **X-rays** | |
| | Fixed parameters | |
| $d$ | distance of 4U 0142+61 | 3.78 kpc |
| $N_H$ | columnar density of hydrogen | 6.4 $10^{21}$ cm$^{-2}$ |
| $T_{brem}$ | temperature of the emission for the accretion column | 674.5 keV |
| $M_{WD}$ | WD's mass | 1.41 $M_\odot$ |
| $R_{WD}$ | WD's radius | 1,021 $10^5$ cm |
| | Fitted parameters | |
| $\dot{M}$ | accretion rate | 3.43 $10^{17}$g s$^{-1}$ |
| $R_{brem}$ | radius of the hard X-ray emission | 14.03 $10^5$ cm |
| $H_{brem}$ | height of the accretion column | 1.27 $10^5$ cm |
| $n_e$ | electrons number density | 2.05 $10^{19}$ cm$^{-3}$ |
| $\chi^2_{brem}/dof$ | reduced chi square for the hard X-rays | 0.85 |
| $T_{spot1}$ | temperature of the spot 1 | 0.632 $\pm$ 0.033 keV |
| $R_{spot1}$ | radius of the spot 1 | 2.35$\pm$0.45 $10^5$ cm |
| $T_{spot2}$ | temperature of the spot 2 | 0.337$\pm$0.012 keV |
| $R_{spot2}$ | radius of the spot 2 | 13.83$\pm$0.73 $10^5$ cm |
| $\chi^2/dof$ | reduced chi square for the soft X-rays | 1.06 |
| | **Optical/Infrared** | |
| | Fitted parameters | |
| $T_{WD}$ | WD's effective temperature | 9.4$\pm$7.3 $10^4$ K |
| $T_{in}$ | inner temperature of the debris disk | 1,991$\pm$16 K |
| $T_{out}$ | outer temperature of the debris disk | 285 $\pm$ 200 K |
| $R_{in}$ | inner radius of the debris disk | 2.35 $\pm$ 0.03 $R_\odot$ |
| $R_{out}$ | outer radius of the debris disk | $31^{+127}_{-16}$ $R_\odot$ |

**Note.** The fixed parameters were derived before the fit by independent methods. For the infrared/optical fit all the X-rays parameters are considered fixed, therefore, $R_{wd}$ is not a fitted parameter for this range of energy. The $1\sigma$ uncertainties for the last digit for the fitted parameters are in parenthesis.
